metabarcoding, iDNA, eDNA, leeches

Abstract

Background

The use of environmental DNA, 'eDNA,' for species detection via metabarcoding is growing rapidly. We present a co-designed lab workflow and bioinformatic pipeline to mitigate the two most important risks of eDNA: sample contamination and taxonomic mis-assignment. These risks arise from the need for PCR amplification to detect the trace amounts of DNA combined with the necessity of using short target regions due to DNA degradation.

Findings

Our high-throughput workflow minimises these risks via a four-step strategy: (1) technical replication with two *PCR replicates* and two *extraction replicates*; (2) using multi-markers (*12S*, *16S*, *CytB*); (3) a 'twin-tagging,' two-step PCR protocol;(4) use of the probabilistic taxonomic assignment method *PROTAX*, which can account for incomplete reference databases.

As annotation errors in the reference sequences can result in taxonomic mis-assignment, we supply a protocol for curating sequence datasets. For some taxonomic groups and some markers, curation resulted in over 50% of sequences being deleted from public reference databases, due to (1) limited overlap between our target amplicon and reference sequences; (2) mislabelling of reference sequences; (3) redundancy.
Finally, we provide a bioinformatic pipeline to process amplicons and conduct *PROTAX* assignment and tested it on an 'invertebrate derived DNA' (iDNA) dataset from 1532 leeches from Sabah, Malaysia. Twin-tagging allowed us to detect and exclude sequences with non-matching tags. The smallest DNA fragment (*16S*) amplified most frequently for all samples, but was less powerful for discriminating at species rank. Using a stringent and lax acceptance criteria we found 170 (stringent) and 196 (lax) vertebrate detections of 97 (stringent) and 109 (lax) leech samples.

Conclusions

Our metabarcoding workflow should help research groups increase the robustness of their results and therefore facilitate wider usage of e/iDNA, which is turning into a valuable source of ecological and conservation information on tetrapods.

Introduction

Monitoring, or even detecting, elusive or cryptic species in the wild can be challenging. In recent years there has been a rise in the availability of cost-effective DNA-based methods made possible by advances in high-throughput DNA sequencing (HTS). One such method is eDNA metabarcoding, which seeks to identify the species present in a habitat from traces of 'environmental DNA' (eDNA) in substrates such as water, soil, or faeces. A variant of eDNA metabarcoding, known as 'invertebrate-derived DNA' (iDNA) metabarcoding, targets the genetic material of prey or host species extracted from copro-, sarco- or haematophagous invertebrates. Examples include tick [1] s, blow or carrion flies [2; 3; 4; 5], mosquitoes [6; 7; 8; 9] and leeches [10; 11; 12; 13]. Many of these parasites are ubiquitous, highly abundant, and easy to collect, making them an ideal source of biodiversity data, especially for terrestrial vertebrates that are otherwise difficult to detect [10; 14; 15]. In particular, the possibility for bulk collection and sequencing in order to screen large areas and minimise costs is attractive. However, most of the recent studies on iDNA studies focus on single-specimen DNA extracts and Sanger sequencing and thus are not making use of the advances of HTS and a metabarcoding framework for carrying out larger scale biodiversity surveys.

That said, e/iDNA metabarcoding also poses several challenges, due to the low quality and low amounts of target DNA available, relative to non-target DNA (including the high-quality DNA of the live-collected, invertebrate vector). In bulk iDNA samples comprised of many invertebrate specimens, this problem is further exacerbated by the variable time since each individual has fed, if at all, leading to differences in the relative amounts and degradation of target DNA per specimen. This makes e/iDNA studies similar to ancient DNA samples, which also pose the problem of low quality and low amounts of target DNA [16; 17]. The great disparity in the ratio of target to non-target DNA and the low overall amount of the former requires an enrichment step, which is achieved via the amplification of a short target sequence (amplicon) by polymerase chain reaction (PCR) to obtain enough target material for sequencing. However, this enrichment step can result in false positive species detections, either through sample cross-contamination or through volatile short PCR amplicons in the laboratory, and in false-negative results, through primer bias and low concentrations of template DNA. Although laboratory standards to prevent and control for such false results are well established in the field of ancient DNA, there are still no best-practice guidelines for e/iDNA studies, and thus few studies sufficiently account for such problems [18].

