Abstract:

High throughput amplicon sequencing (HTAS) of conserved regions of DNA has emerged as a powerful technique to characterize environmental communities. Depending on the taxa of interest, several molecular markers have been developed to use as templates for HTAS; small subunit (16S) rRNA, large subunit (LSU) rRNA, internal transcribed spacer (ITS) rRNA, or mitochondrial cytochrome oxidase 1 (mtCO1). A major challenge in analyzing HTAS experimental data is differentiating sequencing errors versus those of real biological sequence variation. One strategy that has been employed is the inclusion of spike-in mock communities as a tool to measure the accuracy of the sequencing platform and subsequent data processing. HTAS for identification of fungi via the ITS region requires a pipeline that can accurately deal with amplicons of variable length, variable GC content, and large homopolymer stretches. To assess the ability of sequencing platforms and data processing pipelines using fungal ITS amplicons, we created two fungal ITS spike-in control mock communities composed of single copy plasmid DNA; the biological mock community (BioMock) consists of cloned ITS sequences whereas the synthetic mock community (SynMock) consists of non-biological ITS-like sequences. Using these spike-in controls we show that pre-clustering steps for variable length amplicons are critically important. Additionally, a major source of bias is attributed to the primary DNA sequence of individuals as well as the initial PCR reaction, indicating that read abundances are not representative of fungal communities. These data indicate that using non-biological ITS-like sequences as a spike-in control allows for accurate estimation of data processing and identification of index-bleed (index-hopping or barcode crossover) between samples. Finally, we developed AMPtk (amplicon toolkit), a versatile software solution equipped to deal with variable length amplicons as well as a built-in method to quality filter HTAS data based on spike-in controls. While we describe herein a non-biological (synthetic) mock community for ITS sequences, the concept can be widely applied to any HTAS dataset.

45 **Introduction:**

46 High-throughput amplicon sequencing (HTAS) is a powerful tool that is frequently used
47 for examining community composition of environmental samples. HTAS has proven to be a
48 robust and cost-effective solution due to the ability to multiplex hundreds of samples on a single
49 next-generation sequencing (NGS) run. However, HTAS output from environmental samples
50 requires careful interpretation and appropriate and consistent use of positive and negative
51 controls (1). One of the major challenges in HTAS is to differentiate sequencing error versus
52 real biological sequence variation. Considerable progress has been made in the last several
53 years through improved quality of sequencing results through manufacturer upgrades to
54 reagents as well as improved quality filtering and "clustering" algorithms. While most algorithm
55 development in HTAS is focused on the prokaryotic microbiome - using the 16S subunit of the
56 rRNA array, i.e. QIIME (2), Mothur (3), UPARSE (4), DADA2 (5), many of these same tools have
57 been adopted for use with other groups of organisms, such as fungi.

58 The internal transcribed spacer (ITS) region of the rRNA array has emerged as the
59 molecular barcode for examining fungal communities in environmental samples. The ITS region
60 is multi-copy and thus easily amplifiable via PCR even from environmental samples with low
61 quantities of fungal DNA. The entire ITS region consists of two internal transcribed spacers,
62 ITS1 and ITS2, and is generally conserved within a species yet possess enough variability to
63 allow differentiation between species in many taxonomic groups. Because of its widespread use
64 several public databases are rich with reference fungal ITS sequences (6). However, there are
65 several properties of the fungal ITS region that are potentially problematic for HTAS that
66 include: i) fungi have variable cell wall properties making DNA extraction efficiency unequal for
67 different taxa and/or cell types (hyphae, fruiting bodies, spores, etc) (7), ii) number of nuclei per
68 "cell" is variable between taxa (8), iii) the number of copies of the rRNA array are different
69 between taxa and in some cases isolates of the same taxa (9), iv) a single isolate can have
70 multiple ITS sequences (intragenomic variability; (10, 11), v) the ITS region is highly variable in
71 length, vi) ITS sequences vary in GC content, and vii) there are a variable number of
72 homopolymer repeats in the ITS region. Additionally, current read lengths of next-generation
73 sequencing platforms, Illumina Miseq currently covers ~ 500 bp (2 x 300) and Ion Torrent is 450
74 bp, are not long enough to cover the entire length of the ITS region which is typically larger than
75 500 bp. However, conserved priming sites exist to amplify either the ITS1 region or the ITS2
76 region which has been shown to be sufficient for taxonomic identification. While several studies
77 have used the ITS1 region for HTAS, the ITS1 region contains introns in some taxa and thus to

avoid potential bias it has been suggested that ITS2 region should be the preferred region for fungi (12) (Figure 1A).

Sequencing error is a known problem across NGS platforms used for HTAS. To address issues with sequencing error and reliability of results from HTAS, it has become increasingly common practice to use spiked-in “mock” community samples as positive controls for the parameterization and optimization of experimental workflows and data processing. Spike-in mock community controls for fungal ITS that have been used (1, 12-15), which consisted of fungal genomic DNA (gDNA) extracted from tissue from fruiting bodies, cultures, or spores of a number of taxa which are then (usually) combined in equimolar amounts. Mock communities composed of fungal gDNA from fruiting bodies, spores, and/or hyphae provide a measure of success of extraction, PCR, and sequencing and thus are useful in the HTAS workflow. However, such mock communities are of limited value if used to validate/parameterize data processing workflows due to intrinsic properties of the ITS region mentioned previously (variable copy number, intraspecific variation, variable length, etc.). Therefore, there is a need for fungal ITS spike-in control mock communities that function to validate laboratory experimental design, validate data processing steps, and compare results between sequencing runs and platforms.

HTAS is cost-effective due to the ability to massively multiplex environmental samples on a single sequencing run. This process depends on the attachment of a unique sequence identifier (referred to as a barcode, an index, or a tag, depending on sequencing platform) to each piece of DNA to be sequenced. In recent years, “index-bleed (“index hopping”, “tag jumping”, “barcode jumping”, “tag switching”, or “barcode switching”) has been noted to occur on Roche 454 platforms as well as Illumina platforms (16-20). Index-bleed can lead to over-estimation of diversity in environmental samples (17, 18) and mis-assignment of sequences to samples. It has been noted that spike-in mock communities may be useful to help detect bleed-over, and subsequent filters may be applied for use with the HTAS pipeline of choice (17, 20).

In this study, we generated a biological mock community (BioMock) composed of cloned ITS sequences (single insert plasmids) from a diverse set of fungal taxa. We show how this BioMock can be used to parameterize a data processing workflow. Subsequently, we found that current “off-the-shelf” software solutions performed poorly with our BioMock community of fungal ITS sequences and thus developed AMPtk (amplicon toolkit) which produces improved results of variable length amplicons from HTAS. Furthermore, we demonstrate that read abundances are an unreliable proxy for measuring relative abundances in fungal communities on both Illumina and Ion Torrent sequencing platforms. Additionally, we developed a non-biological synthetic spike-in mock community consisting of ITS-like sequences (SynMock) that

