Abstract

Hyphal growth is strongly associated with virulence in the human fungal pathogen *Candida albicans*. While hyphal transcriptional networks have been the subject of intense study, relatively little is known about post-transcriptional regulation. Previous work reported that P-Body (PB) factors Dhh1 and Edc3 were required for *C. albicans* virulence and filamentation, suggesting an essential role for post-transcriptional regulation of these processes. However, the molecular roles of these factors have not been determined. To further study the function of PB factors in filamentation, we generated homozygous deletions of *DHH1* and *EDC3* in diverse prototrophic clinical strains using transient CRISPR-Cas9. Homozygous *DHH1* deletion strongly impaired growth, altered filamentation, and exhibited unusual colony morphology in response to heat stress in five strain backgrounds. Using RNA-seq, we found *DHH1* deletion disrupts the regulation of thousands of genes under both yeast and hyphal growth conditions in SC5314 and P57055. This included upregulation of many stress response genes in the absence of external stress, similar to deletion of the *S. cerevisiae DHH1* homolog. In contrast, we found *EDC3* was

not required for heat tolerance or filamentation in diverse strains. These results support a model in which *DHH1*, but not *EDC3*, represses hyphal stress response transcripts in yeast and remodels the transcriptome during filamentation. Our work supports distinct requirements for specific mRNA decay factors, bolstering evidence for post-transcriptional regulation of filamentation in *C. albicans*.

Author summary

In the dimorphic fungal pathogen *C. albicans*, the hyphal phenotype strongly correlates with pathogenicity. While transcriptional control of hyphal growth has been extensively studied, comparatively little is known about post-transcriptional regulation of this significant morphological shift. PB factors are associated with mRNA decay and translational repression. Here we investigate the roles of two PB factors in growth, filamentation, and gene expression. Although deletion of PB factor *EDC3* did not impact growth or filamentation, *dhh1Δ/Δ* had greatly impaired growth and heat tolerance as well as unusual hyphal phenotypes in multiple clinical isolate strains. Additionally, we found that the transcriptomes of SC5314 and P57055 *dhh1Δ/Δ* yeast and hyphae were highly dysregulated. The extensive transcriptomic impacts of the absence of Dhh1 correlated with our phenotypic findings. Stress-associated genes were induced under non-stress conditions and the filamentation response was blunted under physiologically relevant *in vitro* conditions. We demonstrate that mRNA decay factors play distinct roles in regulating *C. albicans* morphology and that Dhh1 contributes to environmentally appropriate expression of the stress response and hyphal growth.

Introduction

Candida albicans is an opportunistic pathogen that causes blood and deep tissue infections (candidiasis) in immunocompromised individuals [1, 2]. Pathogenicity requires responding to stress in divergent physiological microenvironments [3, 4]. Under stress, *C. albicans* undergoes

filamentation, shifting from commensal yeast to virulent hyphae. Hyphal growth correlates with the release of the peptide toxin candidalysin [5] and adherent biofilm formation [6–8]. Both contribute to pathogenicity. Foundational research on transcriptional regulation of filamentation identified dozens of transcription factors (TFs) and signaling cascades controlling core filamentation response networks [9–12]. Under different hyphal-inducing conditions, *C. albicans* activates distinct transcriptional programs [13]. Notably, these transcriptional programs have been found to vary dramatically across different clinical isolates, even under the same filamentation conditions [14]. Despite deep exploration into transcriptional control of filamentation, comparatively little work has addressed post-transcriptional regulation of filamentation [15, 16].

Eukaryotes implement swift and precise post-transcriptional stress responses [17, 18] appropriate for regulating the acute stage of *C. albicans* filamentation [15, 16]. Post-transcriptional regulation of gene expression integrates mRNA translation, localization, and decay [19, 20]. Indeed, mRNA decay has been found to regulate adaptation to the host environment and virulence in several human fungal pathogens [3, 16, 21, 22]. Localization to ribonucleoprotein (RNP) granules represses translation and initiates decay in many organisms [23, 24]. P-bodies (PBs) are RNPs associated with the Ccr4-not deadenylase complex [24–27] and mRNA degradation [23, 24, 28]. In *C. albicans*, several PB mRNA decay factors have been reported to function in hyphal development and virulence, including Ccr4, Pop2, Not5, Xrn1, Dhh1, and Edc3 [29–37]. However, all of these studies used auxotrophic derivatives of SC5314 such as BWP17 and CAI4, therefore it is unknown how important these factors are in clinical isolates. In addition, the effects of these factors on gene regulation during filamentation have not been elucidated.

Stochastic transcriptional noise generates different phenotypic outcomes in clonal microbial populations that serves as a mechanism of “bet-hedging” for acute environmental stressors [38–40]. In this context, mRNA decay provides a system of transcript buffering preventing gene

73 expression under inappropriate conditions [41]. Genes identified as both transcriptionally noisy
74 and poorly translated have these features conserved between *S. cerevisiae* and *C. albicans*
75 homologs [42]. However, the extent to which mRNA decay factors buffer or control noisy
76 expression of hyphal genes under yeast-form conditions or conversely yeast genes under
77 hyphal conditions remains unclear in *C. albicans*. Furthermore, the roles of *C. albicans* PB
78 factors in buffering noisy transcription for environmentally appropriate gene expression remain
79 unknown.

80 In the model yeast *S. cerevisiae*, the functions of PB factors Dhh1 and Edc3 have been
81 extensively studied [43]. The DEAD-box helicase and activator of mRNA decapping Dhh1
82 rapidly exchange between the cytoplasm and PBs [44, 45], and may repress translation and
83 stimulate the decay of mRNAs with poor codon optimality [46, 47]. Under optimal growth
84 conditions it has been reported that Dhh1 represses genes associated with nutrient limitation,
85 cell wall components, autophagy, and metabolism of non-preferred carbon and nitrogen sources
86 [48]. Loss of *DHH1* in *S. cerevisiae* downregulates *STE12* translation leading to defects in
87 pseudohyphal growth and mating [35, 49, 50], and the *C. neoformans* Dhh1 homolog (Vad1)
88 plays a similar role in regulating mating [51]. Kinase signaling via Dhh1 phosphorylation sites
89 are critical to pseudohyphal development in *S. cerevisiae* [35, 52]. Edc3 is a non-essential
90 enhancer of mRNA decapping and a PB scaffolding factor in *S. cerevisiae* [43, 44, 53, 54]. In *S.*
91 *cerevisiae*, the absence of Edc3 reduces PB assembly size, but does not impede global mRNA
92 decay [44, 55]. Additionally, Edc3 is dispensable for PB formation in *S. pombe* [56]. In contrast
93 to *S. cerevisiae*, the roles of Dhh1 and Edc3 in *C. albicans* hyphal growth have been minimally
94 explored and the impact of Dhh1 on gene expression remains unknown.

95 Prior work in *C. albicans* reported that both Dhh1 and Edc3 are necessary for WT stress
96 tolerance and filamentation. In a *C. albicans* auxotrophic background, the authors described a
97 heterozygous deletion of *DHH1* (*DHH1/dhh1Δ*) which produced WT colonies on YPD plates, but

98 was filamentation impaired [35]. In the same *C. albicans* auxotrophic background, *edc3Δ/Δ* was
99 noted to have compromised PB condensation, reduced heat tolerance at 37°C, and severely
100 restricted filamentation [36, 37]. This early research implied that *DHH1* and *EDC3* may have
101 distinct roles in *C. albicans* filamentation. However, the gene regulatory effects of *DHH1*
102 deletion in *C. albicans* have not been defined. Thus, our understanding of these important PB
103 factors in filamentation remains limited.

104 In this study, we investigated the roles of PB factor Dhh1 in *C. albicans* heat tolerance,
105 filamentation, and gene expression. Using transient CRISPR-cas9 [57] we deleted *DHH1* and
106 *EDC3* in diverse clinical isolate strains representing the five major *C. albicans* clades [58]. We
107 demonstrated the dispensability of *EDC3* for PB condensation, heat tolerance, and
108 filamentation. Importantly, we found *dhh1Δ/Δ* exhibits impaired yeast-form growth, heat
109 sensitivity, and anomalous filamentation across genetic backgrounds. Finally, we determined
110 the effects of *dhh1Δ/Δ* on genome-wide expression in yeast and early hyphae, and found loss of
111 *DHH1* causes widespread dysregulation of the transcriptome and stress responses in SC5314
112 and P57055.

113 Results

114 Characterizing P-Bodies (PBs) in *C. albicans*

115 To investigate the presence of Dhh1 and Edc3 in PBs, we first fused mScarlet to the C-terminus
116 of Dhh1 (Dhh1-mS) and mNeonGreen to the C-terminus of Edc3 (Edc3-mNG) using CRISPR-
117 Cas mediated genome editing in strain SC5314. Under optimal temperature and acute heat
118 shock, Edc3-mNG condensed into round foci (Fig 1. A-B). To determine if these foci were PBs,
119 we generated a dual labeled strain (Edc3-mNG, Dhh1-mS). Edc3-mNG and Dhh1-mS
120 colocalized, confirming these foci were PBs (Fig 1. C, Fig S1. A). As is the case in *S. cerevisiae*
121 [59], we found a large fraction of Dhh1 was cytoplasmically diffuse, suggesting it functions both

122 in PBs and in the cytoplasm (Fig 1. C, Fig S1. A). We next investigated PB condensation during
123 early filamentation. After 3 hours of acute starvation in PBS, PBs were abundant in yeast cells
124 and along developing hyphal germ tubes (Fig 1. D). PBs also formed and persisted over 4 hours
125 of filamentation (37°C and RPMI), (Fig 1. E). Lastly, we investigated whether these proteins
126 were independently required for PB condensation. In the absence of Edc3, Dhh1-mS retained
127 the capacity to form condensates in response to acute heat shock (Fig 1. F, Fig S1. B).
128 Similarly, Edc3-mNG also condensed in the absence of Dhh1 (Fig 1. G, Fig S1. C). In summary,

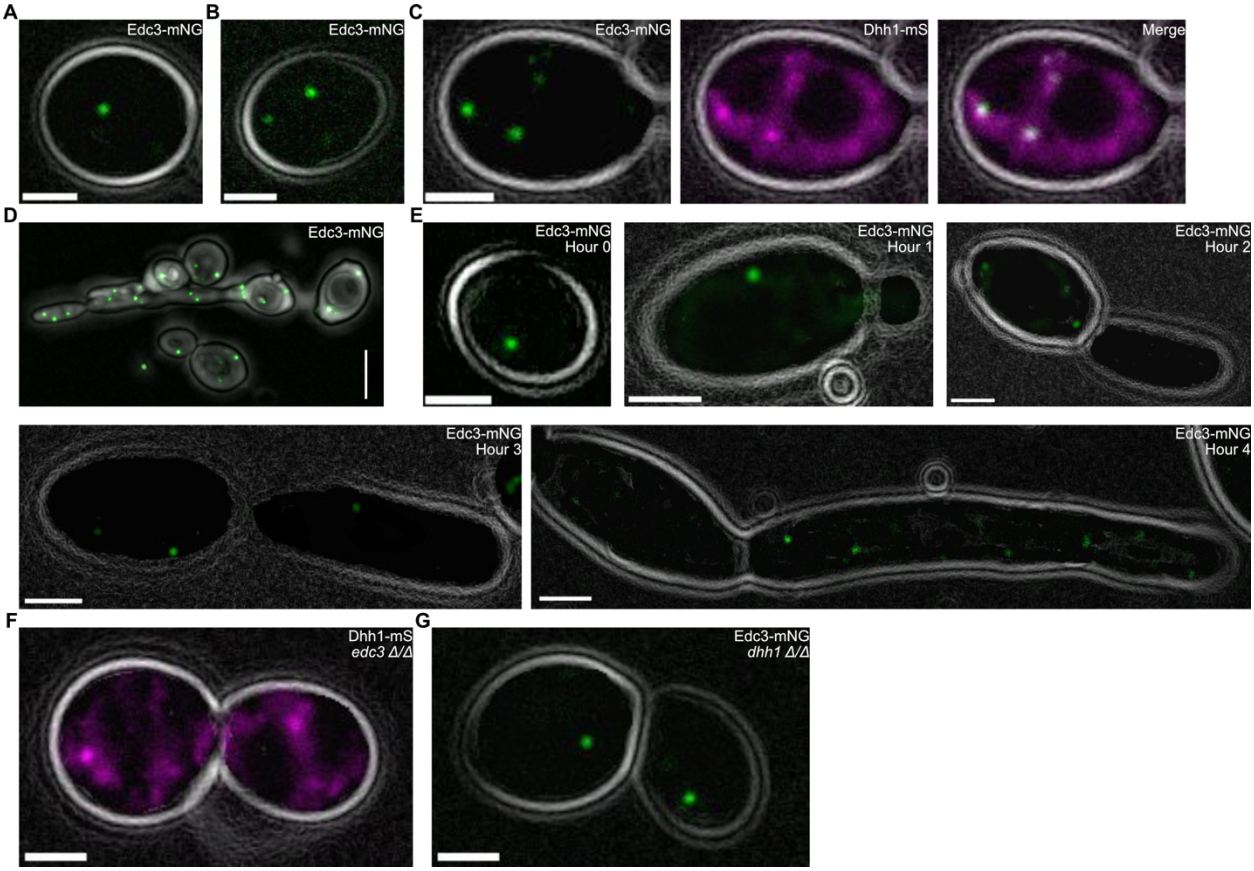

Figure 1. PBs condense during acute stress. Images of PB factors fluorescently tagged in strain SC5314. **A.** Edc3-mNG condensed in live *C. albicans* under non-stress conditions (30°C in complete media (CM)). Scale bar = 5μm. **B.** Edc3-mNG condensed in live *C. albicans* in response to acute heat shock (10 minutes at 46°C in CM). Scale bar = 5μm. **C.** PB factors (Edc3-mNG and DHH1-mS) co-localized during acute heat shock (10 minutes at 46°C in CM) confirming their identity as PBs. Scale bar = 2μm. **D.** After 3-hours of starvation in PBS at room temperature, abundant PBs (Edc3-mNG) were visible with confocal microscopy along the developing germ tube. Scale bar = 5μm. **E.** PBs (Edc3-mNG) also condensed and persisted during hyphal growth (37°C in RPMI). Scale bars = 2μm. **F.** Dhh1-mS condensed in the absence of Edc3 in response to acute heat shock (10 minutes at 46°C in CM). Scale bar = 2μm. **G.** Dhh1 is not required for Edc3-mNG PB formation in response to acute heat shock (10 minutes at 46°C in CM). Scale bar = 5μm.