The problem is exacerbated by the use of 'universal' primers used for the PCR, which maximise the taxonomic diversity of the amplified sequences. This makes the method a powerful biodiversity assessment tool, even where little is known *a priori* about which species might be found. However, using such primers, in combination with low quality and quantity of target DNA, which often requires a high number of PCR cycles to generate enough amplicon products for sequencing, makes metabarcoding studies particularly vulnerable to false results [13; 19; 20]. The high number of PCR cycles, combined with the

high sequencing depth of HTS, also increase the likelihood that contaminants are amplified and detected, possibly to the same or greater extent as some true-positive trace DNA. As e/iDNA have been proposed as tools to detect very rare and priority conservation species such as the Saola, *Pseudoryx nghetinhensis* [10], false detection might result in misdirected conservation activities worth several hundreds of thousands of US dollars like for the ivory-billed woodpecker where most likely false evidence of the bird's existence have been overemphasized to shore up political and financial support for saving it [21]. Therefore, similar to ancient DNA studies, great care must be taken to minimise the possibility for cross-contamination in the laboratory and to maximise the correct detection of species through proper experimental and analytical design. Replication in particular is an important tool for reducing the incidence of false negatives and detection of false positives but the trade-off is increased cost, workload, and analytical complexity [19].

An important source of false positive species detections is the incorrect assignment of taxonomies to the millions of short HTS reads generated by metabarcoding. Although there has been a proliferation of tools focused on this step, most can be categorised into just three groups depending on whether the algorithm utilises sequence similarity searches, sequence composition models, or phylogenetic methods [22; 23; 24]. The one commonality among all methods is the need for a reliable reference database of correctly identified sequences, yet there are few curated databases currently appropriate for use in e/iDNA metabarcoding. Two exceptions are SILVA [25] for the nuclear markers SSU and LSU rRNA used in microbial ecology, and BOLD (Barcode of Life Database; citation) for the COI 'DNA barcode' region. For other loci, a non-curated database downloaded from the INSDC (International Nucleotide Sequence Database Collaboration, e.g. GenBank) is generally used. However, the INSDC places the burden for metadata accuracy, including taxonomy, on the sequence submitters, with no restriction on sequence quality or veracity. For instance, specimen identification is often carried out by non-specialists, which increases error rates, and common laboratory contaminant species (e.g. human DNA sequences) are sometimes submitted in lieu of the sample itself. The rate of sequence mislabelling in fungi has been assessed for GenBank where it was up to 20% [26] and it is an issue that is often neglected [27; 28]. For several curated microbial databases (Greengenes, LTP, RDP, SILVA), mislabelling rates have been estimated at between 0.2% and 2.5% [29]. Given the lack of professional curation it is likely that the true proportion of mislabelled samples in GenBank is somewhere between these numbers. Moreover, correctly identifying such errors is labour-intensive, so most metabarcoding studies simply base their taxonomic assignments on sequence-similarity searches of the whole INSDC database (e.g. with BLAST) [3; 10; 12] and thus can only detect errors if assignments are ecologically unlikely. Furthermore, reference sequences for the species that are likely to be sampled in e/iDNA studies are often underrepresented in or absent from these databases, which increases the possibility of incorrect assignment. For instance, fewer than 50% of species occurring in a tropical megadiverse rainforest are represented in Genbank (see findings below). When species-level matches are ambiguous, it might still be possible to assign a sequence to a higher

taxonomic rank by using an appropriate algorithm such as Metagenome Analyzer's (MEGAN) Lowest Common Ancestor [30] or *PROTAX* [31].

