Abstract

The current understanding of the genetic architecture of lipids has largely come from genome-wide association studies. To date, few studies have examined the genetic architecture of lipids in Polynesians, and none have in Samoans, whose unique population history, including many population bottlenecks, may provide insight into the biological foundations of variation in lipid levels. Here we performed a genome-wide association study of four fasting serum lipid levels: total cholesterol (TC), high-density lipoprotein (HDL), low-density lipoprotein (LDL), and triglycerides (TG) in a sample of 2,849 Samoans, with validation genotyping for associations in a replication cohort comprising 1,798 Samoans and American Samoans. We identified multiple genome-wide significant associations ($P < 5 \times 10^{-8}$) previously seen in other populations – *APOA1* with TG, *CETP* with HDL, and *APOE* with TC and LDL – and several suggestive associations ($P < 1 \times 10^{-5}$), including an association of variants downstream of *MGAT1* and *RAB21* with HDL. However, we observed different association signals for variants near *APOE* than what has been previously reported in non-Polynesian populations. The association with several known lipid loci combined with the newly-identified associations with variants near *MGAT1* and *RAB21* suggest that while some of the genetic architecture of lipids is shared between Samoans and other populations, part of the genetic architecture may be Polynesian-specific.

Key words: complex trait genetics; founder population genetics; lipids; genome-wide association study; Polynesia

Introduction

The Samoan Islands, comprising both the U.S. Territory of American Samoa (American Samoan) and the Independent State of Samoa (Samoa), have experienced a rise in prevalence of cardiovascular disease and other non-communicable diseases in the last 30 years partly due to economic modernization, rapid urbanization, and lifestyle changes such as increased caloric intake and sedentary behavior [1–3]. A 2010 population-based survey in Samoa, which gathered the "discovery cohort" studied further here, found that many Samoans are at elevated risk of cardiovascular disease based on known risk factors—increased total cholesterol (TC), low-density lipoprotein cholesterol (LDL), and triglycerides (TG), as well as decreased high-density lipoprotein (HDL) [4–6]—with 47% of the 2,938 adult Samoans examined in the study having elevated TC (≥ 5.2 mmol/L), 88% of men and 91% of women having elevated LDL (> 2.59 mmol/L), and 43% of women having low HDL (< 1.29 mmol/L) [1].

Our current understanding of the genetic component of serum lipid level variation has been largely due to genome-wide association studies (GWAS) [7]. The Global Lipids Genetics Consortium found strong evidence for 157 loci associated with one or more of these traits using a sample of 188,577 individuals of European, East Asian, South Asian, and African ancestry [8]. However, few GWAS of serum lipid levels have been conducted in Pacific Islanders [9, 10] and to our knowledge only one has included a small number of Polynesians [11]. Previous studies have estimated the heritability of serum lipid levels in Samoans, ranging from 16% for HDL to 23% for TG, and have identified genetic susceptibility loci via linkage analysis [12], warranting further study of

46 the genetic architecture of serum lipid levels in Samoans. Samoans are a genetically-
47 isolated founder population, with unique evolutionary history, making them particularly
48 useful in genomic studies [13, 14]. Thus, genomic studies of serum lipid levels could
49 reveal novel lipid-altering loci specific to Pacific Islander populations, as well as highlight
50 susceptibility loci shared with global populations.
51
52 Here we report the results of a GWAS of fasting TC, LDL, HDL, and TG in up to
53 2,849 individuals from independent Samoa followed by replication in up to 1,798
54 individuals from independent Samoa and American Samoa, as part of ongoing genome-
55 wide association studies of cardiometabolic disease and adiposity-related traits in the
56 Samoan Islands [1]. We identified multiple genome-wide significant associations
57 previously seen in other populations – *APOA1* with TG, *CETP* with HDL, and *APOE*
58 with TC and LDL – and several suggestive associations, including an association
59 between variants downstream of *MGAT1* and *RAB21* with HDL.
60