112 functions to accurately measure index-bleed. Finally, we show how AMPtk paired with SynMock
113 can be used to quality filter HTAS data by detecting and mitigating the effects of index-bleed
114 between multiplexed samples.
115
116 **Materials and Methods:**
117 *Biological mock community (BioMock)*
118 To construct the Biomock we selected 26 known fungal cultures (Supplementary Table
119 S1) from the Center for Forest Mycology Research (CFMR) culture collection. These cultures
120 were purposefully chosen to represent a taxonomic range of fungi, including paralogs, fungi with
121 GC rich ITS regions, a variety of ITS lengths, and fungi with a variety of homopolymers in the
122 ITS region. To measure the sensitivity of our bioinformatics approach, we also included two ITS
123 sequences from *Leptoporus mollis* that were isolated from the same culture as an example of
124 intragenomic variation in the fungal ITS region. These two sequences are more than 3%
125 divergent (95.9% identical) and thus should represent separate operational taxonomic units
126 (OTUs) in a clustering pipeline, despite being from the same fungal isolate. All cultures were
127 grown on cellophane on top of malt extract agar, and DNA was extracted from pure cultures
128 following (21). Following extraction, the genomic DNA was PCR amplified using the fungal ITS
129 specific primers ITS-1F (22) and ITS4 (23). The PCR products were then cloned and Sanger
130 sequenced following the protocol in (11), with the exception that all clones were sequenced
131 using ITS-1F. Sequence identifications were verified via BLAST search and two clones of each
132 isolate were selected and cultured in liquid LB (Luria-Bertani) media and incubated at 37 C for
133 24 hours. Plasmids were purified from the cultures in LB media using standard alkaline lysis,
134 these plasmids will hereafter be termed “purified plasmids”. The purified plasmids were then
135 Sanger sequenced with vector primers T7 and SP6 to verify the insertion of a single copy of the
136 appropriate ITS fragment. We subsequently quantified the purified plasmid DNA concentration
137 using a Qubit® 2.0 fluorometer, following manufacturer’s instructions, and DNA concentrations
138 were equilibrated to 10 nM using DNA-free molecular grade water. Following equilibration, 5 µl
139 of each purified plasmid were combined to make an equimolar “biological mock” community of
140 single-copy purified plasmids (BioMock).
141 PCR has known biases, which are related to different sequence characteristics and are
142 hard to predict in mixed DNA communities of unknown composition. To illustrate the impact of
143 initial PCR bias on the number of reads obtained from each member of a mixed DNA
144 community, we generated individual HTAS-compatible PCR products from each Biomock
145 plasmid which were subsequently mixed (post-PCR) in an equimolar ratio. This was

146 accomplished by PCR amplifying each individual plasmid with the same barcoded primer set,
147 PCR products were purified using E-gel® CloneWell™ 0.8% SYBR® Safe agarose gels
148 (ThermoFisher), quantified using a Qubit® 2.0 fluorometer, and the cleaned PCR products were
149 combined into an equimolar mixture post-amplification. This post-PCR combined mock
150 community can be used to examine sequencing error on NGS platforms.
151
152 *Non-biological mock community (SynMock)*
153 We used the well-annotated ribosomal RNA (rRNA) sequence from *Saccharomyces*
154 *cerevisiae* as a starting point to design ITS-like synthetic sequences. The ITS adjacent regions
155 of small subunit (SSU) and large subunit (LSU) of *S. cerevisiae* were chosen as anchoring
156 points because of the presence of conserved priming sites ITS1/ITS1-F and ITS4. A 5.8S
157 sequence was designed using *S. cerevisiae* as a base but altered nucleotides so it would be
158 compatible with several primers in the 5.8S region including ITS2, ITS3, and fITS7. Random
159 sequences were generated constrained by GC content and sequence length for the ITS1 and
160 ITS2 regions. Twelve unique sequences were synthesized (Genescript) and cloned into pUC57
161 harboring ampicillin resistance. The SynMock sequences and the script to produce them are
162 available in the OSF repository ((https://osf.io/4xd9r/) as well as packaged into AMPtk
163 distributions. Each plasmid was purified by alkaline lysis, quantified, and an equimolar mixture
164 was created as a template for HTAS library prep.
165
166 *Preparation of HTAS libraries and NGS Sequencing*
167 HTAS libraries were generated using a proofreading polymerase, Pfx50 (ThermoFisher),
168 and thermocycler conditions were as follows: initial denaturation of 94°C for 3 min, followed by
169 11 cycles of [94°C for 30 sec, 60°C for 30 sec (drop 0.5°C per cycle), 68°C for 1 min], then 26
170 cycles of [94°C for 30 sec, 55°C for 30 sec, and 68°C for 1 min], with a final extension of 68°C
171 for 7 minutes. PCR products were cleaned using either E-gel® CloneWell™ 0.8% SYBR® Safe
172 agarose gels (Life Technologies) or Zymo Select-a-size spin columns (Zymo Research). All
173 DNA was quantified using a Qubit® 2.0 fluorometer with the high-sensitivity DNA quantification
174 kit (Life Technologies).
175 A single step PCR reaction was used to create Ion Torrent compatible sequencing
176 libraries, primers were designed according to manufacturer's recommendations. Briefly, the
177 forward primer was composed of the Ion A adapter sequence, followed by the Ion key signal
178 sequence, a unique Ion Xpress Barcode sequence (10-12 bp), a single base-pair linker (A),
179 followed by the fITS7 primer (24). The reverse primer was composed of the Ion trP1 adapter

180 sequence followed by the conserved ITS4 primer (23). Sequencing on the Ion Torrent PGM was
181 done according to manufacturer's recommendations using an Ion PGM™ Hi-Q™ OT2 Kit, an
182 Ion PGM™ Hi-Q™ Sequencing Kit, an Ion PGM™ 316v2 sequencing chip, and raw data was
183 processed with the Ion Torrent Suite v5.0.3 with the "--disable-all-filters" flag given to the
184 BaseCaller. Libraries for Illumina MiSeq were generated by a two-step dual indexing strategy,
185 all samples were PCR amplified with Illumina-fITS7 and Illumina-ITS4 primers. PCR products
186 were cleaned up and then dual-barcoded using an 8 cycle PCR reaction using the Illumina
187 Nextera Kit and subsequently sequenced using 2 x 300 bp sequencing kit on the Illumina MiSeq
188 at the University of Wisconsin Biotechnology Center DNA Sequencing Facility. All primers
189 utilized in this study are available via the OSF repository (https://osf.io/4xd9r/).
190
191 *Data processing using AMPtk*
192 AMPtk is publically available at https://github.com/nextgenusfs/amptk. All primary data
193 and data analysis done in this manuscript is available via the Open Science Framework
194 (https://osf.io/4xd9r/). AMPtk is written in Python and relies on several modules: edlib (25),
195 biopython (26), biom-format (27), pandas (28), numpy (29), and matplotlib modules (30).
196 External dependencies are USEARCH v9.1.13 (31) or greater and VSEARCH v2.2.0 (32) or
197 greater. In order to run the DADA2 (5) method R is required along with the shortRead (33) and
198 DADA2 packages. The major steps for processing HTAS data are broken down into i) pre-
199 processing reads, ii) clustering into OTUs, iii) filtering OTU table, iv) assigning taxonomy.
200
201 *Pre-processing reads* – Data structures from Roche 454 and Ion Torrent are similar where
202 reads are in a single file and have a unique barcode at the 5' end of the read followed by the
203 gene-specific priming site, therefore AMPtk processes reads from these two platforms very
204 similarly. As a preliminary quality control step, only reads that have a valid barcode and forward
205 primer are retained. Next, reverse primer sequences are removed and reads are trimmed to a
206 user-defined maximum length. Data from Illumina is processed differently because reads are
207 most often paired-end reads and most sequencing centers provide users with de-multiplexed by
208 sample paired-end data (i.e. output of 'bcl2fastq'). AMPtk first merges the paired end reads
209 using USEARCH or VSEARCH, phiX spike-in control is removed with USEARCH, forward and
210 reverse primers are removed if found, and all data is combined into a single file. Pre-processing
211 reads in AMPtk from any of the sequencing platforms results in a single output file that is
212 compatible with all downstream steps.
213

Clustering reads into OTUs – AMPtk is capable of running several different clustering algorithms including UPARSE, DADA2, UNOISE2, UNOISE3, and reference-based clustering. The algorithms all start with quality filtering using expected errors trimming and are modified slightly in AMPtk to build OTU tables using the original de-multiplexed data, therefore read counts represent what was in the sample prior to quality filtering. This is an important distinction, as expected errors quality trimming (34) can be rather stringent if long read lengths are used and the amplicons are of variable length, which can lead to biases in read abundance counts.