129 we confirmed the presence of PBs in *C. albicans* and found that, as in *S. cerevisiae*, *C. albicans*
130 PBs are robust condensates tolerating the absence of Dhh1 or Edc3 individually.
131

132 **_DHH1_ is required for normal growth and stress response phenotypes in SC5314**

133 We next investigated the role of Dhh1 and Edc3 in *C. albicans* growth and stress responses.
134 We generated heterozygous (*DHH1*/*dhh1Δ*) and homozygous (*dhh1Δ/Δ*) *DHH1* deletions and
135 complements in SC5314. Initially, we conducted spot assays at 30°C and 37°C to test for
136 growth and temperature sensitivity defects. Strains possessing at least one copy of *DHH1*
137 produced colonies identical to WT on YPD plates (Fig 2. A-B). However, *dhh1Δ/Δ* had impaired
138 growth across timepoints and incubation temperatures (Fig 2. A-B). We also observed slow
139 growth of *dhh1Δ/Δ* at 30°C in liquid YPD over 12 hours (Fig 2. C). Uniquely, after 3 days on
140 YPD at 37°C, *dhh1Δ/Δ* colonies exhibited a wrinkled appearance associated with hyphal growth
141 (Fig 2. B). To further investigate, we grew colonies at 37°C for 4 days on YPD. While strains
142 with *DHH1* had a smooth surface and soft texture, *dhh1Δ/Δ* colonies had a wrinkled surface and
143 firm, dry texture reminiscent of hyphal colonies on spider media (Fig 2. D). Surprisingly, DIC
144 microscopy revealed *dhh1Δ/Δ* cells were twice the size of the *DHH1*-containing strains, with
145 enlarged vacuoles (Fig 2. E). The size of the cells (Fig 2. F), vacuoles (Fig 2. G), and proportion
146 of the cell taken up by the vacuole (Fig 2. H) were all significantly greater in *dhh1Δ/Δ* cells. The
147 slow growth and altered cell physiology of *dhh1Δ/Δ* suggested the induction of stress associated
148 phenotypes in the absence of environmental stressors. In contrast, the loss of *EDC3* did not
149 impair colony growth at 30°C and 37°C in SC5314 (Fig S2. A). Thus, we focused the remainder
150 of this study on *DHH1*.
151

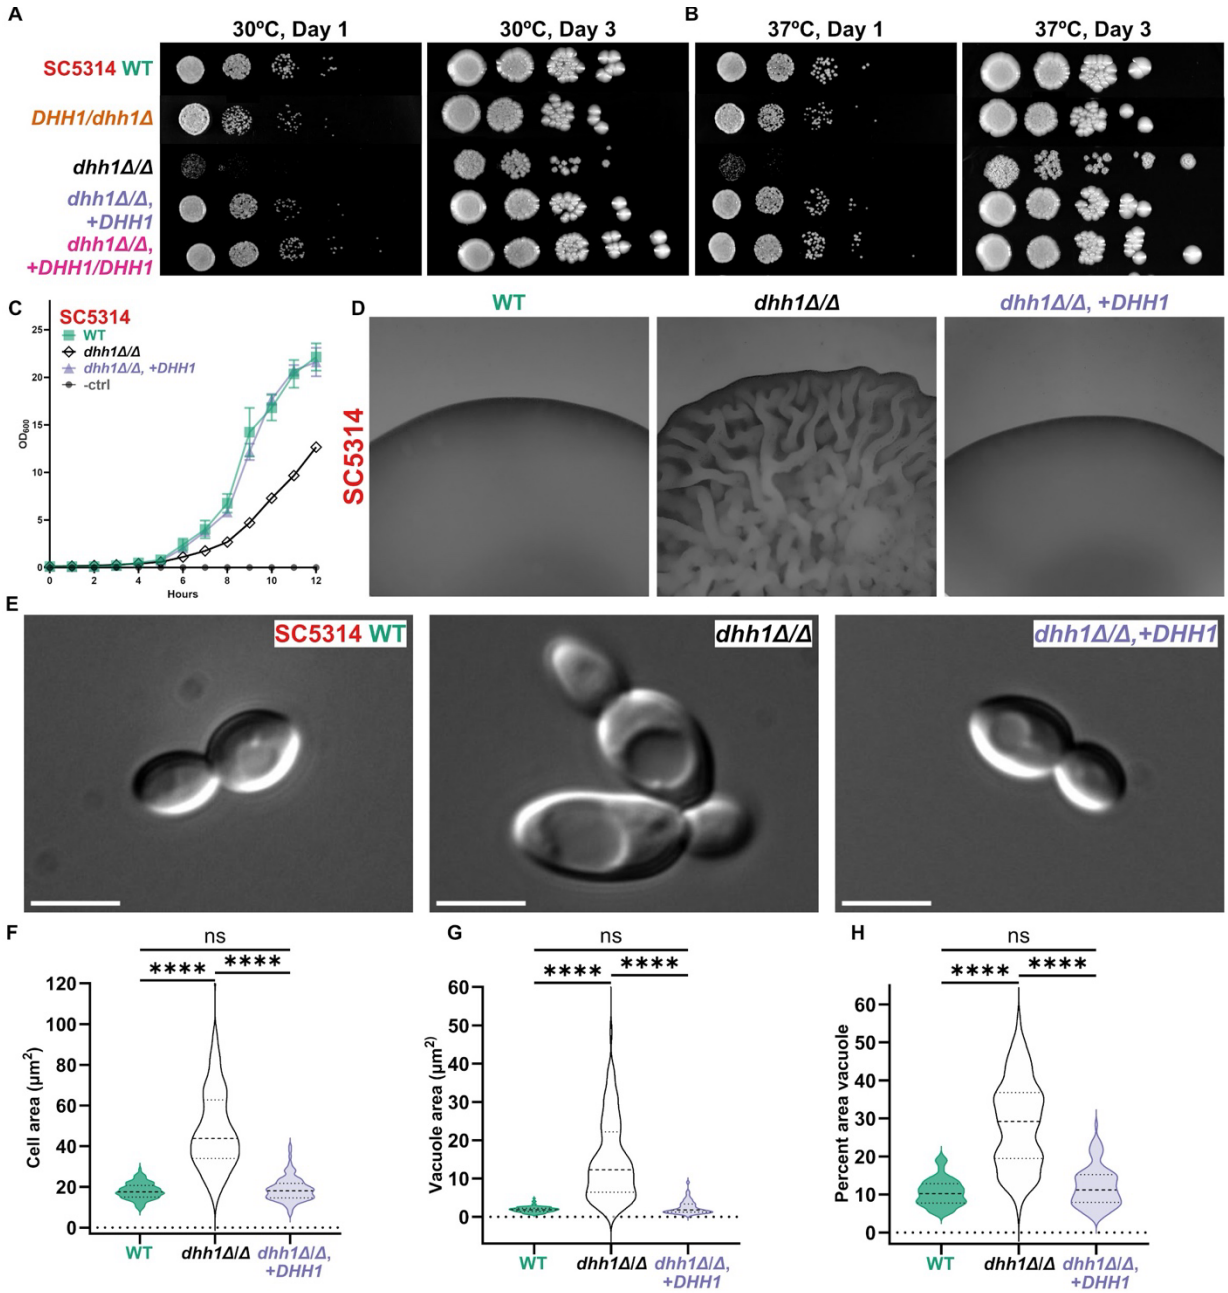

Figure 2. *DHH1* is required for WT growth and morphology in SC5314. A. and **B.** *dhh1Δ/Δ* resulted in slow growth at 30°C and 37°C on YPD plates, which was complemented by a single copy of *DHH1*. **C.** *dhh1Δ/Δ* had reduced growth in liquid YPD (30°C). WT and mutant strains were grown in triplicate. Impaired *dhh1Δ/Δ* exponential growth was rescued by complementation (*dhh1Δ/Δ*, *+DHH1*). Error bars show 95% CI. **D.** Colonies lacking *DHH1* have a wrinkled morphology (4 days, YPD agar, 37°C). 25X magnification. **E.** DIC images of exponentially growing cells (YPD, 30°C) show enlarged cell bodies and vacuoles in *dhh1Δ/Δ*. Scale bars = 5μm. **F.- H.** Quantification of cell and vacuolar enlargement in *dhh1Δ/Δ* (N = 100 cells per strain; ****P < 0.0001, Kruskal-Wallis tests).

152

153

DHH1 is necessary for SC5314 WT filamentation

We next examined filamentation in *dhh1Δ/Δ*. SC5314 *dhh1Δ/Δ* cells were larger than WT and complement strains after 4 hours of filamentation, with the cell body taking up a greater proportion of the total length (Fig 3. A). However, the median length to width ratio of *dhh1Δ/Δ* cells was significantly smaller, due to impaired germ tube elongation (Fig 3. B). After 16 hours of planktonic filamentation, *dhh1Δ/Δ* cells remained enlarged with thick curved germ tubes and fewer septa compared to WT and complement strains (Fig 3. C). The median length to width ratio of *dhh1Δ/Δ* at 16 hours was also significantly less than the other strains (Fig 3. D). In summary, we found that a single copy of *DHH1* sufficiently supported WT planktonic filamentation, while homozygous deletion resulted in abnormal planktonic filamentous growth.

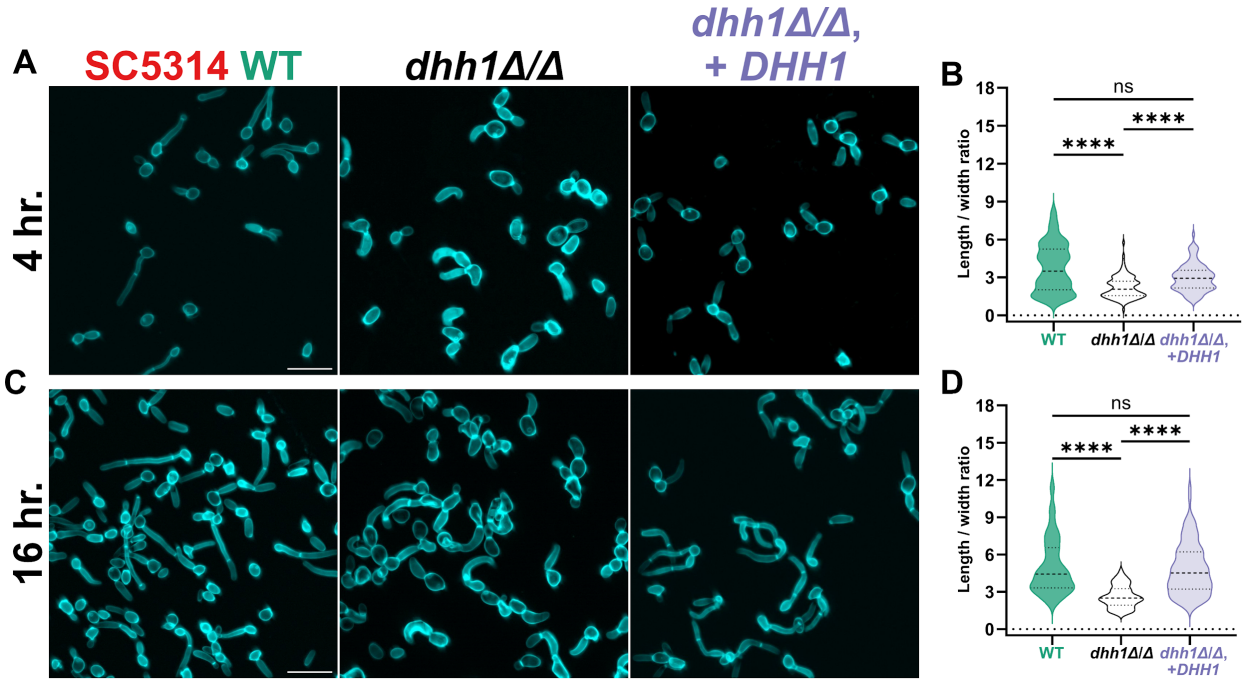

Figure 3. *DHH1* is required for wildtype planktonic filamentation. WT and mutant strains grown under physiologically relevant filamentation conditions (37°C, RPMI + 10% FBS). **A.** and **B.** After 4-hours of filamentation, *dhh1Δ/Δ* had reduced germ tube development defined by the median ratio of cell length to width. **C.** and **D.** After 16-hours of filamentation, *dhh1Δ/Δ* had less developed germ tubes with fewer septa compared to wildtype and complement strains. (Scale bars = 20μm; N = 100 cells, ****P < 0.0001, Kruskal-Wallis tests).

171 Due to the significant impairment of planktonic filamentation in SC5314 *dhh1Δ/Δ,* we expected
172 *dhh1Δ/Δ* to exhibit comparatively short defective biofilms. Surprisingly, *dhh1Δ/Δ* generated
173 deep, diffuse biofilms compared to WT and complement strains (Fig 4. A-B). Nevertheless,
174 *dhh1Δ/Δ* biofilms exhibited other key differences. In WT and *DHH1* complement strains, cells
175 were concentrated near the base of the biofilm (Fig 4. C). Using average pixel intensity as a
176 proxy for cell density, we quantified biofilm architecture, and found *dhh1Δ/Δ* biofilms were
177 altered with a maximum cell density further removed from the basal layer of the biofilm
178 compared to WT and *DHH1* complement (Fig 4. D). This modified biofilm structure may result
179 from the somewhat hyperfilamentous *dhh1Δ/Δ* strain, via decreased yeast cell proliferation at
180 the base of the structure.
181 Next, we surveyed the phenotype of colonies during invasive growth on spider media. After 6
182 days of growth at 37°C, *dhh1Δ/Δ* colonies revealed a wrinkled hyphal phenotype but a marked
183 absence of hyperfilamentous margins found in WT SC5314 (Fig 4. E). Compared to strains with
184 at least one copy of *DHH1*, *dhh1Δ/Δ* colonies grew more vertically with tighter wrinkles (Fig 4.
185 E). Again as in the other filamentation assays, our complement strain with a single *DHH1* copy
186 produced phenotypically WT colonies on spider media (Fig 4. E). Furthermore, in contrast to
187 *dhh1Δ/Δ, edc3Δ/Δ* was not filamentation impaired in all three filamentation assays (Fig S2. B-F).
188 In conclusion, SC5314 *dhh1Δ/Δ* failed to generate WT germ tubes, biofilm composition or
189 invasive colonies on spider media supporting a role for this RNA decay factor in filamentation.

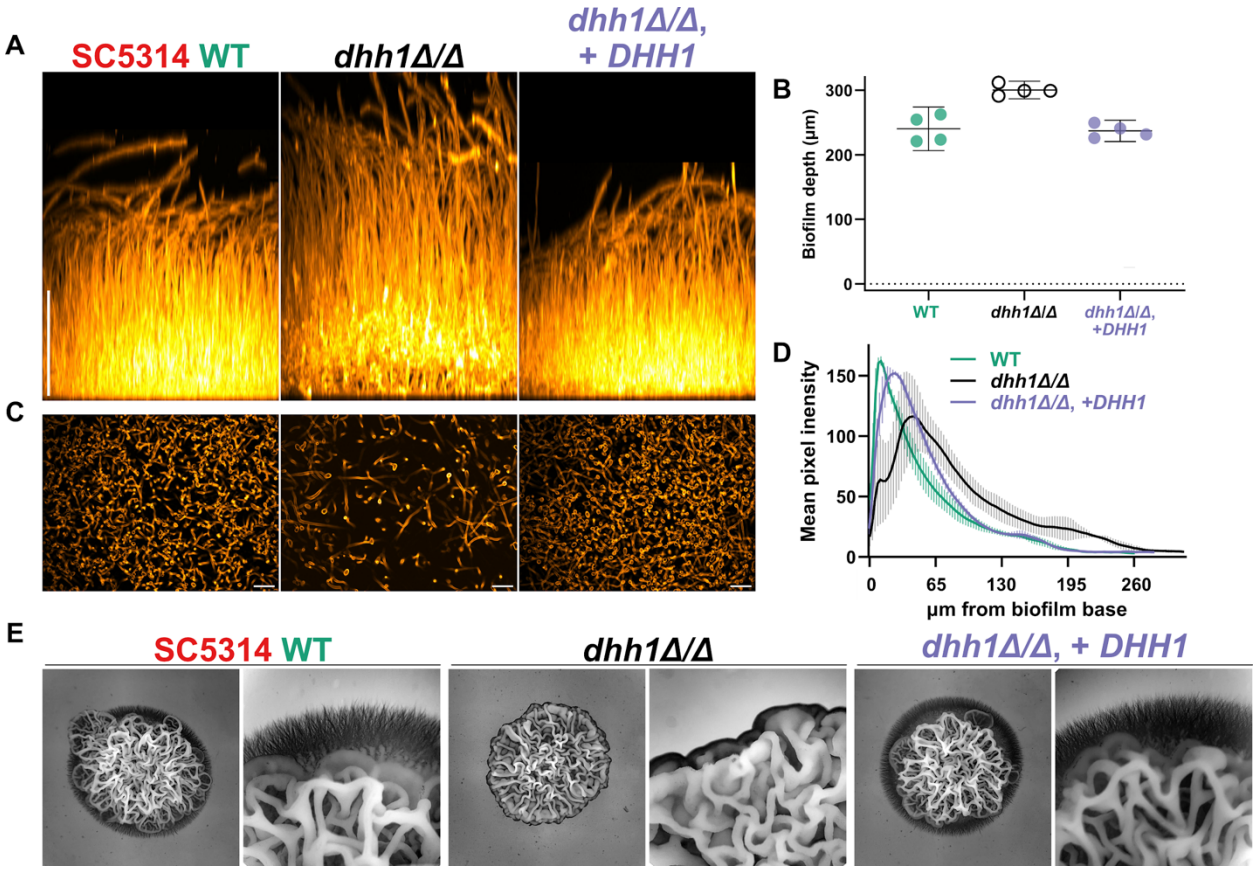

Figure 4. Absence of *DHH1* alters SC5314 biofilm and spider colony morphology. WT and mutant strains grown in two *in vitro* filamentation assays. **A.** and **B.** WT and mutant biofilms after a 24-hours (37°C, RPMI + 10% FBS) *dhh1Δ/Δ* has thicker biofilms. Scale bar = 100µm, 95% CI. **C.** Basal views 26µm from the bottom of the biofilm showed a reduced density of *dhh1Δ/Δ* cells. Scale bar = 20µm. **D.** Average pixel intensity (cell wall stain) from 4 replicate biofilms (SD) varied with biofilm depth. Strains with at least one copy of *DHH1* had a greater concentration of cells closer to the base of the biofilm than *dhh1Δ/Δ*. **E.** Colonies on spider plates require *DHH1* for hyperfilamentous margins (6 days, 37°C). 6X and 25X magnification.