61 Methods

62 Discovery Cohort and Genotyping

63 The discovery cohort data are available from dbGaP (accession number:
64 phs000914.v1.p1). The discovery cohort of 2,849 individuals is drawn from a
65 population-based sample recruited from Samoa in 2010 (Table 1). The sample
66 selection, data collection methods, and phenotyping, including the laboratory assays for
67 serum lipid and lipoprotein levels, have been previously reported [1, 13]. Briefly, serum
68 lipid levels were derived from fasting whole blood samples collected after a minimum

10-hour overnight fast. Genotyping was performed using Genome-Wide Human SNP 6.0 arrays (Affymetrix). Extensive quality control was conducted on the basis of a pipeline developed by Laurie et al [15]. Additional details for sample genotyping and genotype quality control are described in Minster et al [13]. This study was approved by the institutional review board of Brown University and the Health Research Committee of the Samoa Ministry of Health. All participants gave informed consent. Imputation was not performed in this study because prior experience with this population using extant imputation panels such as the Phase 3 1000 Genomes panel showed that the resulting imputed genotypes did not correlate well with observed genotypes [13].

Replication Cohort and Genotyping

The replication cohort of 1,798 individuals contains two sample sets recruited from Samoa and American Samoa (Table 1). Although there is substantial economic variation across the two polities, with American Samoans generally having a higher standard of living, the Samoans from both territories form a single socio-cultural unit with frequent exchange of mates; genetically, they represent a single homogenous population [3, 16]. The first sample set, referred to as the 1990–95 replication sample set, contains 716 unrelated individuals derived from a longitudinal study of adiposity and cardiovascular disease risk factors among adults from American Samoa and Samoa (Table 1). Detailed descriptions of the sampling and recruitment have been reported previously [17–19]. Briefly, participants were recruited from 46 villages and worksites in American Samoa in 1990 and 9 villages in Samoa (Western Samoa, at the time of recruitment) in 1991 and followed up four years later in 1994 and 1995, respectively. All participants were, at baseline, free of self-reported history of heart disease, hypertension, or diabetes. This study was approved by the institutional review board of the Miriam Hospital, Providence, RI. All participants gave informed consent. The second sample set, referred to as the 2002–03 replication sample set, contains 1,082 individuals from American Samoa and Samoa and was drawn from an extended family-based genetic linkage analysis of cardiometabolic traits (Table 1) [12, 20–23]. Probands and relatives were unselected for obesity or related phenotypes. The recruitment process and criteria used for inclusion in this study have been described in detail previously [21, 23]. This study was approved by the institutional review board of Brown University and research ethics review committees in both Samoa and American Samoa.

106 All participants gave informed consent. Imputation was not performed in these studies
107 for the same rationale as the discovery cohort above, but also because genome-wide
108 marker data was not available for the samples in these studies.
109
110 In both replication sample sets, blood samples were collected in the morning
111 after a minimum of 10 hours fasting, from which serum lipid levels were derived using
112 assay methods published previously [12, 17]. Genotyping of variants selected for
113 validation in the replication cohort (described below) was performed using custom-
114 designed TaqMan OpenArray Real-Time PCR assays (Applied Biosystems). SNPs that
115 could not be genotyped using OpenArray assays were genotyped individually using
116 TaqMan SNP Genotyping assays (Applied Biosystems). Eight variants could not be
117 genotyped due to technical difficulties.
118

119 Statistical Analyses

120 Prior to association analyses, residuals were generated for all four lipid traits.
121 First, traits were transformed to normality with the Box–Cox power transformation;
122 secondly, model selection was performed using step-wise linear regression with initial
123 model covariates previously associated with serum lipid levels: age, age^2, sex, log-
124 transformed BMI, fasting glucose, smoking status, farming status (as a measure of
125 physical activity), and interactions between age, age^2, and sex. The final TC model
126 adjusted for age, age^2, sex, age × sex, and age^2 × sex; the final LDL and TG models
127 adjusted for age, age^2, sex, and age^2 × sex; the final HDL model adjusted for age and
128 sex.