Index-bleed filtering of OTU tables – Filtering in AMPtk works optimally when a spike-in mock community is sequenced in the dataset, while by default AMPtk is setup to work with the SynMock described herein, any spike-in mock community can be used. AMPtk identifies which OTUs belong to the mock community and calculate index-bleed of that mock community into other samples as well as bleed into the mock community from samples. This calculated index-bleed percentage is then used to filter the OTU table. Filtering is done on a per OTU basis, such that read counts in each OTU that are below the index-bleed threshold are set to zero as they fall within the range of data that could be attributed to index-bleed.

Assigning taxonomy - AMPtk is pre-configured with databases for fungal ITS, fungal LSU, arthropod mtCO1, and prokaryotic 16S, however custom databases are easily created with the 'amptk database' command. Several tools are available for taxonomy assignment in AMPtk including remote blast of the NCBI nt database, RDP Classifier (35), global alignment to a custom sequence database, UTAX Classifier (RC Edgar, http://drive5.com/usearch/manual9.2/cmd_utax.html), and the SINTAX Classifier (36). The default method for taxonomy assignment in AMPtk is a "hybrid" approach that uses classification from global alignment, UTAX, and SINTAX. The best taxonomy is then chosen as follows: i) if global alignment percent identity is > 97% then the top hit is retained, ii) if global alignment percent identity is < 97%, then the best confidence score from UTAX or SINTAX is used, iii) if there is disagreement between taxonomy levels assigned by each method then a least common ancestor (LCA) approach is utilized to generate a conservative estimate of taxonomy. AMPtk also can take a QIIME-like mapping file which can contain all the metadata associated with the HTAS study, the output is then a multi-fasta file containing taxonomy in the headers, a classic OTU table with taxonomy appended, and a BIOM file incorporating the OTU table, taxonomy, and metadata. The BIOM output of AMPtk is compatible with several downstream statistical and visualization software packages such as PhyloSeq (37).

Accessory scripts in AMPtk - AMPtk has several additional features that will aid the user in analyzing HTAS data. For instance, AMPtk contains a script that will prepare you data for submission to the NCBI SRA archive by formatting it properly and outputting a ready-to-submit SRA submission file. The FunGuild (38) package which assigns OTUs to an annotated database of functional guilds is also incorporated directly into AMPtk. Additionally, users can draw a heatmap of an OTU table as well as summarize taxonomy in a stacked histogram.

Results:

In silico analysis of the fungal ITS region

To gain baseline data on potential amplicons of the ITS1 or ITS2 regions, the ITS1 and ITS2 regions were extracted using priming sites specific for each region (ITS1: ITS1-F and ITS2; ITS2: fITS7 and ITS4) from the UNITE+INSD v7.2 database (39) consisting of 736,375 ITS sequences. For comparison, the commonly sequenced V3-V4 region was extracted from prokaryotic 16S sequences from the Silva v128 database (40). A length histogram for each dataset as well as summary statistics was generated (Figure 1B; Table 1), indicating that all three of these molecular barcodes have an average length of ~ 250 bp (Table1), however there was considerable variation in the lengths of the ITS region in comparison to the V3/V4 region of 16S (Figure 1B). Stretches of homopolymer sequences can also be problematic for some NGS platforms (454 and PGM), thus the number of sequences in this dataset that contained homopolymer stretches greater than 6 nucleotides were calculated (Table 1). Given the small percentage ITS1 and ITS2 regions that are greater than 450 bp (the current upper limit of the Ion Torrent PGM platform), the number of taxa in the reference database that are unlikely to sequence on the Ion Torrent due to amplicon length is relatively small (Table 1). Illumina MiSeq is now capable of paired end 300 bp read lengths (2 x 300), however reads need to overlap for proper processing in NGS software platforms, thus a ~ 500 bp size limit would also be able to sequence most taxa in the reference database.

Table 1. Summary statistics of the fungal ITS molecular barcode in comparison to bacterial 16S.

Region	Num Seqs	Avg Length (bp)	% HP[1] > 6	% HP[1] > 8	% > 450 bp
ITS Full Length	696 704	488	55.07%	8.66%	-
ITS1	685 399	247	36.58%	5.60%	3.27%
ITS2	535 200	264	44.19%	5.54%	0.83%
16S (V3/V4)	627 247	253	23.74%	1.02%	-

[1] HP: homopolymer stretches

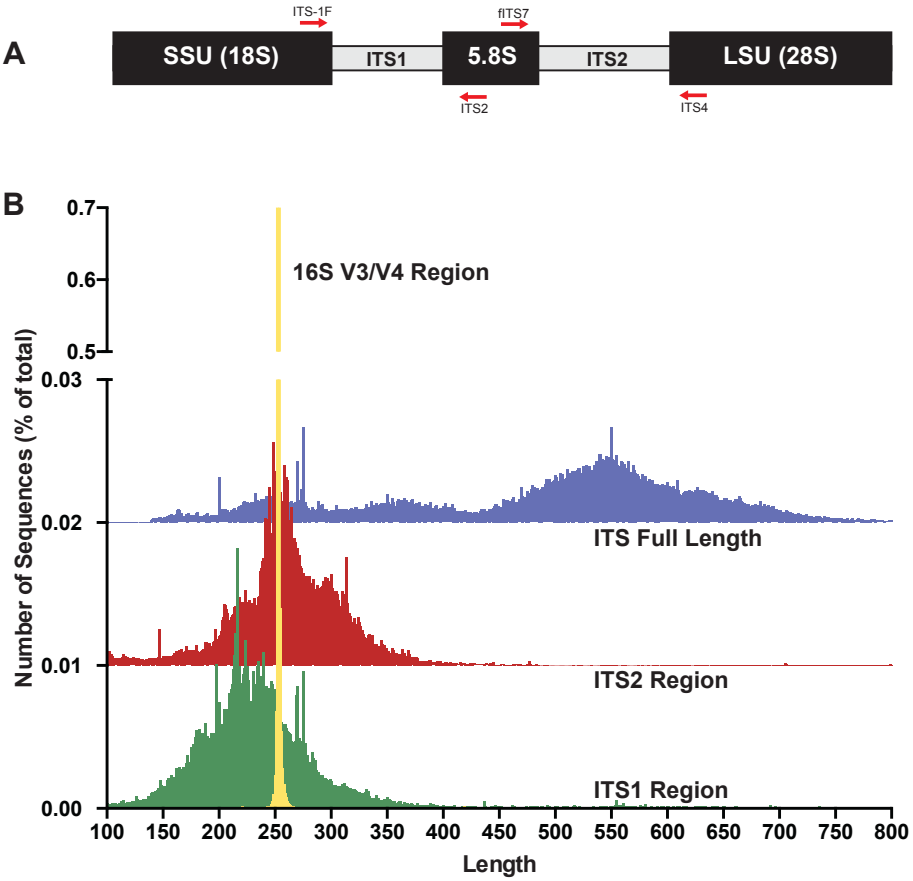

Figure 1. The fungal internal transcribed spacer (ITS) region of the rRNA array is highly variable in length. (A) A schematic of the rRNA array highlights the conserved priming sites commonly used to amplify either the ITS1 or ITS2 region. (B) Size distribution of full length ITS (blue), ITS1 (green), ITS2 (red) sequences in the UNITE v7.2 curated databases shown in comparison to the bacterial 16S V3/V4 amplicon from the Silva v128 database. Current sequencing technologies do not have read lengths long enough to capture full-length ITS sequences, thus ITS1 or ITS2 regions are used for fungal environmental community analysis.