We present here a complete laboratory workflow and complementary bioinformatics pipeline, starting from DNA extraction to taxonomic assignment of HTS reads using a curated reference database. The laboratory workflow allows for efficient screening of hundreds of e/iDNA samples. The workflow includes (1) two *extraction replicates* are separated during DNA extraction, and each is sequenced in two *PCR replicates* (Fig. 1); (2) robustness of taxonomic assignment is improved by using up to three mitochondrial markers; (3) a 'twin-tagged', two-step PCR protocol prevents cross-sample contamination as no unlabelled PCR products are produced (Fig. 2) while also allowing for hundreds of PCR products to be pooled before costly Illumina library preparation; (4) our bioinformatics pipeline includes a standardized, automated, and replicable protocol to create a curated database, which allows updating as new reference sequences become available, and to be expanded to other amplicons. We provide scripts for processing raw sequence data to quality-controlled dereplicated reads and for taxonomic assignment of these reads using *PROTAX* [31], a probabilistic method that has been shown to be robust even when reference databases are incomplete [23; 4] (all scripts are available from URL https://github.com/alexcrampton-platt/screenforbio-mbc).

Methods

Establishment of the tetrapod reference database

Reference database

A custom bash script was written to generate a tetrapod reference database for up to four mitochondrial markers – a short 93 bp fragment of *16S* rRNA (*16S*), a 389 bp fragment of *12S* rRNA (*12S*), a 302 bp fragment of cytochrome b (*CytB*), and a 250 bp mitochondrial cytochrome c oxidase subunit I amplicon (*COI*) that has previously been used in iDNA studies [2]. An important time-saving step was the use of the FASTA-formatted Midori mitochondrial database [32], which is a lightly curated subset of Genbank. Our script updated the FASTA files with a subset of target species, removed errors and redundancy, trimmed the sequences to include only the amplicon regions, and output FASTA files with species names and GenBank accessions in the headers.

The script accepts four data inputs, two of which are optional. The required inputs are: (i) the Midori sequences (December 2015 'UNIQUE', downloaded from http://www.reference-midori.info/download.php#) for the relevant genes and (ii) an initial reference taxonomy of tetrapods. This taxonomy is needed to find or generate a full taxonomic classification for each sequence because the taxonomies in Midori are from Genbank and thus include incorrect, synonymized, or incomplete taxonomies. Here we used the Integrated Taxonomic Information System (ITIS) classification for Tetrapoda, obtained with the R package *taxize* version 0.9.0 ([33], functions *downstream* and *classification*). The optional inputs are: (iii) supplementary FASTA files of reference sequences that should be added to the database,

and (iv) a list of target species to be queried on GenBank to capture any sequences published since the December 2015 Midori dataset was generated.

For this study, 72 recently published [34) and 7 unpublished partial mitochondrial mammal genomes (Accession Numbers MH464789, MH464790, MH464791, MH464792, MH464793, MH464794, MH464795, MH464796, MH464797, MH464798, MH464799, MH464800, MH464801) were added as input (iii). A list of 103 mammal species known to be present in the sampling area plus *Homo sapiens* and our positive control *Myodes glareolus* was added as input (iv).

With the above inputs, the seven curation steps are: 1) remove sequences not identified to species; 2) add extra sequences from optional inputs (iii) and (iv) above; 3) trim the sequences to leave only the target amplicon; 4) remove sequences with ambiguities; 5) compare species names from the Midori dataset to the reference taxonomy from input (ii) and replace with a consensus taxonomy; 6) identify and remove putatively mislabelled sequences; 7) dereplicate sequences, retaining one haplotype per species.

The script is split into four modules, allowing optional manual curation at three key steps. The steps covered by each of the four modules are summarized in Table 2. The main programs used are highlighted and cited in the text where relevant, but many intermediate steps used common UNIX tools and unpublished lightweight utilities freely available from GitHub (Table 3).