129

130 Preliminary associations were performed, and variants were selected for
131 validation without consideration of hypolipidemic medication use, as it was not
132 measured. However, participants did self-report use of heart disease medication.
133 Sensitivity analysis revealed that this self-reported use of medication to treat heart
134 disease was significantly associated with TC and LDL (results not shown); individuals
135 reporting such medication use (n = 17) were excluded from analyses. The prioritization
136 of variants for validation genotyping was updated using these analyses, but only after
137 available resources were fully expended. Unfortunately, not all variants that should have
138 been prioritized for validation genotyping were successfully genotyped. All results
139 presented are those of the corrected analyses, removing the individuals with heart
140 disease medication use.

141

142 Additional sensitivity analysis was performed for TG by excluding one outlying
143 observation (i.e., TG > 4 standard deviations above mean); results did not change
144 qualitatively, and, since the recorded value was within the range of plausible values for
145 TG, the individual was retained for presented analyses.

146

147 Association between lipid residuals and autosomal genotypes of 659,492 SNPs
148 with minor allele frequency (MAF) ≥ 0.05 and Hardy-Weinberg Equilibrium (HWE) test *P*
149 value ≥ 5×10^{-5} was assessed using linear mixed modelling in GenABEL, including
150 previously-derived empirical kinship estimates to adjust for subject relatedness [13, 24].
151 The association between X-chromosome genotypes and the lipid phenotypes were

152 calculated in GenABEL, without adjustment using the empirical kinship estimates.
153 Genomic inflation due to population stratification and cryptic relatedness was assessed
154 by estimating λ_{GC} using the lower 90% of the *P* value distribution [25]. GWAS *P* values
155 in the discovery cohort (P_D) were compared to a threshold for genome-wide significance
156 of $P_D < 5 \times 10^{-8}$ and a suggestive association threshold of $P_D < 1 \times 10^{-5}$. Statistical
157 power to detect signals at these thresholds was calculated using the Genetic Power
158 Calculator [26].
159
160 Gene-set enrichment analysis with MAGENTA was also performed to identify any
161 biological pathways enriched for discovery association signals [27]. Briefly, gene scores
162 were obtained from the most significant *P* value among SNPs located within each gene
163 using the association results from each lipid GWAS. Genes scores were adjusted for
164 confounding factors including gene size, number of variants, and linkage disequilibrium-
165 related properties by using step-wise multiple linear regression. The 95th percentile of
166 all gene scores was used as the enrichment cutoff for each trait [28]. Gene-set
167 enrichment *P* values were obtained for highly ranked gene scores. Gene sets were
168 obtained from Gene Ontology (April 2010), pathway information from the Ingenuity
169 (June 2008) and KEGG (June 2010), and biological processes and molecular function
170 from PANTHER (January 2010).
171
172 For each of the lipid traits, the INRICH program [29] was used to test for
173 enrichment of known genes (as constructed from Teslovich et al. [30] and Willer et al
174 [8]). INRICH tests if more known genes are contained in associated intervals than

175 expected by chance, using permutation based on 1 million replicates to generate
176 experiment-wide empirical *P* values. For each lipid trait, we defined the associated
177 intervals as 100 kb intervals centered on the most significant SNP within association
178 peaks with $P_D < 1 \times 10^{-4}$.
179
180 We selected 21 regions demonstrating at least suggestive association for
181 association validation in the replication cohort. An additional 10 regions which should
182 have selected for validation were not followed-up because their exclusion was based on
183 preliminary analyses that included 17 participants taking heart disease medication—
184 participants who were ultimately excluded from these studies. The variant from each
185 locus with smallest *P* value across the four lipid scans (defined as 1 Mb windows
186 surrounding the peak SNP) or a proxy SNP in high linkage disequilibrium with the
187 lowest-*P* value SNP was selected as representative of the locus for replication
188 genotyping.
189
190 Statistical association was measured in the 1990–95 and 2002–03 replication
191 sample sets independently, and results were combined using meta-analysis (see
192 below). Association analyses for both sample sets were performed using GenABEL [31]
193 in R [32], using the same regression models as in the discovery cohort but additionally
194 adjusting for polity (American Samoa or Samoa); the 2002-03 sample set was
195 additionally adjusted using expected kinship, as derived from familial pedigree
196 information [33].
197