Creation of a representative artificial fungal mock community (BioMock)

Given the results from analysis of the UNITE datasets, we set out to create a representative ITS mock community to be used as a spike-in sequencing control to determine the quantitative nature of ITS HTAS and to measure the performance between the commonly used Illumina MiSeq platform versus the Ion Torrent PGM. To circumvent the problematic issues associated with the ITS region, we reasoned that cloned ITS sequences in plasmid form would allow for accurate quantification and pooling; providing a means to test the accuracy of the sequencer platforms and data processing workflows. Therefore, we cloned known ITS sequences from 26 cultures from the CFMR culture collection that varied in length (237 bp to 548 bp), ranged in GC content (43.8% - 68.4%), and contained sequences with homopolymer

297 stretches with one sequence containing two 9 bp stretches (Figure 4). These plasmids were
298 combined into a BioMock and BioMock-standards as described in materials and methods
299 section. The value of the BioMock-standards is that the library was combined after PCR, thus
300 are free from PCR-induced artefacts that may arise from PCR of a mixed community.
301
302 *Existing data processing workflows perform poorly with fungal ITS sequences*
303 Clustering amplicons into operational taxonomic units (OTUs) is common practice in
304 molecular ecology and there are many software solutions/algorithms that have been developed
305 to deal appropriately with errors associated with next-generation sequencing platforms such as
306 QIIME (2), UPARSE (4), Mothur (3), and DADA2 (5). Many studies using 16S amplicon data
307 have focused on comparing clustering methods (4, 5), while others have focused on quality
308 filtering reads prior to clustering (34). Therefore, we won't compare the different software
309 algorithms here, but will briefly mention that when we did run our data through QIIME the
310 number of OTUs was highly over-estimated and the error rates were very high (Table S2). We
311 were unable to run our data through Mothur due to inability to do a multiple sequence alignment
312 and subsequent distance matrix of the ITS region. The best performing clustering pipeline was
313 UPARSE, however there were several issues with how the reads were pre-processed and
314 quality filtered that lead to suboptimal results (Table S3 and Table S4). It is important to note,
315 that all of these software solutions have been built with 16S amplicons in mind and several have
316 been optimized for Illumina data.
317 The major difference in 16S amplicons versus those of ITS1/ITS2 is that the length of
318 16S amplicons are nearly identical, while ITS1/ITS2 amplicons vary in length (Figure 1B). This
319 distinguishing feature makes ITS sequences from diverse taxa impossible to align (6) and thus
320 represent a major limitation in data processing. To illustrate the importance of properly pre-
321 processing ITS data, we clustered using UPARSE the ITS1 and ITS2 regions using the UNITE
322 reference database (Figure 2). Using the full length ITS1/ITS2 sequences as a benchmark, we
323 then explored the outcome of trimming/truncating the sequences to different length thresholds, a
324 common practice in OTU clustering pipelines. The UPARSE algorithm uses global alignment
325 and as such terminal mismatches count in the alignment (as opposed to local alignment where
326 terminal mismatches are ignored), thus the UPARSE pipeline expects that reads are truncated
327 to a set length. UPARSE achieves this by truncating all reads to a set length threshold which
328 discards reads that are shorter than the length threshold, therefore real ITS sequences are
329 discarded (Figure 2). We then came up with two potential solutions to fix this unintended
330 behavior, i) was simply to only truncate reads that were longer than the threshold and keep all

shorter reads (full length), and ii) was to truncate longer reads and pad the shorter reads with N's out to the length threshold (padding). Using the UNITE v7.2 database of curated sequences (general release June 28th, 2017) as input, both "full-length" and "padding" improved UPARSE results with the "full length" method recovering more than 99% of the expected OTUs (Figure 2).

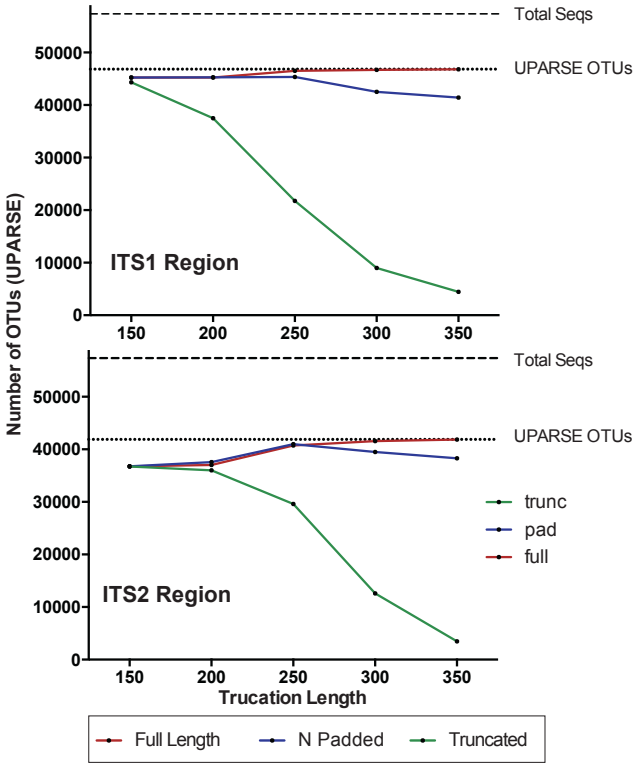

Figure 2. Pre-processing ITS sequences is critically important to accurately recover OTUs using the curated UNITE v7.2 reference database. ITS1 and ITS2 sequences were extracted from the UNITE v7.2 general fasta release database using 'AMPtk database'. Identical sequences were collapsed (dereplication) and remaining sequences were clustering using UPARSE ('cluster_otus) to generate the total number of UPARSE OTUs expected for the ITS1 and ITS2 regions. The data was then processed to five different lengths (150, 200, 250, 300, and 350 bp) and then clustered (UPARSE 'cluster_otus') using i) default UPARSE truncation (longer sequences are truncated and shorter sequences are discarded), ii) padding with ambiguous bases (longer sequences truncated and shorter sequences padded with N's to length threshold), and iii) full-length sequences (longer sequences are truncated and shorter sequences are retained if reverse primer is found). Full-length and padding pre-processing sequences outperforms default UPARSE truncation.

Due to the intrinsic nature of the variable length ITS amplicons, we needed a data processing solution that would be flexible to maintain the full length of the reads, trim reads without data loss, prepare sequencing reads for downstream clustering algorithms, and support all major NGS platforms. Using the BioMock artificial communities as a means to validate the

results of all data processing steps, we wrote a flexible series of scripts for processing Illumina, Ion Torrent, as well as Roche 454 data which are packaged into AMPtk (amplicon tool kit). A flow diagram of AMPtk is illustrated in Figure 3 and a more thorough description of AMPtk is provided in the material and methods section. A manual for AMPtk is available at http://amptk.readthedocs.io/en/latest/. After data is pre-processed with AMPtk via a platform specific method, AMPtk then functions as a wrapper for several popular algorithms including UPARSE, DADA2, UNOISE2, and UNOISE3. All data presented in this manuscript was processed with AMPtk v1.0.1.