Module 1 - The first step is to select the tetrapod sequences from the Midori database for each of the four selected loci (input (i) above). This, and the subsequent step to discard sequences without strict binomial species names and reduce subspecies identifications to species-level, are made possible by the inclusion of the full NCBI taxonomic classification of each sequence in the FASTA header by the Midori pipeline. The headers of the retained sequences are then reformatted to include just the species name and GenBank accession separated by underscores. If desired, additional sequences from local FASTA files are now added to the Midori set (input (iii)). The headers of these FASTA files are required to be in the same format. Next, optional queries are made to the NCBI GenBank and RefSeq databases for each species in a provided list (input (iv)) for each of the four target loci, using NCBI's Entrez Direct [35]. Matching sequences are downloaded in FASTA format, sequences prefixed as "UNVERIFIED" are discarded, the headers are simplified as previously, and those sequences not already in the Midori set are added. Trimming each sequence down to the relevant target marker was carried out in a two-step process in which *usearch* (*-search_pcr*) was used to select sequences where both primers were present, and these were in turn used as a reference dataset for *blastn* to select partially matching sequences from the rest of the dataset [36; 37]. Sequences with a hit length of at least 90% of the expected marker length were retained by extracting the relevant subsequence based on the BLAST hit co-ordinates. Sequences with ambiguous bases were discarded at this stage. In the final step in module 1, a multiple-sequence alignment was generated with MAFFT [38; 39] for each partially curated amplicon dataset (for the SATIVA step below). The script then breaks to

allow the user to check for any obviously problematic sequences that should be discarded before continuing.

Module 2 - The species labels of the edited alignments are compared with the reference taxonomy (input (ii)). Any species not found is queried against the Catalogue of Life database (CoL) via *taxize* in case these are known synonyms, and the correct species label and classification is added to the reference taxonomy. The original species label is retained as a key to facilitate sequence renaming, and a note is added to indicate its status as a synonym. Finally, the genus name of any species not found in the CoL is searched against the consensus taxonomy, and if found, the novel species is added by taking the higher classification levels from one of the other species in the genus. Orphan species labels are printed to a text file, and the script breaks to allow the user to check this list and manually create classifications for some or all if appropriate.

Module 3 - This module begins by checking for any manually generated classification files (from the end of Module 2) and merging them with the reference taxonomy from Module 2. Any remaining sequences with unverifiable classifications are removed at this step. The next steps convert the sequences and taxonomy file to the correct formats for SATIVA [29], which detects possibly mislabelled sequences by generating a maximum likelihood phylogeny from the alignment in Module 1 and comparing each sequence's taxonomy against its phylogenetic neighbors. Sequence headers in the edited MAFFT alignments are reformatted to include only the GenBank accession, and a taxonomy key file is generated with the correct classification listed for each accession number. In cases where the original species label is found to be a synonym, the corrected label is used. Putatively mislabelled sequences in each amplicon are then detected with SATIVA, and the script breaks to allow inspection of the results. The user may choose to make appropriate edits to the taxonomy key file or list of putative mislabels at this point.

Module 4 - Any sequences that are still flagged as mislabelled at the start of the fourth module are deleted from the SATIVA input alignments, and all remaining sequences are relabelled with the correct species name and accession. A final consensus taxonomy file is generated in the format required by *PROTAX*. Alignments are subsequently unaligned prior to species-by-species selection of a single representative per unique haplotype. Sequences that are the only representative of a species are automatically added to the final database. Otherwise, all sequences for each species are extracted in turn, aligned with MAFFT, and collapsed to unique haplotypes with *collapsetypes_4.6.pl* (zero differences allowed; [40]). Representative sequences are then unaligned and added to the final database.

iDNA samples

We used 242 collections of haematophagous terrestrial leeches from Deramakot Forest Reserve in Sabah, Malaysian Borneo stored in RNA fixating saturated ammonium sulfate solution as samples. Each sample consisted of one to 77 leech specimens (median 4). In total, 1532 leeches were collected, exported under the permit (JKM/MBS.1000-2/3 JLD.2 (8)

259 issued by the Sabah Biodiversity Council), and analysed at the laboratories of the Leibniz-
260 IZW.