198 Prior to meta-analysis, quality control was performed using EasyQC to check for
199 strand and allele frequency consistency [34]. *P* value-based meta-analysis using
200 sample sizes as weights was performed using METAL [35] to generate two *P* values:
201 one for the meta-analysis of the two replication cohorts (P_R) and one for the replication
202 cohorts and discovery sample together (P_{DR}). Resulting meta-analysis signals were
203 evaluated based on genome-wide significance and suggestive thresholds (as described
204 above) and by the contribution of the replication sample to the signal. Effect directions
205 for meta-analysis results of peak SNPs were qualitatively compared to those of
206 previously reported lead SNPs.
207
208 For ease of reference, any locus identified here with a corresponding signal
209 within 1 mega base pairs (Mb) in a prior lipid study is referred to by the previously
210 prescribed locus name [8, 10]; for loci not previously associated with lipid traits, the
211 symbol of the gene nearest the peak SNP in the locus or the hyphen-separated symbols
212 of the nearest two genes is used as the locus label.
213

214 Results

215 The demographic, anthropometric, and biochemical characteristics of the 2,849
216 participants composing the discovery cohort for this GWAS of serum lipids levels and
217 the 1,798 participants composing the replication cohort are presented in Table 1. A
218 detailed description of the discovery cohort and its trends compared to the historical
219 sample sets making up the replication cohort has been previously reported [1]. Briefly,
220 the average age was similar for all cohorts; average BMI was higher among women

221 compared to men and in American Samoa compared to Samoa; average BMI for men
222 and women in Samoa was higher in more recent studies; average lipid levels are largely
223 similar across cohorts with minor exceptions.
224
225 We assessed 659,492 unique genome-wide markers for association with 4
226 traits—TC, HDL, LDL and TG—in up to 2,849 Samoans in the discovery cohort.
227 Relatedness within the discovery cohort was well-controlled using the empirical kinship
228 coefficients; λ_{GC} ranged between 1.03 and 1.07 for the four lipid traits (Figs S2, S4, S6,
229 and S8 in S1 Appendix). We observed 38 genome-wide suggestive or significant
230 associations across 31 loci from the four GWAS (Fig 1; Figs S1, S3, S5, and S7 in S1
231 Appendix; Tables S1, S7, S10, and S13 in S1 Appendix).
232
233 **Fig 1. Manhattan plots for GWAS of four lipid traits in the discovery cohort of**
234 **2,849 Samoans.** The dashed and solid lines denote genome-wide suggestive and
235 genome-wide significant *P* value thresholds ($P < 1 \times 10^{-5}$ and $P < 5 \times 10^{-8}$,
236 respectively). Peaks are labeled with the candidate gene or closest gene in the region if
237 they have at least suggestive association in the discovery cohort for at least one trait
238 and demonstrate evidence of replication or have been previously associated.
239
240 Genome-wide significant association was observed in the discovery cohort
241 between all four traits and markers near *APOE*: TC and rs4420638 ($P_D = 2.67 \times 10^{-16}$,
242 Fig 2E); HDL and rs4420638 ($P_D = 9.07 \times 10^{-9}$, Fig 2F); LDL and rs1160985 ($P_D = 2.61$
243 $\times 10^{-20}$; Fig 2G); and TG and rs4420638 ($P_D = 7.44 \times 10^{-10}$, Fig 2H). Additionally, HDL