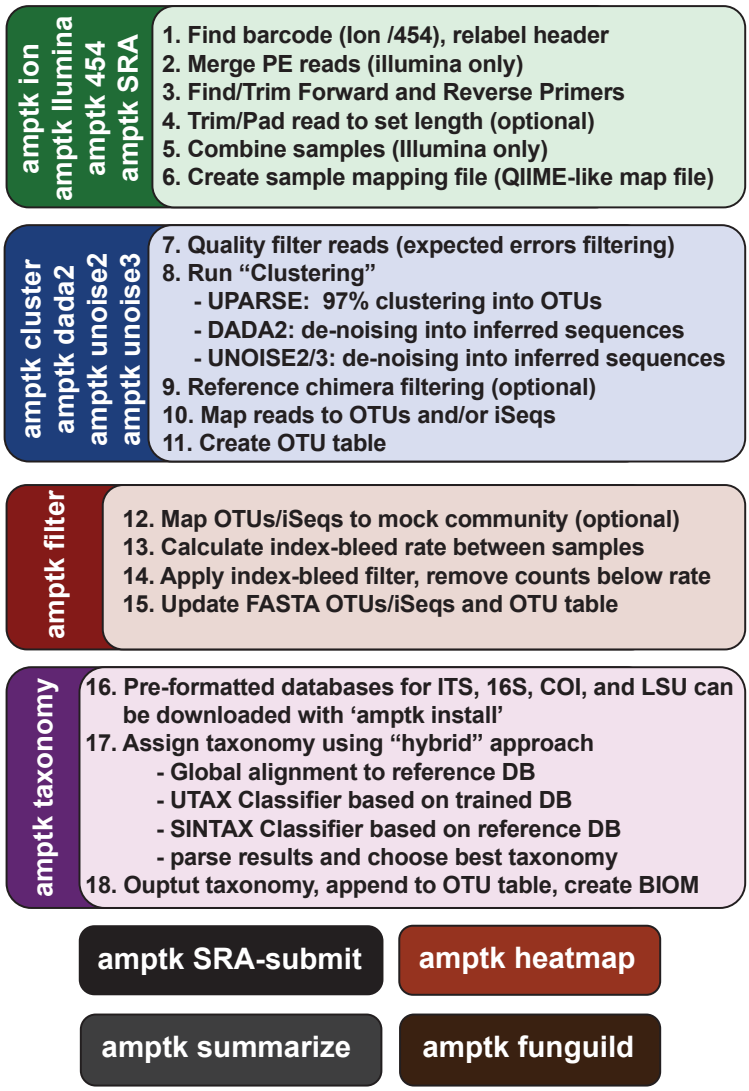

Figure 3. Overview of the commands in AMPtk. AMPtk is built to be compatible with multiple sequencing platforms as well as contains several clustering algorithms.

366 *Read abundances do not represent community abundances: PCR introduces bias*

367 Next-generation sequencing platforms are quantitative if the library to be sequenced is
368 unbiased, as is the case with RNA-sequencing and whole genome sequencing library prep
369 protocols. However, PCR of mixed communities has long been shown to introduce bias in next-
370 generation sequencing workflows (41-43). For HTAS this is an important caveat, as molecular
371 ecologists are interested in diversity metrics of environmental communities as well as their
372 relative abundance. Through the use of mock communities, several studies have pointed out
373 that read abundance from fungal HTAS are not representative of relative biological abundance
374 (13, 14), however, it was recently reported that for a fungal ITS mock community of 8 members
375 abundances were meaningful (12) and many studies continue to use abundance-based metrics
376 to analyze HTAS, without giving any consideration to presence / absence-based metrics.
377 Therefore, we reasoned that we could answer this question using the ITS BioMock artificial
378 community which would not suffer from bias associated with DNA extraction, ITS copy numbers,
379 and intraspecific variation. We compared the relative read abundances of BioMock-standards to
380 3 different combinations of BioMock on both the Ion Torrent PGM and Illumina MiSeq platforms
381 (Figure 4). The BioMock-standards consist of an equimolar mixture of 26 PCR products, while
382 the BioMock communities consist of an equimolar mixture of 23 single-copy plasmids. These
383 data show that even in an extreme example of an equally mixed community of cloned ITS
384 sequences, read abundance does not represent actual abundance in the mock community
385 (Figure 4). The majority of the bias is introduced at the initial PCR step, as the pre-PCR
386 combined BioMock-standards result in a more equal distribution of reads, albeit not a perfect
387 distribution. We also tested PCR conditions, DNA concentrations, and sample reproducibility on
388 the Ion Torrent PGM (Supplemental Figure S1). While the bias via PCR is consistent between
389 sequencing platforms, there is no obvious correlation between length of the read, GC content,
390 nor stretches of homopolymers affecting efficient PCR amplification. For example, *Wolfiporia*
391 *dilatophya* (mock11) contains no homopolymer stretches larger than 5, has GC distribution of
392 54.6%, and is near the median in length, yet it does not PCR amplify well in the BioMock
393 community (Figure 4). These data also show a size limitation in the Ion Torrent PGM workflow,
394 as *Wolfiporia cocos* sequences very poorly due to its very long ITS2 region (Figure 5). Three
395 members of the original 26 members of the BioMock community were dropped (mock24,
396 mock25, mock26) due to persistent problems getting them to amplify/sequence in repeated
397 HTAS on the Ion Torrent platform (Supplemental Figure S1).

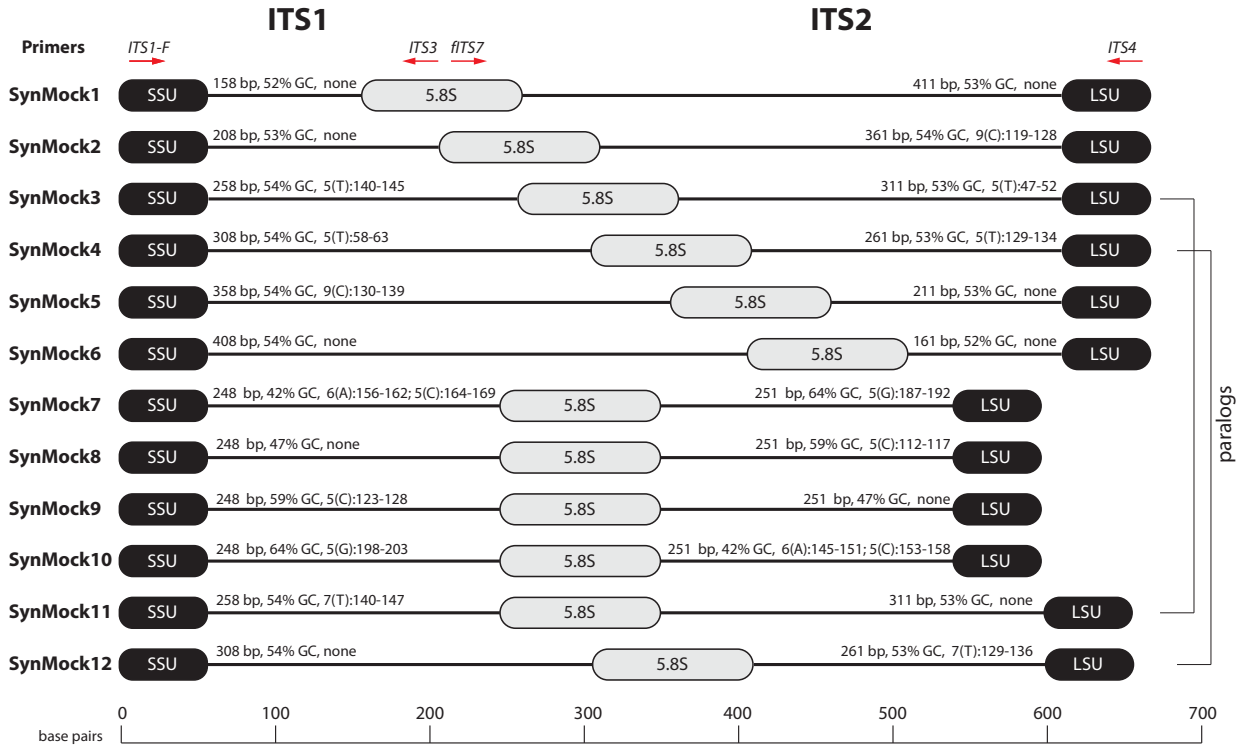
Figure 4. Read abundance is an unreliable proxy for actual abundance within a mixed community. Using an equimolar mixture of cloned ITS sequences in plasmid form (MockA, MockB1, MockB2) in comparison to equimolar mixture of individual PCR products (Stds) illustrates that the initial PCR reaction during library preparation heavily biases the read abundance obtained after sequencing on both the Ion Torrent PGM and Illumina MiSeq platforms. While read abundances are unreliable, all members of the mock community were recovered. MockA represents a 1:16,000 dilution and MockB1/MockB2 are replicates of a 1:32,000 dilution of the BioMock community. The Ion Torrent PGM platform has a length threshold of approximately 450 bp, therefore longer amplicons like *Wolfiporia cocos* ITS2 sequence very poorly.