Loss of DHH1 disrupts numerous pathways involved in metabolism and cellular morphology in SC5314

Given the severe phenotypic defects in SC5314 *dhh1Δ/Δ* yeast and hyphae, we next used RNA-seq to identify differentially expressed genes in yeast (30°C, YPD) and early hyphae (37°C, RPMI + 10% FBS, 4 hours) in triplicate (see methods for details) [60]. After removing poorly transcribed genes (Fig S8. A-B) we evaluated samples by PCA (Fig S9. A) and differential expression using DEseq2 [61]. In YPD, *dhh1Δ/Δ* yeast had 1,244 genes significantly downregulated and 1,408 genes significantly upregulated (Padj < 0.01) compared to wildtype (Fig 5. A, Table S1). Interestingly, *dhh1Δ/Δ* yeast upregulated multiple genes associated with

199 hyphae inducing stress, including *RHR2*, *ECE1*, and *HWP1* (Fig 5. A; Fig S3. C-D). Indeed, GO
200 terms corresponding to hyphal stress, such as hyphal cell wall and carbohydrate transport, were
201 enriched in upregulated genes (Fig 5. B). In RPMI, *dhh1Δ/Δ* hyphae had 1,151 genes
202 downregulated and 1,269 genes upregulated (Padj < 0.01) (Fig 5. C, Table S2). Lactate and
203 sugar transport genes were upregulated in *dhh1Δ/Δ* RPMI including *JEN1* and *HGT12* (Fig 5.
204 C). Under these conditions, *dhh1Δ/Δ* inappropriately expressed many cell wall-associated
205 transcripts. Hyphal adhesin *ALS1* was downregulated while yeast cell wall protein *YWP1* was
206 upregulated (Fig 5. C; Fig S3. E). Genes upregulated in *dhh1Δ/Δ* hyphae were enriched in GO
207 terms related to transport, metabolism, and ergosterol biosynthesis (Fig 5. D). While most
208 changes in expression were specific to environmental conditions, there was significant overlap
209 in the genes affected by *dhh1Δ/Δ* during growth in YPD and RPMI (Hypergeometric test, P <
210 $2.3e^{-22}$; Fig 5. E). Transcription factors regulating cell morphology were also differentially
211 expressed *dhh1Δ/Δ* in both conditions (Fig 5. F). Interestingly, while most TFs shifted in the
212 same direction in both conditions, hyphal repressor *NRG1* [62, 63] and cell cycle/cell wall stress
213 regulator *SWI6* [64, 65] were downregulated in YPD but upregulated in RPMI (Fig 5. F). In
214 summary, RNA-seq established widespread gene expression aberrations in SC5314 *dhh1Δ/Δ*
215 yeast and hyphae.

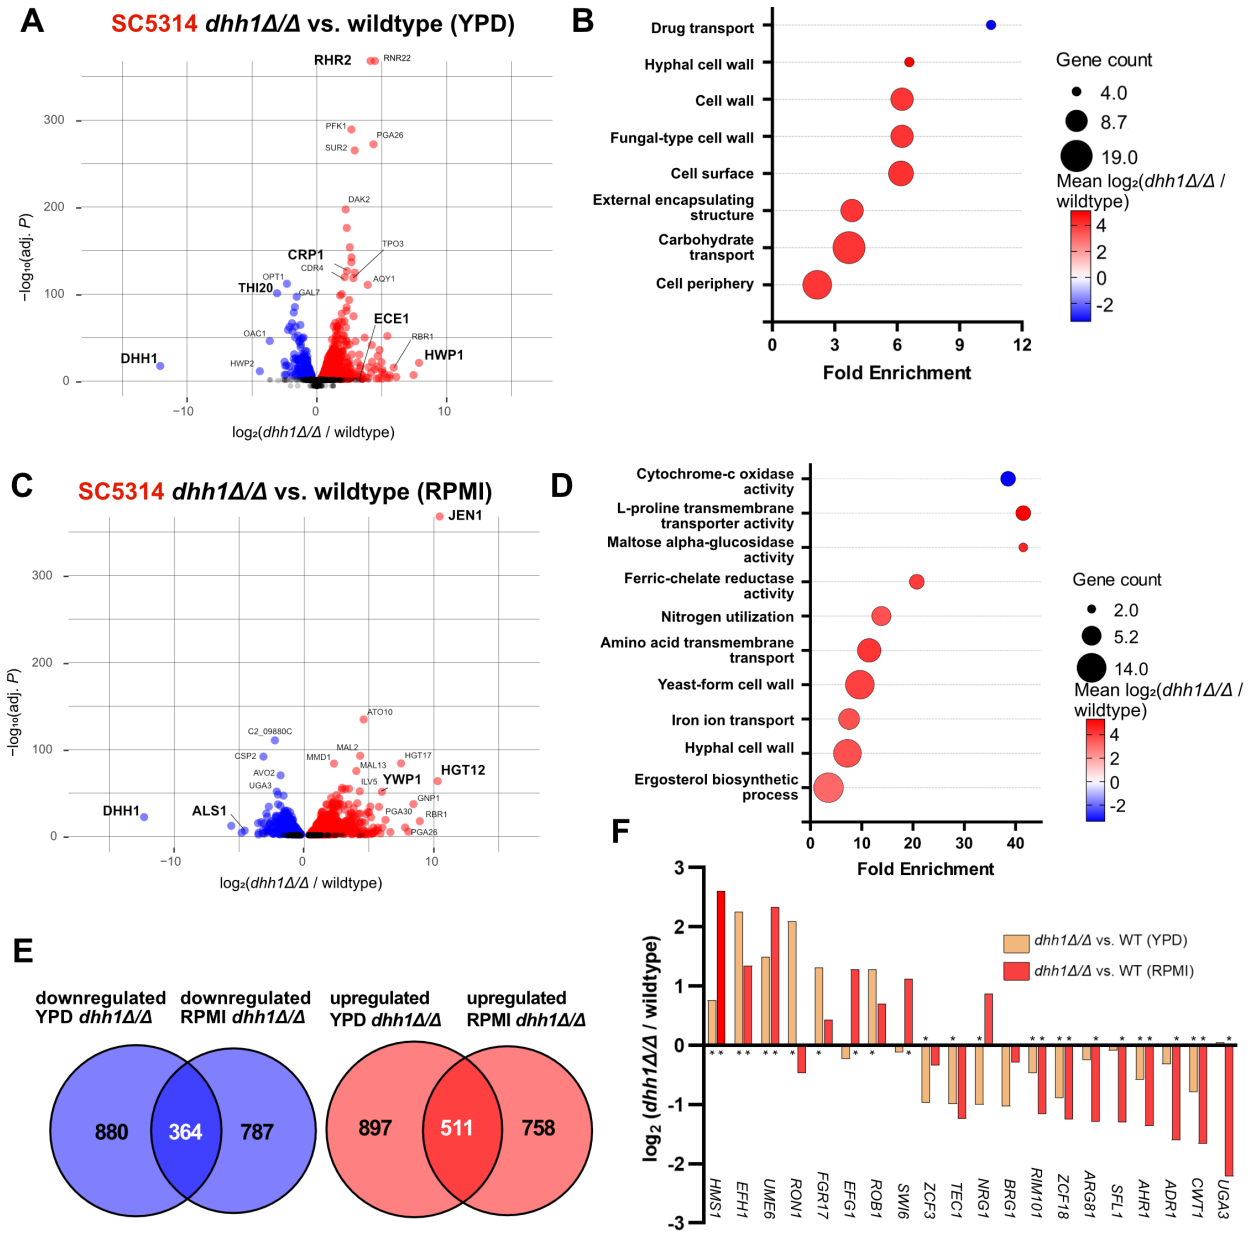

Figure 5. RNA-seq exposed differential gene expression in SC5314 *dhh1Δ/Δ* grown in YPD and RPMI. A. Volcano plot depicts genes are significantly up (red) and down (blue) -regulated in *dhh1Δ/Δ* yeast-form growth compared to wildtype (Padj < 0.01). Genes associated with filamentation stress were prominently upregulated (Table S1). **B.** GO terms enriched in *dhh1Δ/Δ* YPD include transport and cell wall terms (Padj < 0.1). **C.** Volcano plot depicts gene expression differences in *dhh1Δ/Δ* vs wildtype during early hyphal growth (Table S2, Padj < 0.01). Genes associated with metabolite transport and the yeast/hyphal cell wall were differentially expressed in *dhh1Δ/Δ*. **D.** GO terms enriched in *dhh1Δ/Δ* RPMI include transport, cell wall, and metabolic terms (Padj < 0.1). **E.** A significant number of *dhh1Δ/Δ* transcripts were downregulated ($P = 2.28e^{-22}$), and upregulated ($P = 4.37e^{-52}$), respectively, in both YPD and RPMI conditions (Hypergeometric tests). However, most differentially expressed genes were environmentally specific. **F.** Differential expression of transcription factors regulating morphogenesis in *dhh1Δ/Δ* in YPD and RPMI (* indicates Padj < 0.01; DEseq2).

216

217

218 **Filamentation dependent transcriptome remodeling is reduced in *dhh1Δ/Δ***

219 We next investigated the role of *DHH1* in gene regulation during filamentation. Comparing RNA-
220 seq results from WT SC5314 grown in RPMI and YPD showed the known extensive
221 transcriptome remodeling that occurs during filamentation, with 2,488 downregulated and 2,496
222 upregulated genes (Fig 6. A, Table S3). Hyphal cell wall proteins and ubiquitination factors such
223 as *HWP1* and *BUL1* were upregulated in WT RPMI compared to WT YPD (Fig 6. A). GO terms
224 related to ribosomal RNA, ribosomal proteins, and translation elongation were all enriched in
225 genes downregulated in WT hyphae, strongly indicating a general reduction in mRNA
226 translation (Fig 6. B). The majority of upregulated GO terms in WT RPMI were enriched in
227 carbohydrate transporters responding to the shift from rich YPD to carbohydrate poor RPMI (Fig
228 6. C). These results are consistent with known transcriptional changes that occur during WT
229 filamentation [13, 66–72].

230 We hypothesized that impaired mRNA decay in *dhh1Δ/Δ* would blunt the downregulation of a
231 subset of genes during filamentation. Indeed, transcriptional remodeling of *dhh1Δ/Δ* was
232 reduced with 1,795 downregulated and 1,919 upregulated genes, only 75% of the total number
233 of genes remodeled in WT (Fig 6. D). Genes uniquely differentially expressed in WT
234 filamentation were related to metabolism and transmembrane transport (downregulated) and
235 nucleic acid decay (upregulated). The number of up and downregulated genes during WT
236 filamentation was almost equal with only 8 more genes upregulated compared to downregulated
237 (Fig 6. A). However, *dhh1Δ/Δ* had 124 fewer genes downregulated compared to upregulated,
238 possibly due to impaired mRNA degradation (Fig 6. D). Most of the GO terms enriched in
239 downregulated genes in filamenting *dhh1Δ/Δ* were the same as WT (cf. Fig 6. B & E). Similarly,
240 most of the GO terms enriched in upregulated genes in filamenting *dhh1Δ/Δ* were also enriched
241 in filamenting WT cells (cf. Fig 6. C & F). Uniquely, terms related to lipid catabolism were
242 upregulated in *dhh1Δ/Δ* but not WT (cf. Fig 6. C & F). Changes in the expression of
243 morphology-related transcription factors were generally less pronounced in *dhh1Δ/Δ* than WT.

For some genes this was due to increased basal expression in YPD (Fig 5. F, Fig 6. G). Interestingly, unlike in WT, the filamentation repressor gene *NRG1* was not significantly downregulated in filamenting *dhh1Δ/Δ*, suggesting a mechanism for continued repression of select hyphal genes (Fig 6. G). The vast majority of differentially expressed genes in filamenting *dhh1Δ/Δ* were a subset of WT remodeling (Hypergeometric test, P = 0; Fig 6. H). In general,