261 Laboratory workflow

262 The laboratory workflow is designed to both minimize the risk of sample cross-
263 contamination and to aid identification of any instances that do occur. All laboratory steps
264 (extraction, pre and post PCR steps, sequencing) took place in separate laboratories and no
265 samples or materials were allowed to re-enter upstream laboratories at any point in the
266 workflow. All sample handling was carried out under specific hoods that were wiped with
267 bleach, sterilized, and UV irradiated for 30 minutes after each use. All labs are further UV
268 irradiated for four hours each night.

269 *DNA extraction*

270 DNA was extracted from each sample in bulk. Leeches were cut into small pieces with a
271 fresh scalpel blade and incubated in lysate buffer (proteinase K and ATL buffer at a ratio of
272 1:10; 0.2 ml per leech) overnight at 55 °C (12 hours minimum) in an appropriately sized
273 vessel for the number of leeches (2 or 5 ml reaction tube). For samples with more than 35
274 leeches, the reaction volume was split in two and recombined after lysis.

275 Each lysate was split into two *extraction replicates* (A and B; maximum volume 600 µl) and
276 all further steps were applied to these independently. We followed the DNeasy 96 Blood &
277 Tissue protocol for animal tissues (Qiagen, Hilden -Germany) on 96 plates for cleanup. DNA
278 was eluted twice with 100 µl TE buffer. DNA concentration was measured with PicoGreen
279 dsDNA Assay Kit (Quant-iT, ThermoFisherScientific, Waltham -USA) in 384-well plate format
280 using an appropriate plate reader (200 PRO NanoQuant, Tecan Trading AG, Männedorf -
281 Switzerland). Finally, all samples were diluted to a maximum concentration of 10 ng/µl.

282 *Two-round PCR protocol*

283 We amplified three mitochondrial markers – a short 93 bp fragment of *16S* rRNA (*16S*), a
284 389 bp fragment of *12S* rRNA (*12S*), and a 302 bp fragment of cytochrome b (*CytB*). For each
285 marker, we ran a two-round PCR protocol (Figs. 1, 2). The primers were chosen on the
286 expectation of successful DNA amplification over a large number of tetrapod species [41;
287 42], and we tested the fit of candidate primers on an alignment of available mitochondrial
288 sequences of 134 Southeast-Asian mammal species. Primer sequences are in Table 1.

289 *Primer modification*. – We modified primers of the three markers to avoid the production of
290 unlabelled PCR products, to allow the detection and deletion of tag-jumping events [43],
291 and to reduce the cost of primers and library preparation. We used two rounds of PCR. The
292 first round amplified the target gene and attached one of 25 different 'twin-tag' pairs (*tag*
293 *1*), identifying the sample within a given PCR. By 'twin-tag,' we mean that both the forward
294 and reverse primers were given the *same* sample-identifying sequence ('tags') added as
295 primer extensions (Fig. 2). The tags differed with a minimum pairwise distance of three
296 nucleotides ([43]; Supplemental Table 1). These primers also contained different forward

297 and reverse sequences (*Read 1* & *Read 2 sequence primers*) (Supplemental Table 1) to act
298 priming sites for the second PCR round (Fig. 2).

299 The second round added the Illumina adapters for sequencing and attached one of 20 twin-
300 tag pairs (*tag 2*) identifying the PCR, with a minimum pairwise distance of three [44]. These
301 primers also contained the Illumina P5 and P7 adapter sequences (Fig. 2). Thus no
302 unlabelled PCR products were ever produced, and the combination of *tags 1* and *2* allowed
303 the pooling of up to 480 (=24 X 20) samples in a single library preparation step (one *tag 1*
304 was reserved for controls). Twin tags allowed us later to detect and delete tag jumping
305 events [43] (Fig. 2).