In HTAS experiments, considerable effort is made to try to sequence to an equal depth for each sample, however, in practice this rarely works perfectly and thus a typical HTAS dataset has a 2-4X range in number of reads per sample. The depth of sequence range for the HTAS runs presented here is within a range of 2X for each run and the smallest number of

413 reads per sample in any of our sequencing runs was nearly 60,000 (Supplemental Table S5).
414 Unequal sequencing depth has been used as rationale for explaining the lack of correlation
415 between read abundance and actual abundance. Therefore, randomly subsampling of reads in
416 each sample prior to clustering (also called rarefying) has been widely used in the literature,
417 despite a compelling statistical argument that this method is flawed (44). Randomly
418 subsampling reads for each sample using our BioMock community yielded nearly identical
419 results (Supplemental Figure S2), which was expected due to the relatively high sequence
420 coverage for all samples in our HTAS runs. Sequencing depth has been shown to be an
421 important variable for HTAS experiments (45), therefore we typically employ a 5,000 reads per
422 sample cutoff when processing environmental datasets.
423
424 *A non-biological (synthetic) mock community to measure index-bleed between samples*
425 Index-bleed is a phenomenon that has been described on Roche 454 platform (16) as
426 well as Illumina platforms (46, 47). A consensus on a mechanism of index-bleed during the
427 sequencing run has yet to be reached. Index-bleed is a significant challenge to overcome as
428 sample crossover has the potential to over-estimate diversity and lead to inaccurate
429 representations of microbial communities, especially considering that read abundance is an
430 unreliable proxy for biological abundance (Figure 4). Using our BioMock sequencing results, we
431 also discovered this phenomenon on both Ion Torrent and Illumina platforms. We calculated the
432 rate of index-bleed in our BioMock Ion Torrent sequencing run to be 0.033% and on Illumina
433 MiSeq between 0.233% and 0.264%. We also confirmed that index-bleed was happening on the
434 Illumina flow-cell by re-running a subset of samples that had shown high index-bleed on
435 different flowcell that did not contain the BioMock (Supplemental Figure S3). One problem that
436 we noticed in measuring index-bleed using a mock community of actual ITS sequences
437 (BioMock) was that these same taxa in the mock community could be present in environmental
438 samples, which would lead to inaccurate estimation of index-bleed. In our environmental data, it
439 was likely that at least one of the BioMock members was present in several of the
440 environmental samples, suggesting the calculated index-bleed could be over-estimated. To
441 overcome this problem, we designed a non-biological (synthetic) mock community composed of
442 ITS-like sequences that contained conserved priming sites (SSU and LSU regions), ITS1
443 region, 5.8S region, and an ITS2 region (Figure 6). We designed the ITS1 and ITS2 portions of
444 the sequences to be non-biological, that is they have no similar sequences in nature and
445 therefore could be used to accurately track index-bleed in HTAS studies. Using the summary

446 statistics from the analysis of the UNITE reference database for guidance, we also varied the
447 length, GC content, and homopolymer stretches to be representative of real ITS sequences.



448

449 **Figure 5.** Schematic drawing of the 12-member non-biological synthetic mock community
450 (SynMock). Conserved priming sites for either ITS1 or ITS2 amplicons are retained for
451 versatility. The length distribution, GC content, and homopolymer stretches are representative of
452 curated public databases, however, the sequences are non-biological and thus not found in
453 nature.

454 The SynMock was tested as a spike-in control on both the Ion Torrent and Illumina
455 MiSeq platforms. The raw data were processed using AMPtk and clustered using UPARSE.
456 These data illustrate that the synthetic sequences are able to be processed simultaneously with
457 real ITS sequences and provide a way to track the level of index-bleed between multiplexed
458 samples (Figure 6). The increased benefit of being able to track the SynMock sequences as
459 they “bleed” out of the sample allows for a more accurate measurement of index-bleed. Using
460 default Illumina de-multiplexing (allowing 1 mismatch in the index sequence), index-bleed using
461 the SynMock community was 0.072% (Figure 6C). To determine if allowing mismatches in the
462 index reads was increasing index-bleed, we reprocessed the data with 0 mismatches and found
463 that index-bleed was reduced to 0.046%. While index-bleed was reduced by nearly half the
464 tradeoff was that 0 mismatches resulted in approximately 10% fewer reads. For most datasets,
465 a loss of 10% of the sequencing reads shouldn’t be problematic, especially if the benefit is to
466 reduce index-bleed in the data. We noted that in our Illumina dual-indexing library prep that

467 there was increased index-bleed on samples that had a shared reverse index (i7), suggesting
468 that errors are increased at later stages of an Illumina sequencing run (Figure 6B). A similar
469 pattern was observed with Ion Torrent PGM data, although not as drastic, allowing 1 mismatch
470 in the barcode resulted in 0.167% index-bleed while allowing 0 mismatches in the barcode
471 resulted in 0.156% index-bleed (Figure 6C). While these data would suggest that index-bleed is
472 perhaps higher in Ion Torrent PGM datasets, we have subsequently used the SynMock on more
473 than 10 different HTAS Ion Torrent PGM experiments and have since seen much lower levels of
474 index-bleed, occasionally approaching 0% index-bleed.
475 Many environmental samples can contain hundreds of taxa and thus a legitimate
476 concern is that the 12 member SynMock community does not represent a realistic community in
477 terms of diversity in a sample. To test if the SynMock was able to be recovered in a more
478 complex community, we mixed SynMock together with two environmental samples that had
479 more than 200 OTUs in previous sequencing runs. These mixed samples show that SynMock
480 could be recovered from a complex community and the sequences behave like real ITS
481 sequences (Figure 6A). While many studies have set a read count threshold to filter “noisy” data
482 from OTU tables, this threshold has been typically selected arbitrarily, i.e. OTUs with read
483 counts less than 100 or less than 10% of the total, etc. Use of the SynMock spike-in control
484 allowed for data driven thresholds to be measured and moreover for the ability to filter the OTU
485 table based on the calculated index-bleed. The AMPtk filter command calculates index-bleed by
486 mapping the OTUs to the mock community and then provides a way to filter the OTU table
487 based on this calculated value. AMPtk filters across each OTU in the table such that difficult to
488 sequence or “low abundance” OTUs are not indiscriminately dropped. Taken together, these
489 data illustrate the utility of a non-biological mock community in parameterizing data processing
490 steps and importantly providing a method in AMPtk to reduce index-bleed from HTAS datasets.
491 AMPtk provides an easy to use method to accurately process variable length amplicons, cluster
492 them into OTUs or denoise sequences, generate an OTU table, filter the OTU table for index-
493 bleed, and assign taxonomy.