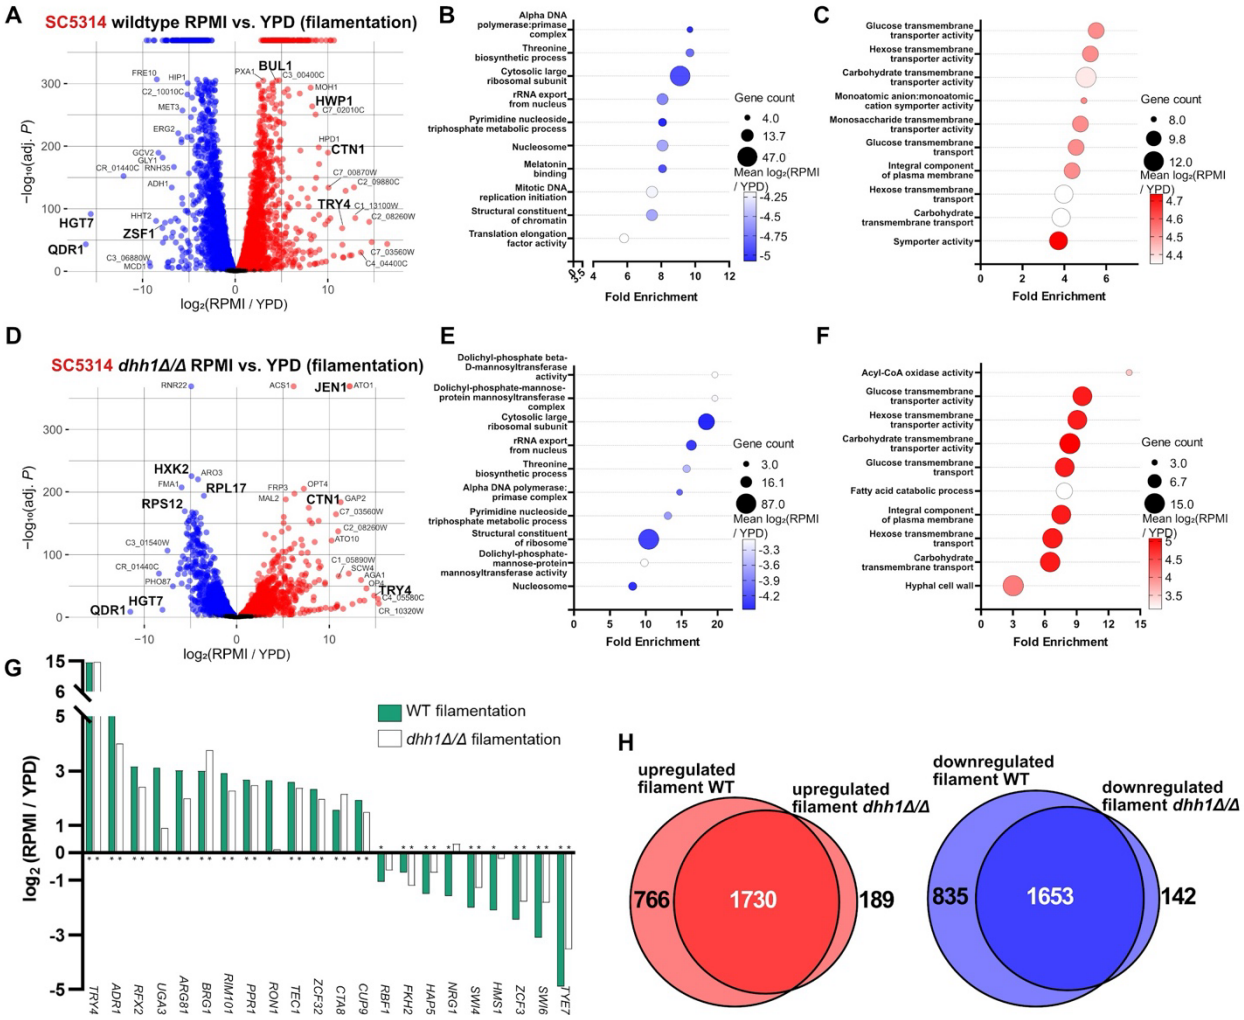

Figure 6. RNA-seq reveals transcriptome differences between SC5314 wildtype and *dhh1Δ/Δ* during filamentation. A. Volcano plots comparing the transcriptomes of WT SC5314 grown in YPD and RPMI demonstrate extensive remodeling during filamentation (Table S3, Padj < 0.01). **B.** Expected GO terms were downregulated, and **C.** upregulated during WT filamentation (Padj < 0.1). **D.** Comparing the transcriptomes of *dhh1Δ/Δ* grown in YPD and RPMI showed impaired remodeling during filamentation (Table S4, Padj < 0.01). **E.** Similar GO terms were downregulated, and **F.** upregulated in filamenting *dhh1Δ/Δ* and WT (Padj < 0.1). Unlike wildtype, *dhh1Δ/Δ* upregulated terms related to lipid catabolism during filamentation. **G.** Transcription factors regulating morphogenesis had blunted remodeling in *dhh1Δ/Δ*. (* indicates Padj < 0.01; DEseq2). **H.** Most genes differentially expressed during *dhh1Δ/Δ* filamentation are subsets of the WT remodeling response. A significant number of genes were downregulated or upregulated in both filamenting *dhh1Δ/Δ* and wild type (Hypergeometric tests, P = 0).

249 SC5314 *dhh1Δ/Δ* had a more modest transcriptome remodeling response during filamentation
250 than WT.

251 **Absence of *DHH1* alters growth, heat tolerance, and filamentation in diverse**
252 **strains**

253 Recent studies have identified considerable heterogeneity in regulatory networks that control
254 filamentation in diverse *C. albicans* strains [14, 73]. We next investigated the morphological
255 impacts of *DHH1* deletion in four additional strains representing the major *C. albicans* clades
256 [58], that we have previously used in studies of gene regulation [14]. In all backgrounds, we
257 found *dhh1Δ/Δ* impaired YPD colony growth at both 30°C and 37°C, and only a single copy of
258 *DHH1* was necessary for a WT appearance (Fig 7. A). Interestingly, the extent of *dhh1Δ/Δ*
259 growth reduction varied with the background strain. For example, P75010 *dhh1Δ/Δ* colonies
260 appeared similar in size to WT by Day 3, while P76067 and P57055 *dhh1Δ/Δ* colonies were
261 growth impaired across all temperatures and time points (Fig 7. A). A similar trend was
262 observed in liquid YPD, with P75010 exhibiting a relatively modest decrease in growth (Fig 7.
263 B). While none of the other *dhh1Δ/Δ* strains phenocopied the extensive wrinkled morphology of
264 SC5314 *dhh1Δ/Δ* grown at 37°C on YPD plates (Fig 2. D), they each diverged from WT with
265 distinct texture in the center of the colony (Fig 7. C). In the absence of *DHH1,* hyperfilamentous
266 backgrounds (P76067, P87) lost their distinct invasive margins on spider media (Fig 7. D), while
267 less filamentous strains (P75010, P57055) produced *dhh1Δ/Δ* colonies with wrinkling
268 reminiscent of SC5314 *dhh1Δ/Δ* (Fig 4. E, Fig 7. D). Thus, as in SC5314, loss of *DHH1* in four
269 diverse *C. albicans* strains reduced yeast growth, altered colony morphology under heat stress,
270 and produced phenotypically non-WT colonies on spider media. These data support a central

271 role in growth and filamentation for the RNA decay factor Dhh1 across *C. albicans* strain

272 backgrounds.

273

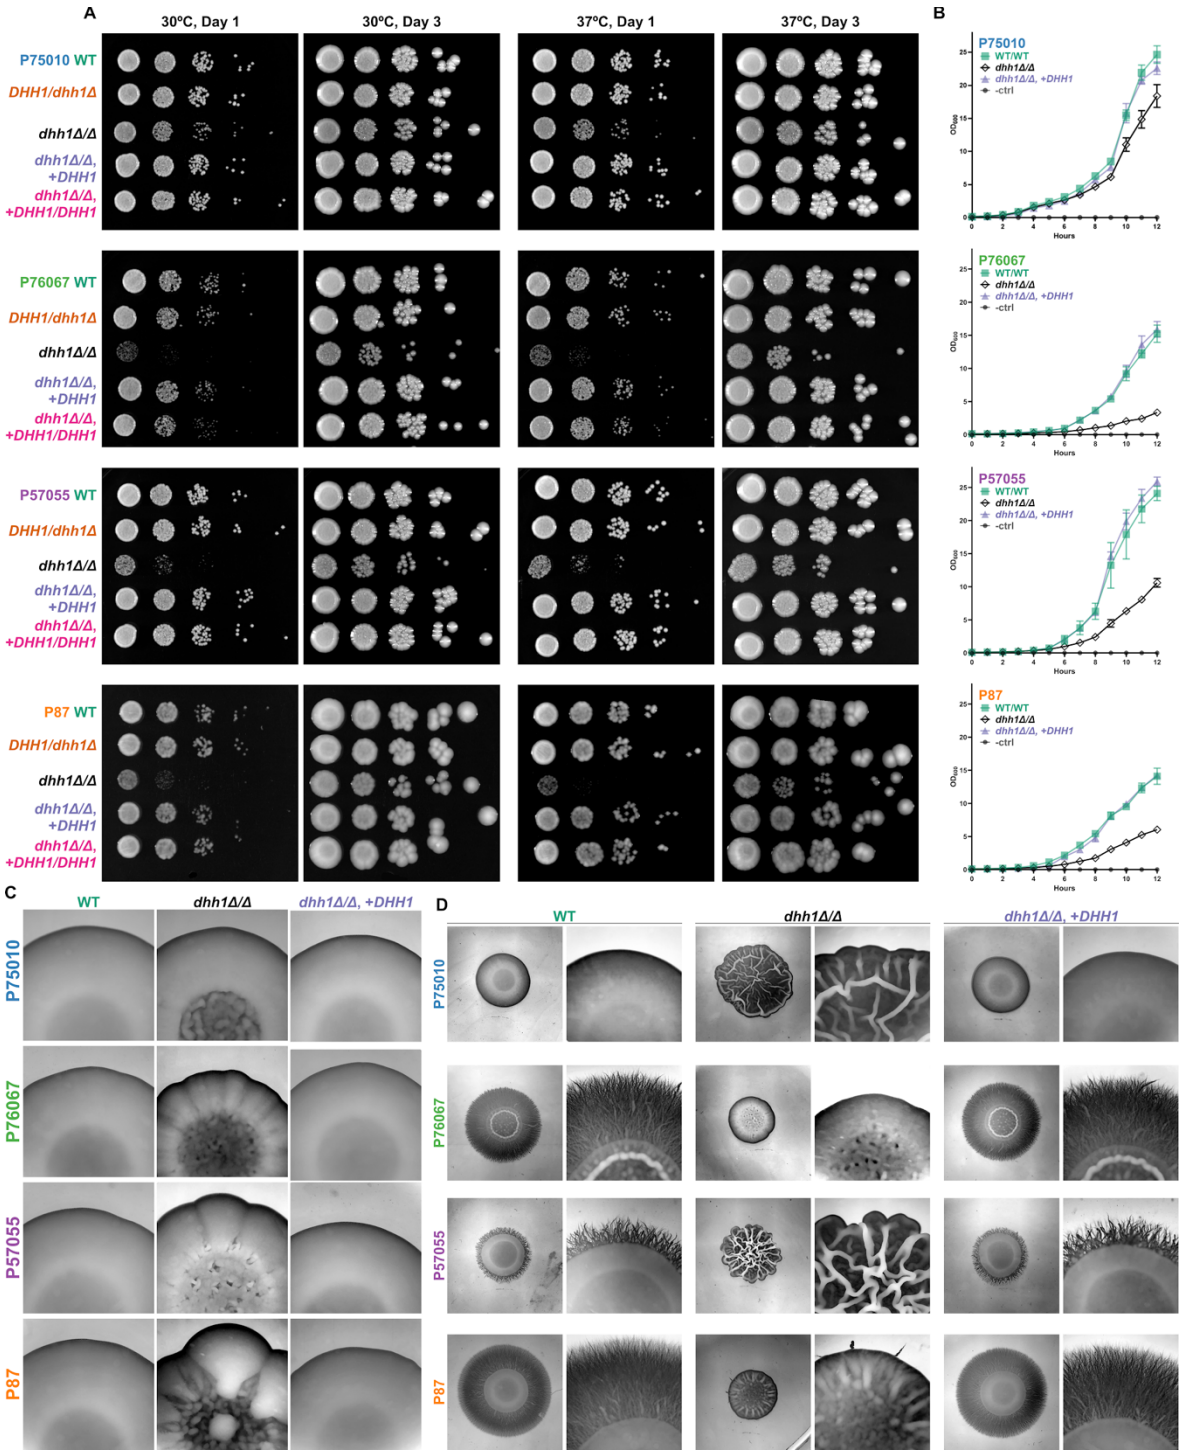

Figure 7. *DHH1* is required for wildtype growth and colony morphology in diverse strains. As in SC5314, DHH1 is required for wildtype growth, heat tolerance, and filamentation on spider media. Additionally, *dhh1Δ/Δ* impaired growth to a greater extent in hyperfilamentous strains. **A.** *dhh1Δ/Δ* resulted in slow colony growth at 30°C and 37°C on YPD plates, the extent of which varied with background strain. **B.** *dhh1Δ/Δ* reduced growth in liquid YPD (30°C). WT and mutant strains were grown in triplicate. Impairment of *dhh1Δ/Δ* exponential growth varied with strain and was rescued by complementation (*dhh1Δ/Δ*, +*DHH1*). Error bars show CI = 95%. **C.** Colonies lacking *DHH1* have a non-WT textured morphology during mild heat stress (4 days, YPD agar, 37°C). 25X magnification. **D.** Spider colony morphology varies between strains and requires *DHH1* for WT phenotype (6 days, 37°C). 6X and 25X magnification.

275 **SC5314 and P57055 transcriptomes exhibit analogous responses to *DHH1***
276 **deletion**

277 Our RNA-seq results indicated that *dhh1Δ/Δ* disrupts the expression of a wide variety of genes
278 and blunts the induction of the hyphal gene regulatory program in SC5314. To validate these
279 effects and identify genes whose expression is impacted by *dhh1Δ/Δ* in other genetic
280 backgrounds, we next used RNA-seq to identify differentially expressed genes in P57055 yeast
281 (30°C, YPD) and early hyphae (37°C, RPMI + 10% FBS, 4 hours) in triplicate (see methods for
282 details). We chose the P57055 strain because of the four strains it was the second most
283 phylogenetically distant from SC5314 [58] while displaying a similar WT filamentation capacity
284 and *dhh1Δ/Δ* phenotypic aberrations (Fig. 7, Fig S2. B-F). As in SC3514, loss of *DHH1* in
285 P57055 extensively altered the transcriptome in both yeast and hyphae (Fig. S4, Table S5-S6)
286 as well as during filamentation (Fig. S5, Table S7-S8). Comparison of the RNA-seq data from
287 SC5314 and P57055 grown in YPD, revealed a core of down (457) and upregulated (632)
288 genes in *dhh1Δ/Δ* strains compared to their respective wildtype (Fig 8. A, Table S12). Strikingly,
289 this core set was enriched with GO terms relating to catabolism, metabolism, and hyphal cell
290 wall (Fig 8. B-C). The effects of Dhh1 deletion on gene expression were more similar during
291 growth in RPMI, with 883 genes down and 901 genes upregulated in both deletion strains (Fig
292 8. D, Table S13). Genes downregulated in both deletion strains were enriched for GO terms
293 relating to transcription, transport, and zinc binding (Fig 8. E), while metabolic terms and yeast-
294 form cell wall were enriched in genes upregulated (Fig 8. F) in both *dhh1Δ/Δ* strains grown in
295 RPMI. Interestingly, morphology related TFs were differentially expressed in both *dhh1Δ/Δ*
296 strains (Fig 5. F, Fig S4. F). For example the hyphal repressor *NRG1* was significantly
297 downregulated in YPD *dhh1Δ/Δ* SC5314 (Padj = 0) and P57055 (Padj = $3.96e^{-15}$) (Table S1,
298 S5). While regulators of hyphal growth *EFH1* and *UME6* were upregulated in both *dhh1Δ/Δ*

299 strains in YPD and RPMI (Fig 5. F, Fig S4. F). These results define a core set of genes and
300 pathways dependent on Dhh1 in divergent *C. albicans* strains (Table S12-S13).

301 Finally, we examined the impact of *dhh1Δ/Δ* on filamentation in SC5314 and P57055. In
302 wildtype strains, transcriptome remodeling was highly correlated (2,085 genes downregulated
303 and 2,084 genes upregulated) (Fig 8. G) and largely involved known transcriptional changes
304 that occur during filamentation (Fig 8. H-I) [13, 66–72]. In comparison, the transcriptional
305 response to filamentation in the two *dhh1Δ/Δ* strains was somewhat less consistent with 1,375
306 genes downregulated and 1,268 genes upregulated (Fig 8. J). As in filamenting SC5314
307 *dhh1Δ/Δ* alone (Fig 6. B-C, E-F), the majority of the overlapping enriched GO terms in
308 filamenting *dhh1Δ/Δ* SC5314 and P57055 (Fig 8. K-L) were a subset of the WT terms (Fig 8. H-
309 I). In both filamenting *dhh1Δ/Δ* strains, the expression of morphology-related transcription
310 factors was blunted compared to WT (Fig 6. G, Fig S5. G). Notably, genes downregulated in
311 both *dhh1Δ/Δ* deletion strains were enriched in hyphal cell wall functions (Fig 8. K), suggesting
312 a common defect in appropriate induction of hyphal wall programs during filamentation.
313 Together, these results indicate that loss of *DHH1* causes consistent defects in the
314 morphological transition between yeast and hyphal growth in two diverse clinical isolates of *C.*
315 *albicans* (Fig 9. A-B).