306 *Cycle number considerations*. – Because we know that our target DNA is at low
307 concentration in the samples, we are faced with a trade-off between (1) using fewer PCR
308 cycles (e.g. 30) to minimise amplification bias (caused by some target DNA binding better to
309 the primer sequences and thus outcompeting other target sequences that bind less well
310 [45]) and (2) using more PCR cycles (e.g. 40) to ensure that low-concentration target DNA is
311 sufficiently amplified in the first place. Rather than choose between these two extremes, we
312 ran both low- and high-cycle protocols and sequenced both sets of amplicons.

313 Thus, each of the two *extraction replicates* A and B was split and amplified using different
314 cycle numbers (*PCR replicates* 1 and 2) for a total of four (= 2 *extraction replicates* x 2 *PCR*
315 *replicates* -> *A1/A2* and *B1/B2*) replicates per sample per marker (Fig. 1). For *PCR replicates*
316 A1/B1, we used 30 cycles in the first PCR round to minimize the effect of amplification bias.
317 For *PCR replicates* A2/B2, we used 40 cycles in the first PCR round to increase the likelihood
318 of detecting species with very low input DNA (Fig. 1).

319 *PCR protocol*. – The first-round PCR reaction volume was 20 µl, including 0.1 µM primer mix,
320 0.2 mM dNTPs, 1.5 mM $MgCl_2$, 1x PCR buffer, 0.5 U AmpliTaq Gold™ (Invitrogen, Karlsruhe -
321 Germany), and 2 µl of template DNA. Initial denaturation was 5 minutes at 95°C, followed
322 by repeated cycles of 30 seconds at 95°C, 30 seconds at 54°C, and 45 seconds at 72°C. Final
323 elongation was 5 minutes at 72°C. Samples were amplified in batches of 24 plus a negative
324 (water) and a positive control (bank vole, *Myodes glareolus* DNA). All three markers were
325 amplified simultaneously for each batch of samples in a single PCR plate. Non-target by-
326 products were removed as required from some *12S* PCRs by purification with magnetic
327 Agencourt AMPure beads (Beckman Coulter, Krefeld -Germany).

328 In the second-round PCR, we used the same PCR protocol as above with 2 µl of the product
329 of the first-round PCR and 10 PCR cycles.

330 *Quality control and sequencing*

331 Amplification was visually verified after the second-round PCR by gel electrophoresis on
332 1.5% agarose gels. Controls were additionally checked with a TapeStation 2200 (D1000
333 ScreenTape assay, Agilent, Waldbronn -Germany). All samples were purified with AMPure
334 beads, using a bead-to-template ratio of 0.7:1 for *12S* and *CytB* products, and a ratio of 1:1
335 for *16S* products. DNA concentration was measured with PicoGreen dsDNA as described

above. Sequencing libraries were made by equimolar pooling of all positive amplifications; final concentrations were between 2 and 4 nmol. Because of different amplicon lengths and therefore different binding affinities to the flow cell, *12S* and *CytB* products were combined in a single library, whereas positive *16S* products were always combined in a separate library. Apart from our negative controls, we did not include samples that did not amplify, as this would have resulted in highly diluted libraries. Up to 11 libraries were sequenced on each run of Illumina MiSeq, following standard protocols. Libraries were sequenced with MiSeq Reagent Kit V3 (600 cycles, 300 bp paired-end reads) and had a final concentration of 11 pM spiked with 20 to 30% of PhiX control.