244 was associated with markers near *CETP* (rs289708, $P_D = 1.19 \times 10^{-11}$), and TG, with
245 *APOA1* (rs6589566, $P_D = 3.98 \times 10^{-18}$, Fig 2C). Suggestive associations were observed
246 between lipid levels and markers at an additional 28 loci, including the *MGAT1* and
247 *RAB21* loci and HDL (Fig 2A,D), and *APOA1* with TC (rs3741298, $P_D = 1.63 \times 10^{-7}$, Fig
248 2B). We had 80% power at $\alpha = 1 \times 10^{-5}$ and $\alpha = 5 \times 10^{-8}$ to detect SNPs that account
249 for 1.0% and 1.5%, respectively, of the residual variance in a phenotype.
250
251 **Fig 2. Regional association plots for selected loci.** Regional association plots
252 generated in LocusZoom [36] showing –log10(*P* values) for SNPs in the (A) *MGAT1*
253 locus and HDL, (B) *APOA1* locus and TC, (C) *APOA1* locus and TG, (D) *RAB21* locus
254 and HDL, and the *APOE* locus and (E) TC, (F) HDL, (G) LDL, and (H) TG. Points are
255 color coded within each plot according to pairwise linkage disequilibrium (r^2) with the
256 labeled SNPs; the saturation of the color of each plotted SNP measures the linkage
257 disequilibrium (r^2) with the labeled SNP sharing the same color.
258
259 Gene-set enrichment analysis with MAGENTA highlighted, at a < 5% false-
260 discovery rate (FDR), several lipid homeostasis pathways and gene ontologies for HDL
261 and TG (Tables S8 and S14 in S1 Appendix). Four gene sets were below the FDR for
262 both HDL and TG: HDL particle remodeling, reverse cholesterol transport, cholesterol
263 efflux, and phospholipid efflux. An additional 12 gene sets were implicated for HDL and
264 three gene sets for TG. The HDL particle remodeling and reverse cholesterol transport
265 gene sets had significant enrichment for TC (Table S3 in S1 Appendix), and a single
266 gene set was implicated with LDL, the amylase pathway (Table S11 in S1 Appendix). All

267 four traits had significant enrichment for known TC, HDL, LDL, and TG loci using the
268 INRICH method (Tables S5, S9, S12, and S15 in S1 Appendix).
269
270 Validation of peak SNPs was attempted for 21 loci. At loci with multiple
271 associated variants, the most significant variant was chosen as representative of the
272 locus. For some loci, the exclusion of participants using self-reported heart disease
273 medication resulted in a different peak SNP. Thus, for the *APOE* locus rs1160985 was
274 genotyped instead of rs4420638 ($P_D = 2.67 \times 10^{-16}$ for TC, $P_D = 9.07\times 10^{-9}$ for HDL,
275 and $P_D = 7.44 \times 10^{-10}$ for TG); for the *APOA1* locus rs964184 was genotyped instead of
276 rs3741298 ($P_D = 1.63 \times 10^{-7}$ for TC) or rs6589566 ($P_D = 3.98 \times 10^{-18}$ for TG); for the
277 *MGAT1* locus rs1038143 was genotyped instead of rs249356 ($P_D = 1.06 \times 10^{-6}$ for
278 HDL); for the *APOB* locus rs754523 was genotyped instead of rs1469513 ($P_D = 2.71 \times$
279 10^{-6} for LDL).
280
281 We successfully genotyped the peak SNP, or a proxy SNP, in the replication
282 cohorts for 15 loci. Two loci (*APOA1* with TG, $P_{DR} = 1.81 \times 10^{-29}$; *APOE* with TC, $P_{DR} =$
283 4.29×10^{-21}, and LDL, $P_{DR} = 1.53 \times 10^{-27}$) demonstrated genome-wide significant
284 associations in the discovery-replication meta-analysis (Table 2 and Tables S1, S7,
285 S10, and S13 in S1 Appendix). An additional four associations demonstrated evidence
286 of replication with consistent directions of effect and suggestive joint P_{DR} values (*GCKR*
287 with TG, $P_{DR} = 5.62 \times 10^{-8}$; *MGAT1* with HDL, $P_{DR} = 2.91 \times 10^{-7}$; *APOA1* with TC, $P_{DR} =$
288 1.72×10^{-6}; *RAB21* with HDL, $P_{DR} = 5.92 \times 10^{-7}$). Three associations had suggestive
289 joint P_{DR} values driven by the discovery associations only (*APOB* with LDL, $P_{DR} = 5.81 \times$

290 10^{-6}; *LIPC* with HDL, $P_{DR} = 9.15 \times 10^{-7}$; *CDH4* with HDL, $P_{DR} = 8.77 \times 10^{-6}$);

291 associations at *APOB* and *CDH4* had consistent directions of effect. Among the

292 remaining loci with at least suggestive association in the discovery sample, but not in

293 the discovery-replication meta-analysis, consistent effect directions were also seen for