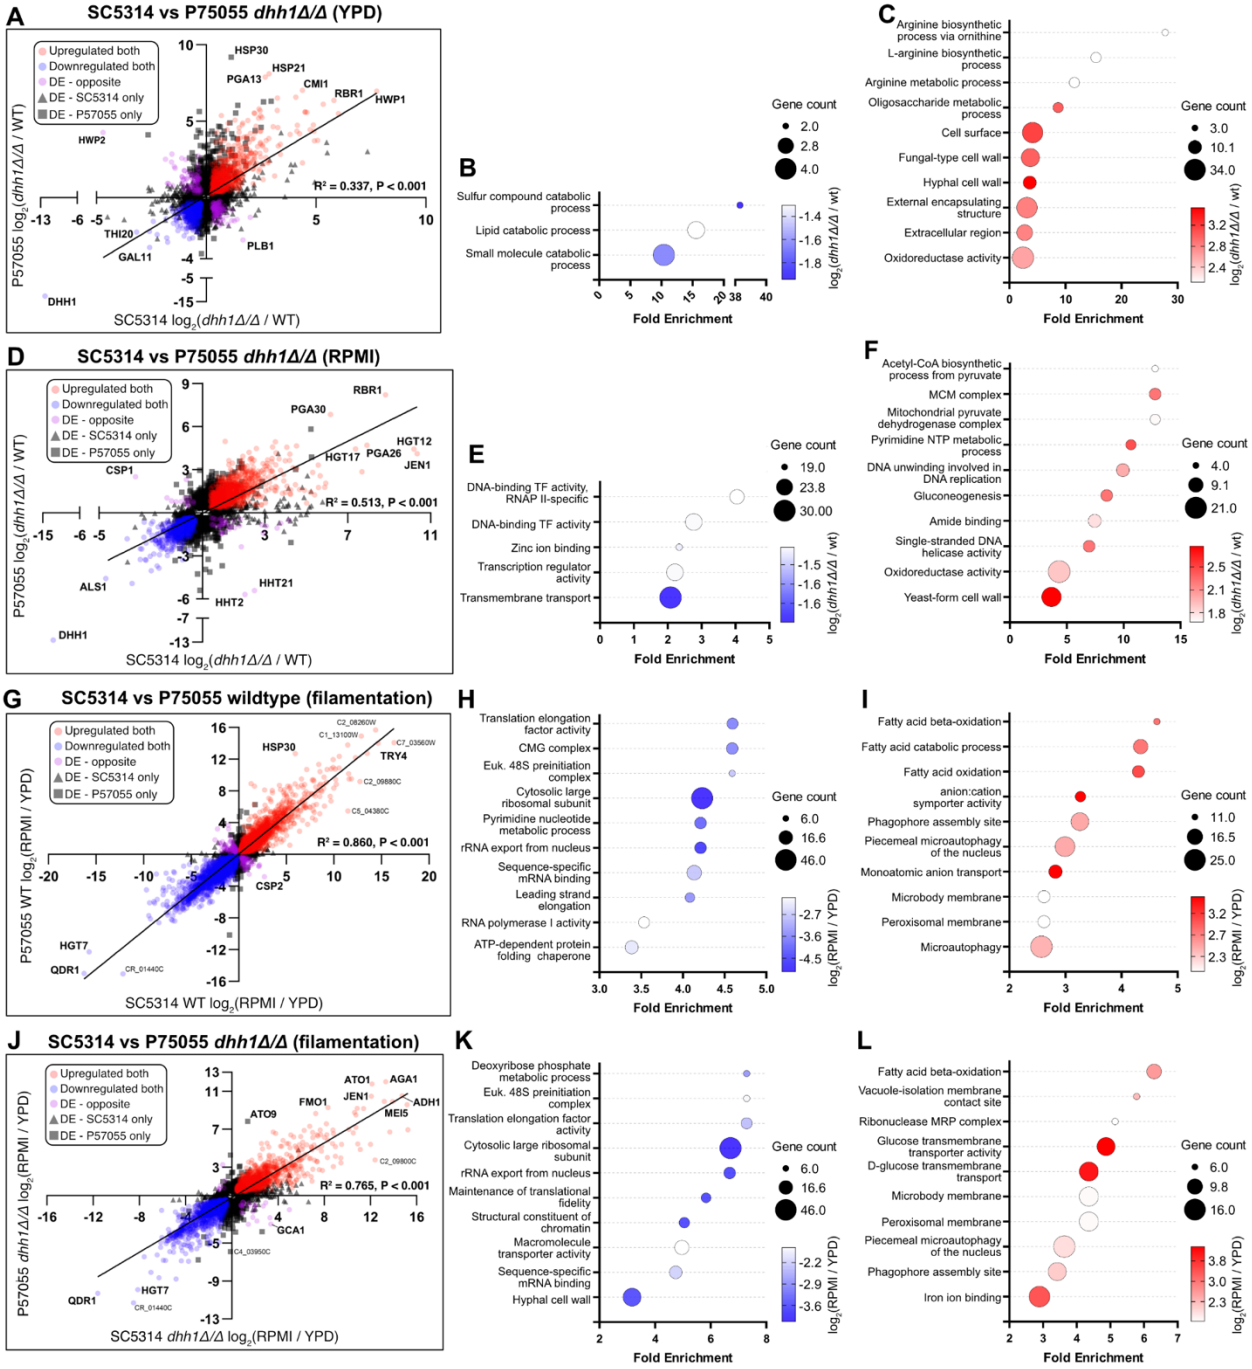

Figure 8. Differentially expressed genes and GO terms in *dhh1Δ/Δ* and WT strains correlated between SC5314 and P57055. A. Scatter plot of DE genes (Padj < 0.01) in both SC5314 *dhh1Δ/Δ* and P57055 *dhh1Δ/Δ* in YPD is moderately correlated. GO analysis of core genes **B.** down and **C.** upregulated in both *dhh1Δ/Δ* strains in YPD, emphasize terms related to the cell wall and biosynthesis. **D.** Scatter plot of DE genes (Padj < 0.01) in both SC5314 *dhh1Δ/Δ* and P57055 *dhh1Δ/Δ* in RPMI has a greater correlation than in YPD reflecting a common stress response. GO analysis of core genes **E.** downregulated and **F.** upregulated in both *dhh1Δ/Δ* strains in RPMI. **G.** Scatter plot of DE genes in both WT SC5314 and WT P57055 during filamentation (Padj < 0.01) is highly correlated. GO analysis of core genes **H.** down and **I.** upregulated during SC5314 and P57055 WT filamentation shows expected regulatory changes. **J.** Scatter plot of DE genes in SC5314 *dhh1Δ/Δ* and P57055 *dhh1Δ/Δ* during filamentation are still correlated (Padj < 0.01). GO analysis of core genes **K.** down and **L**. upregulated are generally a subset of WT except for downregulation of hyphal wall genes.

316

317 ## Discussion

318 Foundational research on the genetic bases of filamentation largely focused on transcription
319 factors [9] such as *BRG1* [74], *UME6* [75], and *EFG1* [12]. More recently, growing evidence for
320 post-transcriptional regulation of filamentation has added an additional layer of control [15, 16,
321 22]. Previous studies reported that loss of a single *DHH1* copy impairs filamentation [35] and the
322 requirement of *EDC3* for WT stress tolerance and filamentation [36, 37]. These results
323 suggested PB factors have different functions in *C. albicans* as compared to their homologs in
324 *S. cerevisiae* and *S. pombe* [35, 43, 56, 76, 77]. However, the molecular methods originally
325 used to generate *C. albicans DHH1/dhh1Δ* and *edc3Δ/Δ* can lead to confounding effects that
326 require complementation controls [78–80]. Unlike *S. cerevisiae* [46, 48, 81], the gene regulatory
327 effects of *DHH1* deletion, both during yeast and hyphal growth, were not previously
328 characterized in *C. albicans*. Here we investigated the roles of PB factors Dhh1 and Edc3 in *C.*
329 *albicans* growth, filamentation, and gene expression across multiple strains.
330 Our work helps refine our understanding of Dhh1 and Edc3 in PB formation. Previous studies
331 reported Edc3 was necessary for observable PBs during *C. albicans* glucose starvation [36].
332 Contrary to this, *S. cerevisiae* PBs condense in the absence of many individual protein factors,
333 including Dhh1 and Edc3 [44]. Our findings align with the roles of these genes in *S. cerevisiae*
334 and other eukaryotes. In *C. albicans*, PBs condense during heat shock without Dhh1 or Edc3
335 (Fig 1. F-G, Fig S1. B-C). Our results suggest that, as in *S. cerevisiae* [27, 44, 82], the absence
336 of multiple scaffolding proteins would be required to completely disassemble *C. albicans* P-
337 bodies [27, 44, 82]. Additionally, we found Dhh1 was both present in PBs and cytoplasmically
338 diffuse, suggesting a PB-independent function in the cytoplasm (Fig 1. B), as in *S. cerevisiae*
339 [44, 45]. For example, in *S. cerevisiae*, impaired ATPase activity of Dhh1 caused it to
340 accumulate in PBs and impaired mRNA decay of specific transcripts possibly due to decreased

concentration in the cytoplasm [25, 45]. Thus, *C. albicans* PBs may share many of the well documented functions and characteristics of their homologous condensates from *S. cerevisiae*.

Our phenotypic results differ from previous work. First, haploinsufficiency in filamentation was previously reported for *DHH1/dhh1Δ* in BWP17 [35]. In contrast, we found that only homozygous *dhh1Δ/Δ* mutations had aberrant filamentation in five diverse *C. albicans* strains (Fig. 3-4, 7D). Additionally, a single copy of *DHH1* complements these growth defects (Fig. 3-4, 7D). This suggests *DHH1* is not a rate limiting factor for mRNA decay. Additionally, we found that *EDC3* is not required for heat tolerance or filamentation in five different strains, contrary to results from BWP17 [36, 37] (Fig. S2). While *EDC3* may not be essential for filamentation, retaining this gene likely confers an as of yet unknown evolutionary advantage to *C. albicans*. For example, Edc3 contributes to suppressing the misexpression of starvation genes in *S. cerevisiae* [54]. Although we found different phenotypes for deletion of *DHH1* and *EDC3* than in prior studies, this earlier work used a deletion approach that can cause off-target effects [78–80] and complementation studies confirming the deletions were not performed [35, 36, 83]. Our results highlight the power of targeted deletion through CRISPR-Cas9 and the importance of complementation analysis of genetic phenotypes.

Recently, a number of studies have reported considerable heterogeneity in the phenotypes of diverse *C. albicans* strains, which can vary depending on environmental conditions [58, 84, 85]. Comparison of phenotypes across diverse strains has also been used to identify core functions of genes [14, 73]. We used this strategy to compare the functions of Dhh1 in filamentation in SC5314 and four additional strains. After growing diverse *dhh1Δ/Δ* strains on spider media, we found deletions in hyperfilamentous strains produced colonies that failed to invade agar, yet presented other aspects of hyphal morphology (Fig 4. E, Fig 7. D). Interestingly, in strains with minimal filamentation potential (P75010 and P57055), *dhh1Δ/Δ* presented colonies with more pronounced wrinkling (Fig 7. D). Furthermore, *dhh1Δ/Δ* in non-filamentous P75010 had a

366 minimal reduction in yeast-form growth rates as compared to highly filamentous strains like
367 P76067 (Fig 7. A-B). One intriguing possibility is that highly filamentous strains are more reliant
368 on mRNA decay to prevent the inappropriate expression of stress response and filamentation
369 genes (Fig 9A). In conclusion, *dhh1Δ/Δ* impacts growth and colony morphology in multiple
370 backgrounds in a manner correlated with their intrinsic filamentation propensity.

371 We also investigated the effects of *dhh1Δ/Δ* on the transcriptomes of *C. albicans* under both
372 yeast and filamentous growth. Strikingly, we found the absence of *DHH1* induces major
373 transcriptomic changes in both yeast (YPD) and hyphae (RPMI) in SC5314 and P57055 (Fig. 5,
374 Fig. S4). These changes suggest an "identity crisis", such that the deletion strains express
375 hyphal genes under yeast-growth conditions (Fig 9. B). In YPD, *dhh1Δ/Δ* upregulates genes
376 normally associated with hyphal virulence such as *RHR2* [86], *ECE1* [5], and *HWP1* [87] in
377 SC5314 and P57055 (Figs 5. A, S3 C-D, S4 A; Tables S1 & S5). However, *ECE1* and *RHR2*
378 upregulation is more modest in *dhh1Δ/Δ* P57055 and only approaches statistical significance
379 (Padj = 0.076 and 0.013), respectively. (Table S1, Table S5). Under both yeast and hyphal
380 conditions, genes upregulated by *dhh1Δ/Δ* are enriched in cell wall and cell surface GO terms in
381 both SC5314 and P57055 (Fig. 5-6, Fig. S4-S5). The resulting effect is expression of cell wall
382 genes that are unsuitable to the growth condition (Fig 9B). For example, in both strains *dhh1Δ/Δ*
383 upregulates yeast cell wall protein *YWP1* and downregulates hyphal adhesion *ALS1* in RPMI
384 (Figs 5 C, S3 E, S4 C; Tables S2 & S6). These results support a model in which Dhh1 prevents
385 the misexpression of genes involved in the transition between yeast and hyphal growth.

386 A number of transcription factors are known to regulate filamentation [9, 68, 75]. Our results
387 show that DHH1 deletion led to inappropriate expression of several key transcriptional
388 regulators in both SC5314 and P57055 (Fig 5. F, Fig S4. F). Hyphal repressor *NRG1* [62, 63]
389 was downregulated in YPD, potentially de-repressing downstream hyphal associated genes
390 across both *dhh1Δ/Δ* strains (Fig 5. F, Table S1, S5). Similarly, regulators of hyphal growth

391 *EFH1* and *UME6* were upregulated in both *dhh1Δ/Δ* strains in YPD and RPMI (Fig 5. F, Fig S4.
392 F). We find the upregulation of *UME6* particularly interesting because *UME6* constitutive
393 expression produces hyphae under non-filament inducing conditions [75]. Furthermore, *UME6*
394 has an extremely long 5' UTR mediating translational efficiency, and it has been proposed that
395 sequences in the *UME6* 5' UTR could direct its transcripts to PBs [88]. The misregulation of
396 these transcription factors could directly upregulate hyphal cell wall genes and contribute to the
397 textured phenotype seen in all our *dhh1Δ/Δ* strains at 37°C (Fig 2. D, Fig 7. C). Interestingly,
398 under filamentation conditions SC5314 and P57055 *dhh1Δ/Δ* strains upregulated select hyphal
399 transcription factors (e.g. *UME6*, *SWI6*) more than their respective WT strains (Fig 5. F, Fig S4.
400 F). We propose that loss of *DHH1* leads to pleiotropic hyphal morphology through alterations in
401 the expression of hyphal transcription factors and their downstream regulatory networks (Figs 7
402 D & S4 F).

403 In many species stochastic transcriptional noise serves as a form of "bet-hedging" for acute
404 environmental stressors [38–40]. For example, within a population of *C. albicans*, individual cells
405 heterogeneously express the hyphal transcription factor Efg1, adapting colonization to host
406 immune status [89]. Our data support a model where *C. albicans* adapts to diverse host
407 microenvironments by transcribing multiple stress-associated genes, while simultaneously
408 buffering expression via mRNA decay. This strategy promotes rapid responses to diverse
409 stressors without investing energy towards environmentally inappropriate proteomic and
410 phenotypic remodeling. Consistent with this model, we find blunted transcriptome remodeling
411 during filamentation in both *dhh1Δ/Δ* strains as compared to their respective wildtype strains
412 (Fig 6. A, D, Fig S5. A, D). We postulate this results from upregulation of stress-response genes
413 in YPD and defective mRNA decay in the absence of *DHH1*. Further work is needed to test this
414 model of decay-mediated suppression of noisy stress-response genes in *C. albicans* as a
415 mechanism to regulate appropriate environmental adaptation.