Bioinformatics workflow

Read processing

Although the curation of the reference databases is our main focus, it is just one part of the bioinformatics workflow for e/iDNA metabarcoding. A custom bash script was used to process raw basecall files into demultiplexed, cleaned, and dereplicated reads in FASTQ format on a run-by-run basis. All runs and amplicons were processed with the same settings unless otherwise indicated. *bcl2fastq* (Illumina) was used to convert the basecall file from each library to paired-end FASTQ files, demultiplexed into the separate PCRs via the *tag 2* pairs, allowing up to 1 mismatch in each *tag 2*. Each FASTQ file was further demultiplexed into samples via the *tag 1* pairs using *AdapterRemoval* [46], again allowing up to 1 mismatch in each tag. These steps allowed reads to be assigned to the correct samples.

In all cases, amplicons were short enough to expect paired reads to overlap. For libraries with more than 1000 reads pairs were merged with *usearch* (*-fastq_mergepairs*; [47; 48]), and only successfully merged pairs were retained. For libraries with more than 500 merged pairs the primer sequences were trimmed away with *cutadapt* [49], and only successfully trimmed reads at least 90% of expected amplicon length were passed to a quality filtering step with *usearch* (*-fastq_filter*). Lastly, reads were dereplicated with *usearch* (*-derep_fulllength*), and singletons were discarded. The number of replicates that each unique sequence represented was also added to the read header at this step (option *-sizeout*). The number of reads processed at each step for each sample are reported in a standard tab delimited txt-file.

Taxonomic assignment

The curated reference sequences and associated taxonomy were used for *PROTAX* taxonomic assignment of the dereplicated reads [24; 31]. *PROTAX* gives unbiased estimates of placement probability for each read at each taxonomic rank, allowing assignments to be made to a higher rank even when there is uncertainty at the species level. In other words, and unlike other taxonomic assignment methods, *PROTAX* can estimate the probability that a sequence belongs to a taxon that is not present in the reference database. This was considered an important feature due to the known incompleteness of the reference databases for tetrapods in the sampled location. As other studies have compared *PROTAX*

375 with more established methods, e.g. MEGAN [30] (see [4; 24]), it was beyond the scope of
376 this study to evaluate the performance of *PROTAX*.

377 Classification with *PROTAX* is a two-step process. Firstly, PROTAX selected a subset of the
378 reference database that was used as training data to parameterise a *PROTAX* model for
379 each marker, and secondly, the fitted models were used to assign four taxonomic ranks
380 (species, genus, family, order) to each of the dereplicated reads, along with a probability
381 estimate at each level. We also included the best similarity score of the assigned species or
382 genus, mined from the LAST results (see below) for each read. This was helpful for flagging
383 problematic assignments for downstream manual inspection, i.e. high probability
384 assignments based on low similarity scores (implying that there are no better matches
385 available) and low probability assignments based on high similarity scores (indicates
386 conflicting database signal from several species with highly similar sequences).

387 Fitting the *PROTAX* model followed Somervuo et al. [31] except that 5000 training
388 sequences were randomly selected for each target marker due to the large size of the
389 reference database. In each case, 4500 training sequences represented a mix of known
390 species with reference sequences (conspecific sequences retained in the database) and
391 known species without reference sequences (conspecific sequences omitted, simulating
392 species missing from the database), and 500 sequences represented previously unknown
393 lineages distributed evenly across the four taxonomic levels (i.e. mimicked a mix of
394 completely novel species, genera, families and orders). Pairwise sequence similarities of
395 queries and references were calculated with LAST [50] following the approach of Somervuo
396 et al. [31]. The models were weighted towards the Bornean mammals expected in the
397 sampled area by assigning a prior probability of 90% to these 103 species and a 10%
398 probability to all others ([31]; Supplemental Table 2). In cases of missing interspecific
399 variation, this helped to avoid assignments to geographically impossible taxa, especially in
400 case of the very short 93 bp fragment of *16S*. Maximum *a posteriori* (MAP) parameter
401 estimates were obtained following the approach of Somervuo et al. [24], but the models
402 were parameterised for each of the four taxonomic levels independently, with a total of five
403 parameters at each level (four regression coefficients and the probability of mislabelling).