294 TC and *APOB* and *ZHX2*; LDL and *ALG10* and *CPNE8* (Table 2 and Tables S1, S7,

295 S10, and S13 in S1 Appendix).

EA = effect allele
OA = other allele (reference allele)
Dir = direction of the effect in each of the four samples (+ indicates the effect allele is increasing the trait value on the raw scale)
P_D = discovery cohort GWAS *p*-value
P_R = replication cohort *p*-value
P_{DR} = joint discovery and replication cohorts *p*-value
Known gene = Loci observed in Teslovich et al. 2010 or Willer et al. 2013
Traits = Traits locus associated with in Teslovich et al. 2010 or Willer et al. 2013
C = TC
H = HDL
L = LDL
T = TG
SAM = Samoan effect allele frequency (EAF)
EAS = East Asian EAF
SAS = South Asian EAF
EUR = European EAF
AMR = Admixed American EAF
AFR = African EAF

*The SNP genotyped in the replication population was not the peak SNP at this locus for this trait.

320 We compared the directions of effect to those previously reported in Willer et al.
321 [8] and Teslovich et al. [30] for *APOB*, *GCKR*, *APOA1*, *LIPC*, *LIPG*, and *APOE* (i.e.,
322 genome-wide suggestive loci that have been previously associated with lipid traits). We
323 observed a consistent direction of effect for the representative SNP for all associations
324 except for *LIPG* and HDL (Table 2).
325
326 The effect allele frequencies in the two samples—discovery and replication—
327 were largely similar for each of the 15 successfully genotyped SNPs (Tables S1, S7,
328 S10, and S13 Appendix). However, many loci had markedly different effect allele
329 frequencies between Samoans and other 1000 Genomes populations (Table 2). For
330 example, compared to 1000 Genomes populations, there were higher effect allele
331 frequencies (EAFs) in Samoans for rs964184 near *APOA1* (G allele frequency: 0.440 in
332 Samoans vs. < 0.277 in 1000 Genomes populations), rs1160985 near *APOE* (C allele
333 frequency: 0.724 in Samoans vs. < 0.659 in 1000 Genomes populations), and
334 rs1038143 near *MGAT1* (A allele frequency: 0.309 in Samoans vs. < 0.148 in 1000
335 Genomes populations).
336
337

338 Discussion

339 In this study, we examined four measures of fasting lipid levels—TC, HDL, LDL
340 and TG—for associations with 659,492 SNPs from a genome-wide array in a discovery
341 cohort of 2,849 Samoans, with follow-up genotyping of significant and suggestive
342 findings in a replication cohort comprising 1,798 Samoans from Samoa and American

343 Samoa. Thirty-one loci had at least suggestive evidence of association with one or more
344 lipid traits in the discovery cohort, of which eight have been reported to be associated
345 with lipid levels previously: *APOB, GCKR, MGAT1, APOA1*, *LIPC*, *CETP, LIPG,* and
346 *APOE* [8, 10, 30] although the direction of effect for the variant near LIPG was in the
347 opposite direction from previous results. Enrichment analyses highlighted known lipid
348 metabolism gene sets and previously associated lipid loci.
349
350 We observed a difference in the architecture of the statistical association signals
351 between the four lipid traits and variants near *APOE* (Fig 2E-H). The peak SNP for TC
352 and LDL was rs1160985, an intronic variant in *TOMM40* upstream of *APOE*; whereas
353 the peak SNP for HDL and TG was rs4420638, an intergenic variant downstream of
354 *APOC1* and *APOE*. rs1160985 demonstrated evidence of replication for TC and LDL
355 but not for HDL and TG, consistent with the discovery findings. These markers are in
356 low linkage disequilibrium with each other (r^2 = 0.093) and may represent distinct
357 association signals. While this could support a shared genetic architecture for TC and
358 LDL and for HDL and TG in Polynesians, this study was not positioned to adequately
359 capture the association signal present at this locus. Future studies with sequencing or
360 imputation of the 19q13.2 region will be necessary to dissect the genetic architecture of
361 *APOE* and lipid levels in Polynesians.
362
363 We did not observe suggestive or genome-wide significant association with
364 several loci which have figured prominently in multiple lipid GWAS (e.g., *LPL*, *LDLR*,
365 *CILP2*, *FADS1*/*2*/*3*, *ANGPTL3*, *SORT1*, *PPP1R3B*, *MIXIPL*, *HNF4A*, *PCSK9*, *GALNT2*,