B

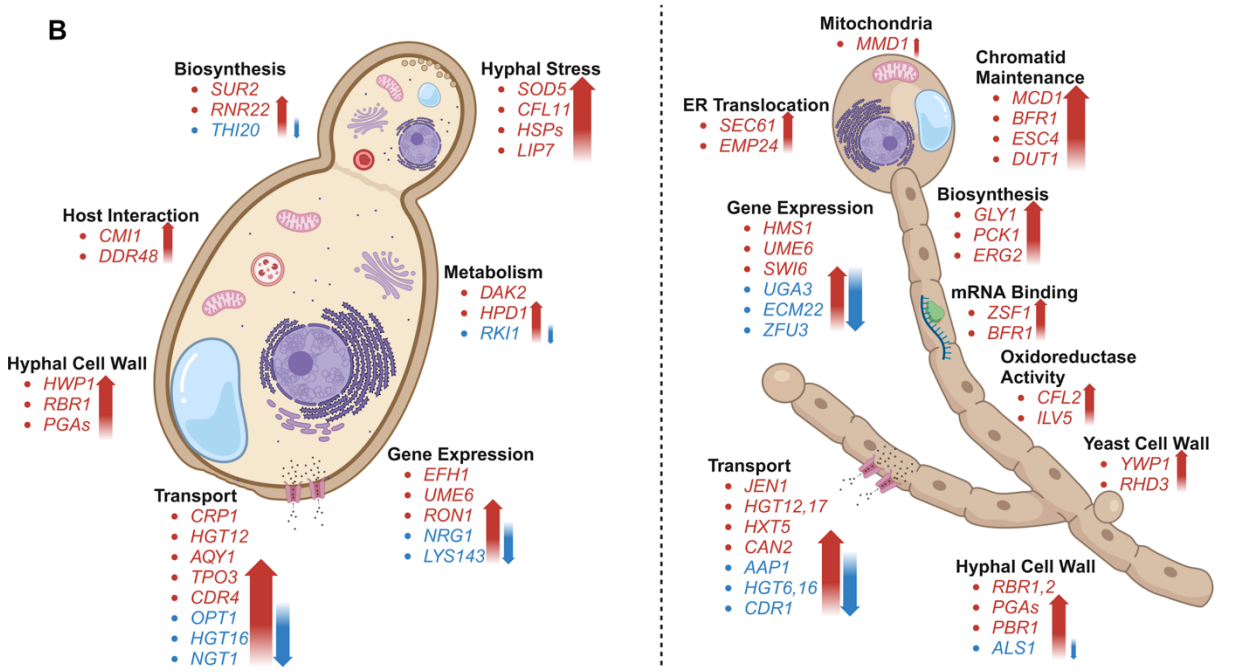

Figure 9. Phenotypic and transcriptomic outcomes in diverse *dhh1Δ/Δ* strains. Despite differences between WT background strains, loss of *DHH1* is associated with specific morphological and transcriptomic outcomes across diverse clades. **A**. Hyperfilamentous strains are more phenotypically sensitive to the loss of *DHH1*. **B.** Diagram of overlapping transcripts and terms in SC5314 *dhh1Δ/Δ* and P57055 *dhh1Δ/Δ* in YPD and RPMI. Under yeast-form growth conditions *dhh1Δ/Δ* fails to repress the hyphal stress response. Under hyphal growth conditions *dhh1Δ/Δ* presents a misregulated transcriptome including persistence of yeast features. Genes in red were significantly upregulated, while genes in blue were significantly downregulated (Padj < 0.01).

416 As with our phenotype results, our transcriptome analysis of *C. albicans DHH1* deletion strains
417 suggests a similar regulatory role as its homologs in other fungi. For example, in *C. neoformans*,
418 the Dhh1 homologue Vad1 is required for virulence and suppresses the transcript of mating
419 pheromone *MFα* under vegetative conditions [51, 90, 91]. This suggests Dhh1/Vad1-mediated
420 RNA decay for environmentally suitable gene expression. In *S. cerevisiae*, Dhh1 has been
421 reported to repress genes associated with nutrient limitation under optimal growth conditions
422 [48]. Additionally, it has been proposed that transcripts with slow translation and poor codon
423 optimality are targeted for Dhh1 dependent mRNA decay [46, 47]. Our results suggest rare

424 codons do not mark genes for Dhh1-mediated mRNA decay in *C. albicans,* as genes
425 upregulated in SC5314 and P57055 *dhh1Δ/Δ* had higher codon adaptation index (CAI) values
426 than downregulated genes (Fig. S6). However, we found both *C. albicans dhh1Δ/Δ* strains
427 upregulate genes involved in cell wall and non-preferred carbon/nitrogen metabolism –
428 pathways similar to those that were de-repressed in *S. cerevisiae dhh1Δ* [48]. Thus, our results
429 are consistent with the observation that Dhh1 suppresses genes associated with nutrient
430 limitation in *S. cerevisiae.* We hypothesize that *C. albicans* Dhh1 and its homologues in other
431 fungi support environmentally optimal gene expression by buffering noisy transcription through
432 mRNA decay.

433 Altogether, our work identifies an important role for Dhh1 in regulating filamentation in *C.*
434 *albicans* and implicates post-transcriptional regulation in the control of key regulators of hyphal
435 growth. Future studies are needed to elucidate the features of transcripts repressed by Dhh1 in
436 *C. albicans* under different growth conditions. For example, 4-thioU pulse-chase experiments
437 could identify changes in RNA stability in the *dhh1Δ/Δ* mutant to further investigate if Dhh1
438 promotes decay of noisy stress-response transcripts. Additionally, an auxin inducible
439 degradation system [92] knocking down Dhh1, could distinguish direct targets of Dhh1 mediated
440 decay from downstream stress-responses to dysregulated RNA metabolism. Regardless of the
441 outcomes of such studies, our work clearly defines an important role for Dhh1 in regulating
442 filamentous growth and gene expression in *C. albicans*.

443 Materials and methods

444 Strains and media

445 All strains (Table S9) were maintained as 15% glycerol stocks stored at -80°C. Before all
446 experiments, strains were streaked on YPD agar (MP Biomedicals) and grown for two days at
447 30°C. Single colonies were picked and grown in liquid YPD (2% Bacto Peptone, 2% dextrose,

448 1% yeast extract) on a rotator overnight at 30°C. For PB imaging in live yeast (Fig. 1 A-C, F-G
449 and Fig. S1 A-C), we used complete media (CM) (0.68% yeast nitrogenous base, 0.079% CSM
450 complete AA mixture, 2% dextrose) to minimize background fluorescence. The growth media for
451 planktonic filamentation and biofilm assays was RPMI 1640 (Gibco, minus phenol red) with 10%
452 FBS (Gibco). For PB (Edc3-mNeonGreen) imaging during filamentation (Fig. 1 E), we used
453 100% RPMI without phenol red due to background fluorescence of FBS. We evaluated
454 filamentous colony morphology with spider plates [93] (1% nutrient broth, 1% D-mannitol, 0.2%
455 K_2HPO_4, 2% agar).

456 **Strain construction**

457 WT strains and plasmids pV1093 and pRS316 were used for CRISPR-Cas9 genome editing
458 [57, 94]. mNeonGreen [95] was appended to the C-terminus of *EDC3* using lithium acetate
459 transformation and the SAT1 FLP/FRT cassette (pRS316) [94] without the CRISPR-Cas9
460 system. For all other gene insertions (including *DHH1*-mScarlet (Fig S7. A)) and our whole-gene
461 deletions, we used transient CRISPR-Cas9 [57] with the SAT1 FLP/FRT cassette [94] which
462 leaves a 34bp FRT scar in the genome. Optimal Cas9 guide RNAs and PAM sites were
463 selected from a database of unique sites [96]. The SAT1 FLP/FRT cassettes with C-terminal
464 *EDC3*-mNeonGreen and *DHH1*-mScarlet tags included sequences homologous to the 3' end of
465 the target genes and a GGSG linker [95]. To completely delete *EDC3* and *DHH1*, our cassettes
466 used homologous sequences upstream and downstream of the CDS (Fig S7. B). Additionally,
467 for the *DHH1* complement (*dhh1Δ/Δ* background) we inserted *DHH1* fused to the *TPI1* promoter
468 at the *MDR1* locus replacing the entire gene (Fig S7. C).

469 For plasmid transformations, single colonies were picked from 2 day YPD plates and incubated
470 in 5mL YPD on a rotator overnight at 30°C. The next day, the overnight culture was diluted to
471 OD_{600} = 0.2 in 50mL YPD and grown to OD_{600} = 0.8 (30°C, 300 RPM). Cells were collected by
472 centrifugation (1,600 RCF, 5 minutes) in a 50mL falcon tube, washed with 5mL sterile dH_2O,

473 resuspended 500µL LATE solution (0.1M LiAc/TE) and transferred to a 1.5mL microcentrifuge
474 tube. 1µg of each PCR product (sgRNA, caCas9, SAT1 FLP/FRT) and 10µL boiled calf thymus
475 DNA were added and cells were rotated for 30 minutes at 30°C before adding 700µL freshly
476 made PLATE solution (800µL 50% PEG 4,000, 100µL 10X TE, 100µL 1M LiAC). Cells were
477 then rotated overnight at 30°C. The next day, cells were gently mixed and incubated at 44°C for
478 15 minutes. The cells were harvested by centrifugation (1,500 RCF, 30 seconds), washed and
479 resuspended in 2mL YPD. Cells were then incubated for 5 hours at 30°C on the rotator in 15 mL
480 falcon tubes. After this recovery period, cells were harvested by centrifugation (1,600 RCF, 3
481 minutes and resuspended in 200µL YPD. 100µL of resuspended cells were plated on each of
482 two YPD plates with 400µg/mL nourseothricin (clonNAT/NTC; Goldbio #N-500-1) and incubated
483 at 30°C for 48 hours. We extracted gDNA [57, 97] and verified insertion of SAT1 FLP/FRT and
484 homo/heterozygosity in colonies by PCR.

485 Transformed colonies were incubated in a 15mL falcon tube with 10mL YPM (2% Bacto
486 Peptone, 2% maltose, 1% yeast extract) overnight to induce excision of the SAT1 FLP/FRT
487 cassette. Overnight YPM cultures were serially diluted by $1:10^5$ to $1:10^6$ and 100µL was spread
488 on YPD + 40µg/mL clonNAT plates and incubated at 30°C. After 48 hours, small colonies were
489 selected, indicative of SAT1 FLP excision. All strains were validated by gDNA PCR for cassette
490 insertion, homo/heterozygosity, and excision of SAT1 [57, 97]. We used *TDH3* as the control for
491 gDNA extraction and amplification. All strains, plasmids, guide RNA and PAM sites as well as
492 primers for strain construction and verification are listed in Table S9.

493 **Phenotype assays**

494 For PB imaging in live cells, strains were grown overnight in a rotator at 30°C in CM, diluted to
495 an OD_{600} of 0.1, and subcultured (30°C, CM, 300 RPM) for 4 hours before loading into an
496 Bioptechs FCS2 with a coverslip coated with 2% ConA to maintain desired temperature. All
497 OD_{600} measurements were taken with a GENESYS 20 spec with 1mL plastic cuvettes. For PB

498 imaging during heat shock (Fig 1. B-C, F-G & S1), cells were incubated in CM for 10 minutes at
499 46°C. For imaging PBs during starvation (Fig 1. D), SC5314 mNeonGreen tagged strains were
500 incubated in PBS at room temperature for 3 hours. To image PBs (Edc3-mNeonGreen) during
501 filamentation (Fig 1. E), we used 100% RPMI minus phenol red. All other filamentation assays
502 used RPMI supplemented with 10% FBS.

503 For spot plates, strains were grown overnight at 30°C in 5mL of liquid YPD on a rotator, diluted
504 to an OD_{600} of 0.5 and serially diluted 10-fold in YPD. YPD plates were spotted with 5µL of
505 diluted cells and incubated for 1-3 days at 30°C and 37°C prior to imaging with a Bio-Rad
506 ChemiDoc Touch Imaging System. To quantify growth in liquid YPD, strains were grown
507 overnight at 30°C in YPD on a rotator, diluted to an OD_{600} of 0.1 in 25mL YPD and incubated for
508 12 hours at 30°C. Strains were grown in triplicate andOD_{600} was measured hourly with a
509 GENESYS 20 visible spec with 1mL plastic cuvettes. Colony morphology under heat stress (4-
510 days, YPD, 37°C) and filamentation conditions (6-days, spider media, 37°C) was assayed
511 similarly prepared in the same manner. Strains were grown overnight in a rotator at 30°C in 3mL
512 liquid YPD, harvested by centrifugation (1,000 RCF, 5 minutes), washed three times with 6mL
513 PBS, and diluted to OD_{600} = 0.33 in 1mL PBS before spotting 3µL on YPD/spider plates.

514 To evaluate planktonic filamentation we grew strains overnight at 30°C in liquid YPD, diluted
515 them to an OD_{600} of 0.2 the following morning and subcultured them to an OD_{600} of 0.6 in 25mL
516 YPD before centrifuging (2,800 RCF, 5 minutes) the entire volume. We washed the cell pellet
517 with 5mL RPMI + 10% FBS and induced filamentation (25mL RPMI + 10% FBS, 37°C, 300
518 RPM). After 4 and 16 hours, cells were centrifuged (2,800 RCF, 5 minutes), fixed with 2mL 4%
519 formalin, and washed three times with 2mL PBS. 500µL of the washed cells in PBS were
520 stained the sample with 200µg/mL calcofluor white. The fixed and stained cells were allowed to
521 adhere to a glass slide treated with polyallylamine (PA) and washed with PBS prior to imaging

522 To survey biofilm growth, we grew cells overnight at 30°C in 5mL YPD on a rotator and diluted
523 them to an OD_{600} of 0.33 in 1.5mL RPMI + 10% serum. In four wells 200µL of diluted cells were
524 added to a 96-well ibidi plate coated with polyallylamine (PA) and incubated for 90-minutes at
525 37ºC for adherence. After 90 minutes, the media was removed leaving only adherent cells and
526 incubated with 400µL fresh RPMI + 10% serum. After a 24-hour incubation at 37°C, cells were
527 fixed with 350µL 4% formalin, washed twice with 400µL PBS, and stained with 400µL ConA
528 Alexa Fluor 594 conjugate (200µg/mL) overnight. The following morning we removed the ConA
529 Alexa Fluor 594 conjugate and washed the stained biofilms with 400µL PBS prior to adding
530 400µL 50% TDE in PBS and incubating it for 30 minutes. The 50% TDE solution was removed
531 and 400µL100% TDE solution was applied before confocal imaging.

532 Colony morphology under heat stress (4-days, YPD, 37°C) and filamentation conditions (6-days,
533 spider media, 37°C) was assayed similarly. Strains were grown overnight in a rotator at 30°C in
534 3mL liquid YPD, harvested by room temperature centrifugation (1,000 RCF, 5 minutes), washed
535 three times with 6mL PBS, and diluted to OD_{600} = 0.33 in 1mL PBS before spotting 3µL on
536 YPD/spider plates.

537 **Imaging and processing**

538 Single-cell fluorescence, DIC, and transmitted light images were captured with a Zeiss Axiovert
539 200M microscope using a 100X Plan-NEOFLUAR, 25X Plan-Apochromat, or 40X Plan-
540 Apochromat objective. For PB images in Fig. 1, all of the strains were in a SC5314 background
541 and imaged live. Temperature was maintained on the stage using a Bioptechs FCS2 chamber.
542 Only Fig 1. D is a confocal image captured with a 50-micron confocal slit wheel and processed
543 with a Z-projection. The remaining images in Fig. 1 consist of single planes of transmitted light
544 and fluorescence. As such, we were unable to quantify PB number or volume per cell in those
545 images. PB images in Fig. 1 were processed in Fiji by applying the Find Edges tool in the
546 transmitted light images for cell outlines, and background blur was reduced in the fluorescence

547 images using Subtract Background with a rolling ball radius of 30 pixels. Transmitted and
548 fluorescence images were overlaid using the Merge Channels tools. Replicates of the dual
549 labeled strain (Edc3-mNG, Dhh1-mS) are in Fig S1. A in addition to condensates in Dhh1-mS,
550 *edc3Δ/Δ* (Fig S1. B) and Edc3-mNG, *dhh1Δ/Δ* (Fig S1, C).