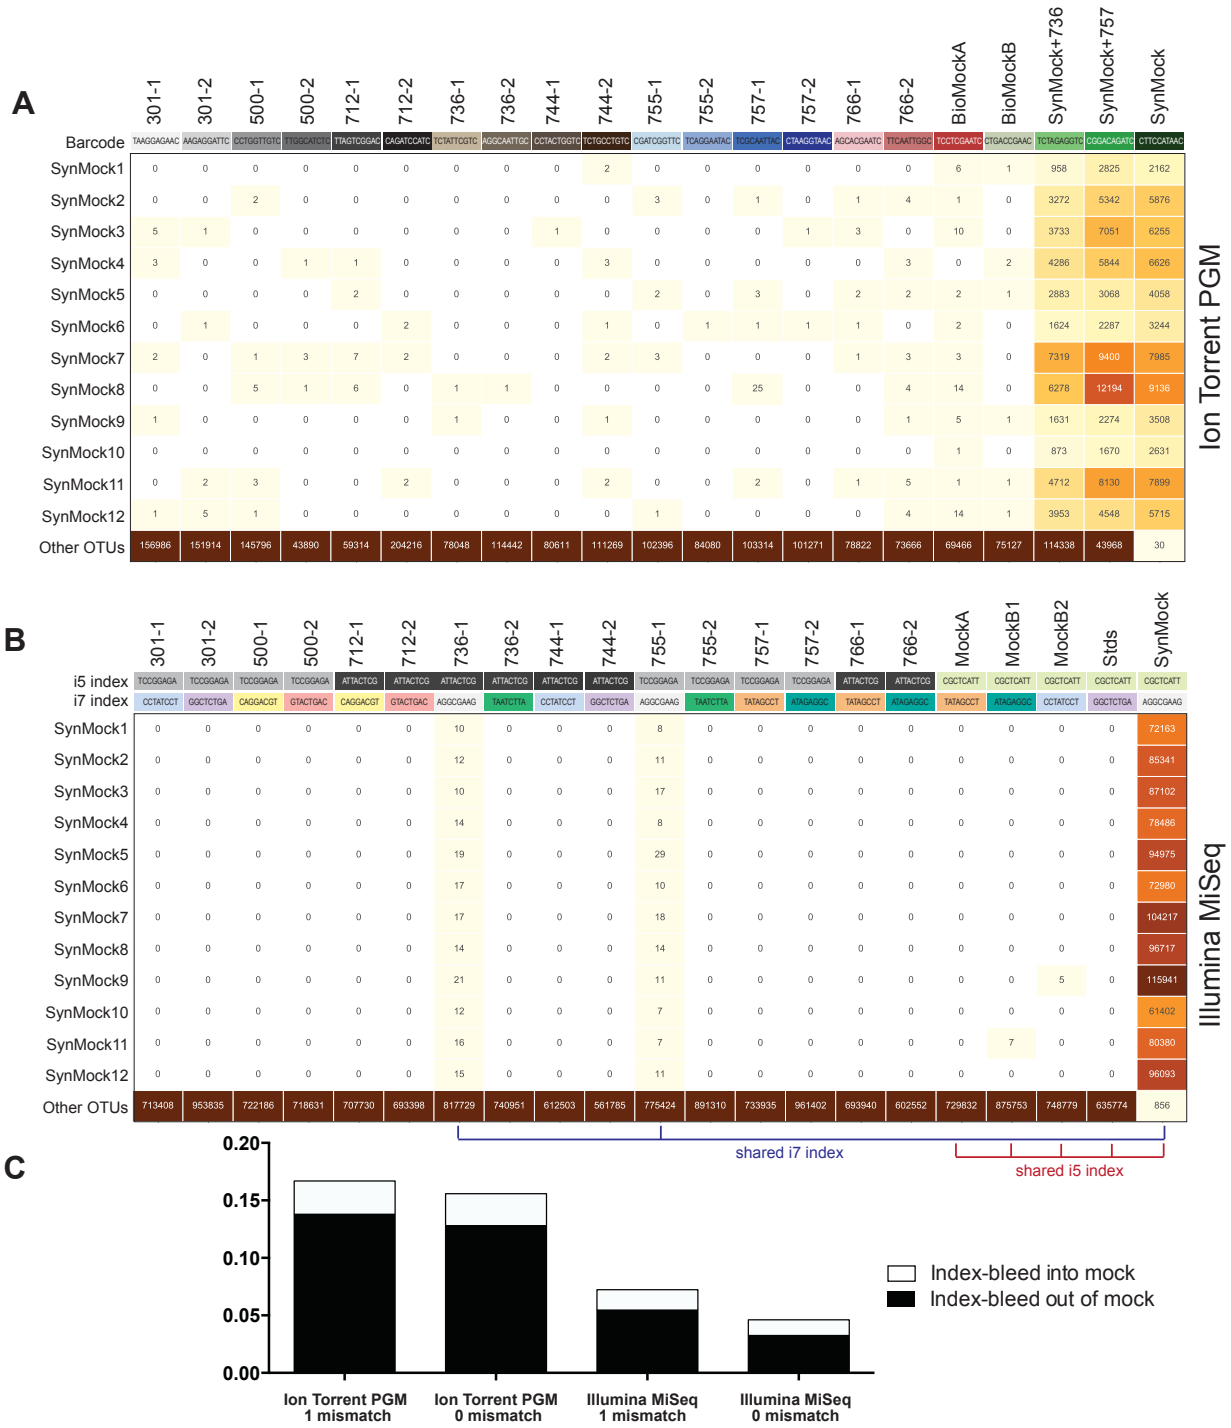


Figure 6. Index-bleed or sample mis-assignment occurs on both Ion Torrent PGM and Illumina Miseq. (A) Read counts from the SynMock community run on the Ion Torrent PGM platform, SynMock reads can be found in environmental samples and reads from the environmental samples are found in the SynMock sample. The data was processed allowing 0 mismatches in the barcode sequence and there is no clear pattern to index-bleed on the Ion Torrent PGM platform. (B) Data processed on the Illumina MiSeq (2x300) allowing 0 mismatches in the index reads show index-bleed in and out of the SynMock sample. Samples that share an index (i5 or i7) show an increase in index-bleed. (C) Index-bleed between samples can be tracked using the

503 SynMock spike-in control, where AMPtk will measure both index-bleed into the SynMock as well
504 as index-bleed into other samples. These calculated values are then used by AMPtk to filter an
505 OTU table to remove read counts that fall below the index-bleed threshold. Index-bleed is
506 reduced if 0 mismatches are allowed in the barcode/index sequence, however, this is still not
507 sufficient to reduce all index-bleed.

508

509 **Discussion**

510 HTAS studies have the goal of measuring environmental diversity, however, there are
511 technical limitations that need to be understood in order to reach a proper conclusion. Mock
512 communities and negative controls have been shown to have great utility for HTAS studies,
513 expanding upon this concept here we present a non-biological synthetic mock community of
514 ITS-like sequences for use as a technical spike-in control for fungal biodiversity studies.
515 Additionally, we describe AMPtk, a software tool kit for analyzing variable length amplicon
516 studies such as the fungal ITS1 or ITS2 molecular barcodes. The two tools can be coupled
517 together to validate data processing pipelines and reduce index-bleed from OTU tables prior to
518 downstream community ecology analyses. The concept of a non-biological synthetic spike-in
519 control can be expanded to many different genes and organisms, including 16S for microbiome
520 studies.

521 The ITS region is widely used as a molecular barcode in fungal biodiversity studies as it
522 is easy to amplify and public reference databases are robust. However, HTAS with the ITS
523 region presents some unique challenges due to variability in sequence characteristics such as
524 length and copy number. Most HTAS software development and optimization has been focused
525 on the 16S molecular barcode, a region that is near uniform in length across prokaryotic taxa,
526 thus there was a need for a software solution that could more accurately account for variable
527 length amplicons. We developed a single-copy mock community based on cloned ITS
528 sequences as a tool to validate and compare different NGS platforms and data processing
529 pipelines. Using an artificial single-copy mock community of cloned ITS sequences in plasmids
530 (BioMock), we determined that the core clustering/denoising algorithms work for variable length
531 amplicons, however, pre-processing techniques widely used for uniform length amplicons
532 introduce significant error into the pipelines. Simplifying the pre-processing of sequencing reads
533 to identify unique sequence barcodes, forward/reverse primers, and trim reads to a uniform
534 length without data loss resulted in large improvement in downstream OTU clustering. The pre-
535 processing of reads prior to quality filtering is critical for variable length amplicons and is
536 implemented in AMPtk.