366 *HMGCR*) either because we lacked sufficient power to detect their effects, the effects
367 are negligible in Samoans, or the allele frequencies of associated variants are different
368 enough in Samoans to hinder detection. However, it is important to note that this study
369 was not designed to evaluate the effect of known lipids loci in Samoans, nor were
370 previously-associated loci examined specifically.
371
372 We detected and replicated a suggestive association between HDL and a variant
373 on 5q35.3 (Fig 2A). While the peak SNP lies within an intron of *BTNL8*, the variant
374 selected for follow-up genotyping is intergenic, downstream of *MGAT1*. A suggestive
375 association between variants near *MGAT1* and HDL in a GWAS in the Micronesian
376 population of Kosrae has been previously reported [10]. Although there is no evidence
377 of association between *MGAT1* and lipids as reported in prior studies of non-Pacific
378 Islanders, variation near *MGAT1* has been associated with BMI, serum fatty acid levels
379 and composition, and glucose response in Europeans [37–39]. The encoded MGAT
380 enzyme plays a major role in the absorption of dietary fat in the intestine [40]. Due to the
381 greater frequency of the HDL-associated risk variant observed in Samoans compared to
382 1000 Genomes populations, it is plausible that variation near *MGAT1* may have a
383 unique role in or a stronger effect on the lipid metabolism of Pacific Islanders.
384
385 We also detected and replicated a novel suggestive association between HDL
386 and a variant downstream of *RAB21* (Fig 2D). Unlike the variant downstream of
387 *MGAT1*, we observed similar allele frequencies between Samoans and 1000 Genomes
388 populations (i.e., < 20% difference between Samoans and another 1000 Genomes

389 population) in the HDL-associated variant downstream of *RAB21*. This region, 12q21,
390 was previously seen in linkage analysis with both univariate and bivariate scans of TC
391 and LDL [12]. The individuals included in this linkage analysis are also included in our
392 2002–03 replication sample set, however, they do not appear to be driving the
393 association signal near *RAB21* (Table S7 in S1 Appendix). Variation near *RAB21* has
394 been previously associated with obesity [41]. *RAB21* belongs to the family of
395 monomeric GTPases involved in control of cellular membrane trafficking and is involved
396 in the targeted trafficking of integrins and the regulation of cell adhesion and migration
397 [42, 43].
398
399 This study is limited in drawing conclusions about the genetic architecture of
400 lipids in Samoans, as replication genotyping was unavailable for many loci and due to
401 the lack of genome-wide imputation. Future studies, evaluating the evidence of
402 association between associations seen here in separate cohorts as well fine-mapping
403 loci with genotype imputation (given the availability of a relevant reference panel), are
404 necessary to fully evaluate the genetic architecture of lipids in Samoans.
405
406 This is the first GWAS of lipid phenotypes in Samoans, and we observed
407 association with many known lipid loci, which was further supported by the gene-set
408 enrichment analysis highlighting lipid metabolism gene sets. However, the difference in
409 association results near *APOE*, coupled with evidence of Pacific-Islander–specific
410 associations with *MGAT1* and *RAB21* suggest that some, but not all, of the genetic
411 architecture of lipids is shared between Samoans and other populations. Given this

evidence of a partially distinct genetic architecture of lipids in Samoans, further investigation and fine-mapping of lipid loci, especially that across multiple ethnicities, is warranted.

Acknowledgements

The authors would like to thank the Samoan participants of the study, local village authorities, and the many Samoan and other field workers over the years. We acknowledge the Samoan Ministry of Health, the Samoa Bureau of Statistics, and the American Samoan Department of Health for their support of this research. We give particular thanks to two research assistants, Melania Selu and Vaimoana Lupematasila, who contributed to the 2010 recruitment and continue to assist us in our work in Samoa.