551 Spot plate images were adjusted for brightness/contrast in Fiji for increased visibility (Fig 2. A-B,
552 Fig 7. A, Fig S2. A). For the colonies under heat stress (4-days, YPD, 37°C) and filamentation
553 conditions (6-days, spider media, 37°C), images were collected with a Wild M8 Heerbrugg
554 Stereo Microscope at 6X and 25X and an iPhone 11 (Fig 2. D, Fig 4. E, Fig 7. C-D, Fig S2. F).
555 In Fiji colony images were converted to 8-bit and the LUT was inverted to improve resolution of
556 colony texture. To ensure comparability of colony size all 6X images were cropped to 1,500
557 pixels^2 and 25X images were cropped to 1,900 pixels^2 without any resizing. From DIC images in
558 Fig 2. E, cell and vacuole areas were measured in Fiji using the freehand tool in the Regions of
559 Interest (ROI) manager. A total of 100 cells across at least 4 fields of view were quantified to
560 generate the graphs Fig 2. F-H.

561 For the 4 and 16 hour planktonic filamentation assays we imaged short fluorescence confocal
562 stacks (Fig 3. A, C, Fig S2. B). In Fiji background blur was reduced in the fluorescence images
563 using Subtract Background with a rolling ball radius of 30 pixels prior to Z projection. We
564 quantified the extent of filamentation by measuring length by width in 100 cells in at least 4
565 fields of view using the straight and segmented line tools in the Regions of Interest (ROI)
566 manager (Fig 3. B, D, Fig S2. C).

567 For the biofilm growth assays, we took 25X fluorescence confocal stacks from the base to the
568 apical region of the biofilm (Fig 4. A, Fig S2. D). In Fiji we converted the images to 32 bit and
569 subtracted the background with a rolling ball radius of 13 pixels and set any resulting negative
570 values to zero. To generate a side view of the biofilm we resliced the rectified image, Z

571 projected and rescaled the Y values. The depth of the biofilms was quantified using the straight
572 line tool in the Regions of Interest (ROI) manager (Fig 4. B, Fig S2. E). To estimate cell density
573 throughout the biofilm we used pixel brightness as a proxy from the Plot Z-Axis Profile function
574 that generates a mean brightness (of the cell wall stain) for each slice in the stack (Fig 4. D).

575 **RNA-extraction and sequencing**

576 All experimental strains and conditions were assayed in triplicate (SC5314 WT YPD, SC5314
577 WT RPMI, SC5314 *dhh1Δ/Δ* YPD, SC5314 *dhh1Δ/Δ* RPMI) and (P57055 WT YPD, P57055 WT
578 RPMI, P57055 *dhh1Δ/Δ* YPD, P57055 *dhh1Δ/Δ* RPMI) for a total of 12 samples in each strain
579 background. Strains were grown overnight at 30°C in liquid YPD and diluted to an OD_{600} of 0.2
580 in liquid YPD the next morning. Sub-cultured cells were grown in 120mL YPD at 30°C with 300
581 RPM shaking until the OD_{600} reached 0.8. 20mL of the culture was collected in a 50mL falcon
582 tube and centrifuged at 4°C (3,220 RCF, 3 minutes). The supernatant was removed and the
583 cells were frozen at -80°C. 80mL of yeast cells were washed with PBS and resuspended in
584 80mL pre-warmed RPMI + 10% serum, followed by incubation at 37°C and 300 RPM. After 4
585 hours, 20mL of early hyphae was collected by sterile filtration (500mL Nalgene Rapid-Flow
586 Sterile Disposable Filter Unit with PES 0.2 µm), washed on the filter twice with 5mL ice cold
587 RNA buffer (4M NaCl, 1MTris-HCl pH7.5, EDTA), and frozen at -80°C. Cell pellets were stored
588 at -80°C.

589 RNA extraction was adapted from Cravener and Mitchell, 2020 [60]. Frozen cells in falcon tubes
590 were resuspended in 1mL ice-cold RNA buffer (4M NaCl, 1MTris-HCl pH7.5, EDTA). 500 uL of
591 resuspended cells were mixed with 250µL zirconia beads and 500 uL acid phenol:chloroform
592 pH4.5 (Ambion #AM9722) in 2mL microcentrifuge tubes and subjected to 10 cycles of vortexing
593 and chilling on ice for one minute each. After centrifugation at room temperature (16,873 RCF, 2
594 minutes), the aqueous phase was removed and back-extracted with an equal volume of
595 chloroform-isoamyl alcohol 24:1 (Sigma Aldrich #C0549). The resulting aqueous phase was

596 removed again, added to 3 volumes of ice cold 100% ethanol and precipitated at -80°C
597 overnight. The precipitated RNA was centrifuged at 4°C (20,817 RCF, 15 minutes) . RNA pellets
598 were washed with 1,800µL 70% ice cold ethanol and resuspended in 100µL ultrapure water.
599 Total RNA was quantified with a Thermo Scientific NanoDrop. Genomic DNA was removed from
600 5µg RNA using the invitrogen TURBO DNA-free kit according to manufacturer's specifications.
601 After the DNase treatment, RNA was re-extracted by adding 250µL RNA buffer, 500µL TRizol
602 (Invitrogen #15596026), and 250µL chloroform-isoamyl alcohol 24:1 (Sigma Aldrich #C0549).
603 This was vortexed and centrifuged at 4°C(20,817 RCF, 15 minutes). The aqueous phase was
604 removed and added to an equal volume of 100% ice cold ethanol and recovered using the RNA
605 Clean & Concentrator kit from Zymo Research according to the manufacturers specifications.
606 RNA was eluted in 60µL ultrapure water. RNA concentrations (range = 62.6ng/µL-105.5ng/µL)
607 were measured by NanoDrop and RIN^e was quantified using an Agilent 2200 TapeStation
608 System (range = $7.8RIN^e$ -$9.9RIN^e$). Strand-specific,150bp-paired ends were sequenced by
609 Novogene using the NEBNext Poly(A) mRNA Magnetic Isolation Module (NEB #E7490) to
610 isolate mRNA and the NEBNext Ultra II Directional RNA Library Prep Kit for Illumina (NEB
611 #E7760S/L) and sequenced an Illumina NovaSeq X-Plus Platform.

612 **Transcript alignment, quantification, and quality control**

613 Reads were aligned to the diploid *C. albicans* genome release 22 using HISAT2 version 2.2.1
614 [98] with the options (--known-splicesite-infile --rna-strandness R --max-intronlen 1400).
615 SAMTools version 1.15.1 [99] used to select and sort primary hits (samtools sort), generate a
616 bam.bai index (samtools index) and deeptools was used to generate positive (bamCoverage --
617 normalizeUsing BPM --exactScaling -bs 1 --filterRNAstrand=forward) and negative
618 (bamCoverage --normalizeUsing BPM --exactScaling -bs 1 --filterRNAstrand=reverse) strand
619 specific bigWig coverage tracks for IGV version 2.8.2 [100]. For each background, we quantified
620 the number of transcripts in each strain (WT, *dhh1Δ/Δ*) and growth condition (YPD, RPMI) with

621 the coverageBed function of BEDTools version 2.30.0 [101]. All 12 experimental groups for
622 SC5314 and P57055 were combined into a single file of raw hits for each strain (Tables S10-
623 11). Our aligned read depth ranged from 18.6 million (P57055 WT, RPMI) to 37.5 million
624 (SC5314 dhh1Δ/Δ, RPMI) aligned reads with a mean aligned read depth of 26.6 million.

625 For quality control, coverage tracks of select genes are shown in Fig. S4. We confirmed that
626 *DHH1* transcripts were present in WT cells and absent in *dhh1Δ/Δ* under both growth conditions
627 with IGV (Fig S3. A). Using R version 4.3.1 and the edgeR release 3.20 [102] package we
628 converted raw hits to copies to million (Fig S8. A). Poorly transcribed ORFs (<1 Counts Per
629 Million (CPM) in <3 groups) were screened out leaving only hits with ≥1 CPM in ≥ 3 groups (Fig
630 S8. B). Using the built-in R function prcomp we performed a principal component analysis,
631 confirming replicates are clustered by strain and growth conditions (Fig S9. A-B). The filtered
632 CPM hits were analyzed with DEseq2 release 3.20 [61] with a Padj-value cutoff of 0.01 for strict
633 identification of differentially expressed genes.

634 **GO analysis**

635 For the GO term analysis of DE genes we focused on transcripts that were differentially
636 expressed with a $Log_2FC > +2.5$ or < -2.5 in Figs. 5, 6, S4, and S5. However, due to the smaller
637 number of transcripts DE in the same direction in both SC5314 and P57055 we selected
638 transcripts with a $Log_2FC > +1.0$ or < -1.0 for Fig 8. The analysis was performed in the *Candida*
639 Genome Database [103] CGD Gene Ontology Term Finder (http://www.candidagenome.org/cgi-
640 bin/GO/goTermFinder). Only terms with a corrected P-value of < 0.1 are generated with this
641 tool. However, we selected a maximum of 10 terms with the greatest fold enrichment, an
642 overwhelming majority of which had a Padj < 0.01 from the GO analysis.

643 **Software and data analysis**

644 All images were processed with Fiji [104]. Primers and transformation cassettes were designed
645 using sequences from the *Candida* Genome Database [103] and the *Candida albicans* Umbrella

646 Comparative genomics project [58], NCBI bioproject ID: PRJNA193498. Codon adaptation
647 index (CAI) was calculated using CAIcal [105] and codon usage table from the *Candida*
648 Genome database [103]. Data analysis and statistical tests were performed using GraphPad
649 Prism version 10.0.0 for Windows [106] as well as R version 4.3.1 [107] with ggplot2 3.5.1 [108]
650 and bioconductor packages release 3.20 including edgeR [102] and DESeq2 [61]. We used
651 Affinity Designer for Windows Version 2.5.5, 2024and BioRender.com to compose our figures.

652 **Data accessibility**

653 Raw RNA-seq data have been deposited at the NCBI SRA under bioproject number
654 PRJNA1133750 and are viewable at the following url
655 (https://dataview.ncbi.nlm.nih.gov/object/PRJNA1133750?reviewer=h2g76s1pma70kqsbgtj4746
656 2nt). A GEO submission is also available under accession GSE284543
657 (https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE284543) using reviewer token
658 wvyxcaagzdwzjsh. All other data are provided in the supplemental tables.

659 **Acknowledgements**

660 This study was supported by NIGMS grant R35GM145317 to CJM. We would like to thank
661 Gemma E. May for her cloning expertise and support as well as the members of the McManus
662 laboratory for helpful discussions. Figure 9B and Figure S7 were prepared using images from a
663 licensed copy of Biorender.

915 ## Legends

916 **Figure 1. PBs condense during acute stress.** Images of PB factors fluorescently tagged in strain
917 SC5314. A. Edc3-mNG condensed in live *C. albicans* under non-stress conditions (30°C in complete
918 media (CM)). Scale bar = 5μm. B. Edc3-mNG condensed in live *C. albicans* in response to acute heat
919 shock (10 minutes at 46°C in CM). Scale bar = 5μm. C. PB factors (Edc3-mNG and DHH1-mS) co-
920 localized during acute heat shock (10 minutes at 46°C in CM) confirming their identity as PBs. Scale bar =
921 2μm. D. After 3-hours of starvation in PBS at room temperature, abundant PBs (Edc3-mNG) were visible
922 with confocal microscopy along the developing germ tube. Scale bar = 5μm. E. PBs (Edc3-mNG) also
923 condensed and persisted during hyphal growth (37°C in RPMI). Scale bars = 2μm. F. Dhh1-mS
924 condensed in the absence of Edc3 in response to acute heat shock (10 minutes at 46°C in CM). Scale
925 bar = 2μm. G. Dhh1 is not required for Edc3-mNG PB formation in response to acute heat shock (10
926 minutes at 46°C in CM). Scale bar = 5μm.

927

928 **Figure 2. *DHH1* is required for WT growth and morphology in SC5314. A.** and **B.** *dhh1Δ/Δ* resulted in
929 slow growth at 30°C and 37°C on YPD plates, which was complemented by a single copy of *DHH1*. **C.**
930 *dhh1Δ/Δ* had reduced growth in liquid YPD (30°C). WT and mutant strains were grown in triplicate.

931 Impaired *dhh1Δ/Δ* exponential growth was rescued by complementation (*dhh1Δ/Δ*, +*DHH1*). Error bars
932 show 95% CI. **D.** Colonies lacking *DHH1* have a wrinkled morphology (4 days, YPD agar, 37°C). 25X
933 magnification. **E.** DIC images of exponentially growing cells (YPD, 30°C) show enlarged cell bodies and
934 vacuoles in *dhh1Δ/Δ*. Scale bars = 5μm. **F.- H.** Quantification of cell and vacuolar enlargement in
935 *dhh1Δ/Δ* (N = 100 cells per strain; ****P < 0.0001, Kruskal-Wallis tests).
936
937 **Figure 3. *DHH1* is required for wildtype planktonic filamentation.** WT and mutant strains grown under
938 physiologically relevant filamentation conditions (37°C, RPMI + 10% FBS). **A.** and **B.** After 4-hours of
939 filamentation, *dhh1Δ/Δ* had reduced germ tube development defined by the median ratio of cell length to
940 width. **C.** and **D.** After 16-hours of filamentation, *dhh1Δ/Δ* had less developed germ tubes with fewer
941 septa compared to wildtype and complement strains. (Scale bars = 20μm; N = 100 cells, ****P < 0.0001,
942 Kruskal-Wallis tests).
943
944 **Figure 4. Absence of *DHH1* alters SC5314 biofilm and spider colony morphology.** WT and mutant
945 strains grown in two *in vitro* filamentation assays. **A.** and **B.** WT and mutant biofilms after a 24-hours
946 (37°C, RPMI + 10% FBS) *dhh1Δ/Δ* has thicker biofilms. Scale bar = 100μm, 95% CI. **C.** Basal views
947 26μm from the bottom of the biofilm showed a reduced density of *dhh1Δ/Δ* cells. Scale bar = 20μm. **D.**
948 Average pixel intensity (cell wall stain) from 4 replicate biofilms (SD) varied with biofilm depth. Strains with
949 at least one copy of *DHH1* had a greater concentration of cells closer to the base of the biofilm than
950 *dhh1Δ/Δ*. **E.** Colonies on spider plates require *DHH1* for hyperfilamentous margins (6 days, 37°C). 6X
951 and 25X magnification.
952
953 **Figure 5. RNA-seq exposed differential gene expression in SC5314 *dhh1Δ/Δ* grown in YPD and**
954 **RPMI. A.** Volcano plot depicts genes are significantly up (red) and down (blue) -regulated in *dhh1Δ/Δ*
955 yeast-form growth compared to wildtype (Padj < 0.01). Genes associated with filamentation stress were
956 prominently upregulated (Table S1). **B.** GO terms enriched in *dhh1Δ/Δ* YPD include transport and cell
957 wall terms (Padj < 0.1). **C.** Volcano plot depicts gene expression differences in *dhh1Δ/Δ* vs wildtype
958 during early hyphal growth (Table S2, Padj < 0.01). Genes associated with metabolite transport and the
959 yeast/hyphal cell wall were differentially expressed in *dhh1Δ/Δ*. **D.** GO terms enriched in *dhh1Δ/Δ* RPMI
960 include transport, cell wall, and metabolic terms (Padj < 0.1). **E.** A significant number of *dhh1Δ/Δ*
961 transcripts were downregulated ($P = 2.28e^{-22}$), and upregulated ($P = 4.37e^{-52}$), respectively, in both YPD
962 and RPMI conditions (Hypergeometric tests). However, most differentially expressed genes were
963 environmentally specific. **F.** Differential expression of transcription factors regulating morphogenesis in
964 *dhh1Δ/Δ* in YPD and RPMI (* indicates Padj < 0.01; DEseq2).
965
966 **Figure 6. RNA-seq reveals transcriptome differences between SC5314 wildtype and *dhh1Δ/Δ***
967 **during filamentation. A.** Volcano plots comparing the transcriptomes of WT SC5314 grown in YPD and