537 Proper pre-processing of variable length amplicons improves clustering results
538 substantially, however, the BioMock results illustrated that read abundances obtained from
539 HTAS are not a reliable proxy for inferring biological relative abundance. On the other hand, we
540 were able to recover all of the spike-in mock community members that we added to the HTAS
541 runs, even when they were spiked into a diverse environmental sample. We identified the initial
542 PCR reaction (library construction) as the major source of read number bias, a conclusion
543 consistent with the literature (48-50). To reduce PCR artefacts for any assay it is generally
544 accepted that one should use the fewest cycles possible, the most concentrated DNA possible,
545 and it has been suggested to use a proofreading polymerase (51). We have tested DNA
546 concentration and PCR cycle numbers for HTAS library generation and subsequent sequencing
547 on the Ion Torrent PGM platform, our results were consistent with these general guidelines
548 (Supplemental Figure S1). However, following these guidelines is not sufficient to reduce the
549 bias in read abundance from a mixed community from PCR. The Ion Torrent PGM platform
550 currently has an amplicon size limit of ~ 450 bp, thus some very large ITS sequences are
551 difficult to sequence. However, there are only a small number of known ITS1 or ITS2 sequences
552 that are longer than 450 bp (Table 1) and therefore either platform, Ion Torrent or MiSeq,
553 provided similar results under the conditions tested.
554 Index-bleed has recently been acknowledged by Illumina (https://tinyurl.com/illumina-
555 hopping), although they limit their acknowledgement to a new flow cell on the HiSeq and
556 NovaSeq platforms. Several studies have shown that older instruments/flowcells have also
557 shown index-bleed, albeit at a much lower rate (46, 47) and index-bleed has been identified on
558 Roche 454 (16). Here we report a low rate of index-bleed on both Ion Torrent and Illumina
559 MiSeq platforms. While the effective rate of index-bleed is low (< 0.2%), coupled with the fact
560 that read number isn't a reliable proxy of community abundance, index-bleed in datasets being
561 analyzed by presence-absence metrics is a problematic scenario. To identify and combat index-
562 bleed, we created a non-biological synthetic mock community (SynMock) of ITS-like sequences
563 that behave like real ITS sequences during the HTAS workflow, however are not found in nature
564 and can be effectively used to measure index-bleed in a sequencing run. A similar approach
565 was recently described for 16S amplicons using synthesized oligonucleotides (52). We propose
566 that HTAS studies of fungal ITS communities should employ the SynMock as a technical
567 control. Additional controls such as a biological mock community of mixed fruiting bodies,
568 spores, hyphae, etc. of taxa of interest is also a useful control if the experimental design is
569 looking for the prevalence of particular taxa.

The bioinformatics pipeline presented here, AMPtk, was developed to specifically address the quality issues that we have identified by using spike-in mock communities and to provide the scientific community with a necessary tool to study fungal community diversity. AMPtk is a flexible solution that can be used to study other regions used in HTAS such as mitochondrial cytochrome oxidase 1 (mtCO1) of insects and the large subunit (LSU) of the rRNA array. The goal of AMPtk is to reduce data processing to a few simple steps and to improve the output of HTAS studies. Due to the inherent properties of HTAS and the ITS molecular barcode, we take the position that studies of this nature should be used as a preliminary survey of which taxa might be present in an ecosystem and inferring relative abundance from read numbers should be considered cautiously. To understand relative abundance of particular taxa in a community, additional independent assays such as taxa specific qPCR or digital PCR are warranted.

Acknowledgements

We sincerely thank Rita Rentmeester for assisting with the growth of some the cultures used to create the biological mock community. Funding was provided by the US Forest Service, Northern Research Station.

Data availability

Raw sequencing reads and data processing scripts are available at the Open Science Framework at https://osf.io/4xd9r/.

Author Contributions

All authors conceived and designed the experiments. MAJ and MTB conducted laboratory experiments. JMP analyzed sequence data and wrote AMPtk. JMP wrote the paper with input from all authors.

Figure S1. Read abundances do not correlate with actual abundances even when DNA concentration is high and PCR cycles are low. Creating libraries of the equimolar BioMock community by varying PCR cycles and DNA concentrations for sequencing on the Ion Torrent PGM did little to change read abundances. However, these data are consistent with traditional recommendations to use as few PCR cycles as possible during library prep.

	All data: Figure 4 from main text								Random sub-sample 100,000 reads per sample

Figure S2. Random subsampling reads for each sample does not improve accuracy of read abundances. Each sample was randomly sub-sampled to 100,000 reads using 'amptk sample' and then reads were mapped to the BioMock community. Chi-square test for each of these BioMock samples was significant ($p < 0.001$), indicating the read abundances are not equally distributed.

Figure S3. Index-bleed on Illumina MiSeq occurs during the sequencing run and is not a result of contamination. Sequencing the BioMock on Illumina MiSeq resulted in elevated levels of apparent index-bleed during our first run. To rule out that this was a result of contamination during library prep/cleanup, the same libraries were sequenced on a second run in the absence of any of the BioMock samples. The index-bleed discovered in the first run then disappeared, however, one of the BioMock members (mock3) was actually found in these environmental samples.

Table S2. OTU clustering results using default QIIME pre-processing of reads.

Platform	Clustering method	Reads	Total OTUs	Mock OTUs (n = 12)	Error Rate (mismatches / total)
Ion Torrent PGM (400 bp)	UCLUST	2 562 316	97 175	1 347	3.760%
	USEARCH	2 562 316	9 812	560	4.237%
	SWARM	2 562 316	276 403	225	3.517%
	UPARSE	2 562 316	1 609	82	1.100%
Illumina Miseq (2 x 300)	UCLUST	15 696 636	122 802	528	0.131%
	USEARCH	15 696 636	9 785	545	4.694%
	SWARM	15 696 636	614 133	165	4.447%
	UPARSE	15 696 636	2 483	38	0.077%

Table S3. Expected errors quality trimming removes most errors from Ion Torrent PGM data using 12 member SynMock community.[1]

Method	Aligned reads	Subst. errors	Indel errors	UPARSE OTUs	OTUs (chimera filtered)
No Qual Filter	67 185	0.237%	0.342%	26	21
Cutadapt -q 25	73 092	0.152%	0.222%	28	26
Seqtk (Phred)	75 535	0.204%	0.314%	83	79
Sickle –q 25	71 221	0.098%	0.087%	31	30
Exp. Errors < 1	35 810	0.078%	0.100%	18	14

[1] Total of 78,525 reads from the SynMock Ion Torrent PGM run demuxed with AMPtk.

Table S4. Expected errors quality trimming removes most errors from Illumina MiSeq data using 12 member SynMock community.[1]

Method	Aligned reads	Subst. errors	Indel errors	UPARSE OTUs	OTUs (chimera filtered)
No Qual Filter	1 081 931	0.333%	0.006%	44	27
Cutadapt -q 25	1 148 274	0.253%	0.007%	361	337
Seqtk (Phred)	1 115 657	0.316%	0.007%	173	150
Sickle	1 153 190	0.166%	0.006%	304	285
Exp. Errors < 1	961 458	0.094%	0.006%	45	27

[1] Total of 1,167,662 reads from the SynMock Illumina MiSeq run demuxed with AMPtk.

798 Table S5. Summary statistics for the HTAS runs used in this study.

Run	Platform	Total Reads	Valid Reads	Num Samples	Range reads per sample	Total UPARSE OTUs	Mock Community	Mock Calculated Error Rate	Index-Bleed
Mock3	Ion Torrent PGM	4,332,502	3,029,824	19	107,416 - 217,372	1,010	BioMock	0.086%	0.033%
Mock4a	Illumina Miseq	5,668,955	5,661,700	20	237,035 - 334,455	1,778	BioMock	0.019%	0.264%
Mock4b	Illumina Miseq	659,738	658,730	4	145,405 - 191,095	477	None	NA	NA