968 RPMI demonstrate extensive remodeling during filamentation (Table S3, Padj < 0.01). **B.** Expected GO
969 terms were downregulated, and **C.** upregulated during WT filamentation (Padj < 0.1). **D.** Comparing the
970 transcriptomes of *dhh1Δ/Δ* grown in YPD and RPMI showed impaired remodeling during filamentation
971 (Table S4, Padj < 0.01). **E.** Similar GO terms were downregulated, and **F.** upregulated in filamenting
972 *dhh1Δ/Δ* and WT (Padj < 0.1). Unlike wildtype, *dhh1Δ/Δ* upregulated terms related to lipid catabolism
973 during filamentation. **G.** Transcription factors regulating morphogenesis had blunted remodeling in
974 *dhh1Δ/Δ*. (* indicates Padj < 0.01; DEseq2). **H.** Most genes differentially expressed during *dhh1Δ/Δ*
975 filamentation are subsets of the WT remodeling response. A significant number of genes were
976 downregulated or upregulated in both filamenting *dhh1Δ/Δ* and wild type (Hypergeometric tests, P = 0).
977
978 **Figure 7. *DHH1* is required for wildtype growth and colony morphology in diverse strains.** As in
979 SC5314, DHH1 is required for wildtype growth, heat tolerance, and filamentation on spider media.
980 Additionally, *dhh1Δ/Δ* impaired growth to a greater extent in hyperfilamentous strains. **A.** *dhh1Δ/Δ*
981 resulted in slow colony growth at 30°C and 37°C on YPD plates, the extent of which varied with
982 background strain. **B.** *dhh1Δ/Δ* reduced growth in liquid YPD (30°C). WT and mutant strains were grown
983 in triplicate. Impairment of *dhh1Δ/Δ* exponential growth varied with strain and was rescued by
984 complementation (*dhh1Δ/Δ*, +*DHH1*). Error bars show CI = 95%. **C.** Colonies lacking *DHH1* have a non-
985 WT textured morphology during mild heat stress (4 days, YPD agar, 37°C). 25X magnification. **D.** Spider
986 colony morphology varies between strains and requires *DHH1* for WT phenotype (6 days, 37°C). 6X and
987 25X magnification.
988
989 **Figure 8. Differentially expressed genes and GO terms in *dhh1Δ/Δ* and WT strains correlated**
990 **between SC5314 and P57055. A.** Scatter plot of DE genes (Padj < 0.01) in both SC5314 *dhh1Δ/Δ* and
991 P57055 *dhh1Δ/Δ* in YPD is moderately correlated. GO analysis of core genes **B.** down and **C.**
992 upregulated in both *dhh1Δ/Δ* strains in YPD, emphasize terms related to the cell wall and biosynthesis. **D.**
993 Scatter plot of DE genes (Padj < 0.01) in both SC5314 *dhh1Δ/Δ* and P57055 *dhh1Δ/Δ* in RPMI has a
994 greater correlation than in YPD reflecting a common stress response. GO analysis of core genes **E.**
995 downregulated and **F.** upregulated in both *dhh1Δ/Δ* strains in RPMI. **G.** Scatter plot of DE genes in both
996 WT SC5314 and WT P57055 during filamentation (Padj < 0.01) is highly correlated. GO analysis of core
997 genes **H.** down and **I.** upregulated during SC5314 and P57055 WT filamentation shows expected
998 regulatory changes. **J.** Scatter plot of DE genes in SC5314 *dhh1Δ/Δ* and P57055 *dhh1Δ/Δ* during
999 filamentation are still correlated (Padj < 0.01). GO analysis of core genes **K.** down and **L**. upregulated are
1000 generally a subset of WT except for downregulation of hyphal wall genes.
1001
1002 **Figure 9. Phenotypic and transcriptomic outcomes in diverse *dhh1Δ/Δ* strains.** Despite differences
1003 between WT background strains, loss of *DHH1* is associated with specific morphological and
1004 transcriptomic outcomes across diverse clades. **A**. Hyperfilamentous strains are more phenotypically

1005 sensitive to the loss of *DHH1*. **B.** Diagram of overlapping transcripts and terms in SC5314 *dhh1Δ/Δ* and
1006 P57055 *dhh1Δ/Δ* in YPD and RPMI. Under yeast-form growth conditions *dhh1Δ/Δ* fails to repress the
1007 hyphal stress response. Under hyphal growth conditions *dhh1Δ/Δ* presents a misregulated transcriptome
1008 including persistence of yeast features. Genes in red were significantly upregulated, while genes in blue
1009 were significantly downregulated (Padj < 0.01). Diagram produced using Biorender.
1010
1011 **Fig S1. Replicates of PBs condensation during heat stress in SC5214. A.** PB factors (Edc3-mNG and
1012 DHH1-mS) co-localized during acute heat shock (10 minutes at 46°C in CM) confirming their identity as
1013 PBs. Scale bars = 2μm. **B.** Dhh1-mS condensed in the absence of Edc3 in response to acute heat shock
1014 (10 minutes at 46°C in CM). Scale bars = 2μm. **C.** Edc3-mNG condensed in the absence of Dhh1
1015 response to acute heat shock (10 minutes at 46°C in CM). Scale bars = 5μm.
1016
1017 **Fig S2. Absence of *EDC3* does not impair growth or hyphal morphology in diverse strains.** WT and
1018 *edc3Δ/Δ* strains were subjected to growth, filamentation, biofilm, and spider plate assays. **A.** 24-hour spot
1019 plate assay of *C. albicans* WT and *edc3Δ/Δ* shows *EDC3* is not required for WT growth in all 5 strains. **B.**
1020 *edc3Δ/Δ* strains were subjected to a planktonic 4-hour filamentation assay (37°C, RPMI + 10% serum)
1021 and did not display gross inhibition of filamentation compared to WT. Scale bars = 20μm. **C.** After 4-hours
1022 of filamentation, *edc3Δ/Δ* did not have grossly impaired germ tube development. Only *edc3Δ/Δ* P75010
1023 was significantly less hyphal than WT (N =100 cells, ****P < 0.0001, **P < 0.01, Kruskal-Wallis tests). **D.**
1024 Side-view of WT and *edc3Δ/Δ* strains after a 24-hour biofilm assay (37°C, RPMI + 10% serum). Scale bar
1025 = 100μm. **E.** Depth of 4 replicate biofilms. 95% CI. **F.** Colonies grown on spider plates for 6 days at 37°C.
1026 6X and 25X magnification.
1027
1028 **Fig S3. Normalized IGV tracks for SC5314 and P57055 WT and *dhh1Δ/Δ* strains.** Tracks normalized
1029 by cpm were examined to verify deletions and differentially expressed genes **A.** *DHH1* transcripts are
1030 present in WT backgrounds and absent from *dhh1Δ/Δ*. **B.** In YPD putative trifunctional thiamine
1031 biosynthesis enzyme *THI20* is downregulated in both *dhh1Δ/Δ* strains. **C.** Hyphal wall protein (*HWP1*)
1032 transcripts are upregulated in *dhh1Δ/Δ* compared to WT under yeast-form growth conditions. **D.**
1033 Interestingly, in YPD hyphal associated candidalysin (*ECE1*) is upregulated in SC5341 *dhh1Δ/Δ*, and to a
1034 lesser extent in P57055 *dhh1Δ/Δ*. **E.** Hyphal adhesin (*ALS1*) is downregulated in both *dhh1Δ/Δ* strains in
1035 RPMI, **F.** while GPI-anchored cell wall protein (*RBR1*) is upregulated in both *dhh1Δ/Δ* strains under these
1036 conditions.
1037
1038 **Fig S4. RNA-seq exposed differential gene expression in P57055 *dhh1Δ/Δ* grown under YPD and**
1039 **RPMI conditions. A.** Volcano plot depicts genes significantly up (red) and down (blue) -regulated during
1040 yeast-form growth compared to wildtype (Padj < 0.01). Genes associated with filamentation stress were
1041 prominently upregulated (Table S5). **B.** GO terms enriched in *dhh1Δ/Δ* YPD include transport and cell

1042 wall terms (Padj < 0.1). in. **C.** Volcano plot depicts gene expression differences in *dhh1Δ/Δ* vs wildtype
1043 during early hyphal growth (Table S6, Padj < 0.01). **D.** GO terms enriched in *dhh1Δ/Δ* RPMI are related to
1044 chromatin, replication and biosynthesis (Padj < 0.1). **E.** A significant number of transcripts were
1045 downregulated (P = 0.041), and upregulated (P = 0.0178), respectively, in *dhh1Δ/Δ* in YPD and RPMI
1046 conditions (Hypergeometric tests). However, most differentially expressed genes were environmentally
1047 specific. **F.** Differential expression of transcription factors regulating morphogenesis in *dhh1Δ/Δ* in YPD
1048 and RPMI. (* indicates Padj < 0.01; DEseq2).
1049
1050 **Fig S5. RNA-seq reveals transcriptome differences between WT and *dhh1Δ/Δ* during filamentation.**
1051 **A.** Volcano plots comparing the transcriptomes of WT P57055 grown in YPD and RPMI demonstrate
1052 extensive remodeling during filamentation (Table S7, Padj < 0.01). **B.** Expected GO terms were
1053 downregulated, and **C.** upregulated during WT filamentation (Padj < 0.1). **D.** Comparing the transcriptome
1054 of *dhh1Δ/Δ* grown in YPD and RPMI showed transcriptome remodeling during filamentation (Table S8,
1055 Padj < 0.01). **E.** Similar GO terms were downregulated, and **F.** upregulated in filamenting *dhh1Δ/Δ* and
1056 WT (Padj < 0.1). Unlike WT, *dhh1Δ/Δ* upregulated terms related to lipid catabolism during filamentation.
1057 **G.** Transcription factors regulating morphogenesis were differentially expressed during filamentation in
1058 WT and *dhh1Δ/Δ* (* indicates Padj < 0.01; DEseq2). **H.** Genes differentially expressed during
1059 filamentation overlapped between WT and *dhh1Δ/Δ* strains. Most transcripts differentially expressed
1060 during *dhh1Δ/Δ* filamentation are subsets of the WT remodeling response. A significant number of
1061 transcripts were down- (P = 0) or upregulated (P = 0) in both filamenting *dhh1Δ/Δ* and wild type
1062 (Hypergeometric tests).
1063
1064 **Fig S6. Poor CAI is not associated with de-repression (upregulation) in *dhh1Δ/Δ*.** Upregulated
1065 genes in *C. albicans dhh1Δ/Δ* have higher CAI values than downregulated genes. CAIs of 100 most
1066 upregulated and downregulated genes in SC5314 *dhh1Δ/Δ* and P57055 *dhh1Δ/Δ* strains grown in **A.**
1067 YPD at 30°C and **B.** RPMI + 10% FBS at 37°C . (Mann-Whitney tests. ***P < 0., ****P < 0.0001).
1068
1069 **Fig S7. Transient CRISPR-cas9 cloning diagrams.** Methods for **A.** inserting a fluorescent tag in the
1070 genome, **B.** deleting the entire ORF for a gene leaving only a 34bp FRT scar, and **C.** generating a *DHH1*
1071 complement at the *MDR1* site. Diagram produced using Biorender.
1072
1073 **Fig S8. Filtering out poorly transcribed ORFs in normalized RNAseq hits.** ORFs with less than one
1074 CPM hit in less than 3 experimental groups were removed prior to running DEseq2. **A.** Violin plots show
1075 raw and **B.** filtered hits for each strain and condition with ≥1 CPM in ≥ 3 experimental groups.
1076
1077 **Fig S9. Samples cluster by strain and growth conditions.** PCA plot displaying the filtered CPM from
1078 all 12 experimental groups clustering by condition in **A.** SC5314 and **B.** P57055.

1079

1080 **Table S1. DEseq2 results comparing SC5314 YPD *dhh1Δ/Δ* vs. SC5314 YPD WT for Fig 5. A.**
1081 Exponentially growing *dhh1Δ/Δ* and WT SC5314 yeast cells in YPD at 30°C. RNA extraction performed in
1082 triplicate from three separate samples.

1083 **Table S2. DEseq2 results comparing SC5314 RPMI *dhh1Δ/Δ* vs. SC5314 RPMI WT for Fig 5. C.**
1084 *dhh1Δ/Δ* and WT SC5314 grown under physiologically relevant filamentation conditions (RPMI + 10%
1085 serum at 37°C) for 4 hours. RNA extraction performed in triplicate from three separate samples.

1086 **Table S3. DEseq2 results comparing SC5314 RPMI WT vs SC5314 YPD WT for Fig 6. A.** WT SC5314
1087 yeast cells in YPD at 30°C and WT SC5314 grown under physiologically relevant filamentation conditions
1088 (RPMI + 10% serum at 37°C) for 4 hours. RNA extraction performed in triplicate from three separate
1089 samples.

1090 **Table S4. DEseq2 results comparing SC5314 RPMI *dhh1Δ/Δ* vs SC5314 YPD *dhh1Δ/Δ* for Fig 6. D.**
1091 *dhh1Δ/Δ* yeast cells in YPD at 30°C and *dhh1Δ/Δ* grown under physiologically relevant filamentation
1092 conditions (RPMI + 10% serum at 37°C) for 4 hours. RNA extraction performed in triplicate from three
1093 separate samples.

1094 **Table S5. DEseq2 results comparing P57055 YPD *dhh1Δ/Δ* vs. P57055 YPD WT for Fig S4. A.**
1095 Exponentially growing *dhh1Δ/Δ* and WT P57055 yeast cells in YPD at 30°C. RNA extraction performed in
1096 triplicate from three separate samples.

1097 **Table S6. DEseq2 results comparing P57055 RPMI *dhh1Δ/Δ* vs. P57055 RPMI WT for Fig S4. C.**
1098 *dhh1Δ/Δ* and WT P57055 grown under physiologically relevant filamentation conditions (RPMI + 10%
1099 serum at 37°C) for 4 hours. RNA extraction performed in triplicate from three separate samples.

1100 **Table S7. DEseq2 results comparing P57055 RPMI WT vs P57055 YPD WT for Fig S5. A.** WT
1101 P57055 yeast cells in YPD at 30°C and WT P57055 grown under physiologically relevant filamentation
1102 conditions (RPMI + 10% serum at 37°C) for 4 hours. RNA extraction performed in triplicate from three
1103 separate samples.

1104 **Table S8. DEseq2 results comparing P57055 RPMI *dhh1Δ/Δ* vs P57055 YPD *dhh1Δ/Δ* for Fig S5. D.**
1105 *dhh1Δ/Δ* yeast cells in YPD at 30°C and *dhh1Δ/Δ* grown under physiologically relevant filamentation
1106 conditions (RPMI + 10% serum at 37°C) for 4 hours. RNA extraction performed in triplicate from three
1107 separate samples.

1108 **Table S9. List of strains, plasmids, PAM sites, and primers used in this study.** This table includes
1109 relevant information concerning our strain generation and validation.

1110 **Table S10. Raw RNA-seq hits for SC5314 WT and *dhh1Δ/Δ i*n YPD and RPMI.** Unfiltered raw aligned
1111 RNA-seq hits used for DEseq2 input.

1112 **Table S11. Raw RNA-seq hits for P57055 WT and *dhh1Δ/Δ* in YPD and RPMI.** Unfiltered raw aligned
1113 RNA-seq hits used for DEseq2 input.

1114 **Table S12. Core genes differentially expressed in the same direction for YPD SC5314 *dhh1Δ/Δ* and**
1115 **YPD P57057 *dhh1Δ/Δ*.** In YPD, both *dhh1Δ/Δ* strains had 457 genes downregulated (blue circles Fig 8.
1116 A) and 632 genes upregulated (red circles Fig 8. A). Data from DEseq2 results in Tables S1 and S5.

1117 **Table S13. Core genes differentially expressed in the same direction for RPMI SC5314 *dhh1Δ/Δ***
1118 **and RPMI P57057 *dhh1Δ/Δ*.** In RPMI, both *dhh1Δ/Δ* strains had 883 genes downregulated (blue circles
1119 Fig 8. D) and 901 genes upregulated (red circles Fig 8. D). Data from DEseq2 results in Tables S2 and
1120 S6.