404 Dereplicated reads for each sample were then classified using a custom bash script on a run-
405 by-run basis. For each sample, reads in FASTQ format were converted to FASTA, and
406 pairwise similarities were calculated against the full reference sequence database for the
407 applicable marker with LAST. Assignments of each read to a taxonomic node based on these
408 sequence similarities were made using a Perl script and the trained model for that level. The
409 taxonomy of each node assignment was added with a second Perl script for a final table
410 including the node assignment, probability, taxonomic level, and taxonomic path for each
411 read. Read count information was included directly in the classification output via the size
412 annotation added to the read headers during dereplication. All Perl scripts to convert input
413 files into the formats expected by *PROTAX*, *R* code for training the model following

Somervuo et al. [31], and Perl scripts for taxonomic assignment were provided by P. Somervuo (personal communication).

Acceptance criteria

In total we had twelve PCR reactions per sample: two *extraction replicates A* and *B* X two *PCR replicates* 1 and 2 per extraction replication X the three markers (Fig. 1). We applied two different acceptance criteria to the data with different stringency regimes. One more naive one that accepted any two positives out of the twelve *PCR replicates* (from now on referred to as lax), and one stringent one that only accepted taxonomic assignments that were positively detected in both *extraction replicates* (*A* & *B*, Fig. 3). Our lax approach refers to one of the approaches of Ficetola et al. [19] where they evaluated different statistical approaches developed to estimate occupancy in the presence of observational errors and has been applied in other studies (e.g. [13]). The reason for conservatively omitting assignments that appeared in only one *extraction replicate* was to rule out sample cross-contamination during DNA extraction. In addition, we only accepted assignments with ten or more reads per marker, if only one marker was sequenced. If a species was assigned in more than one marker (e.g. *12S* and *16S*), we accepted the assignment even if in one sequencing run the number of reads was below ten.

Due to the imperfect PCR amplification of markers (the small *16S* fragment amplified better than the longer *CytB* fragment) and missing reference sequences in the database or shared sequence motifs between species, reads sometimes were assigned to species level for one marker but only to genus level for another marker. Thus, the final identification of species could not be automated, and manual inspection and curation was needed. For each assignment, three parameters were taken into consideration: number of sequencing reads, the mean probability estimate derived from *PROTAX*, and the mean sequence similarity to the reference sequences based on LAST.

Shot-gun sequencing to quantify mammalian DNA content

As the success of the metabarcoding largely depends on the mammal DNA quantity in our leech bulk samples we quantified the mammalian DNA content in a subset of 58 of our leech samples using shotgun sequencing. Extracted DNA was sheared with a Covaris M220 focused-ultra-sonicator to a peak target size of 100-200 bp, and re-checked for size distribution. Double-stranded Illumina sequencing libraries were prepared according to a ligation protocol designed by Fortes and Paijmans [51] with single 8 nt indices. All libraries were pooled equimolarly and sequenced on the MiSeq using the v3 150-cycle kit. We demultiplexed reads using bcl2fastq and cutadapt for trimming the adapters. We used BLAST search to identify reads and applied Metagenome Analyzer MEGAN [30] to explore the taxonomic content of the data based on the NCBI taxonomy. Finally we used KRONA [52] for visualisation of the results.

452 ## Findings & Discussion

453 *Database curation*

454 The Midori UNIQUE database (December 2015 version) contains 1,019,391 sequences
455 across the four mitochondrial loci of interest (*12S*: 66,937; *16S*: 146,164; *CytB*: 223,247; *COI*:
456 583,043), covering all Metazoa. Of these, 258,225 (25.3%) derive from the four tetrapod
457 classes (Amphibia: 55,254; Aves: 51,096; Mammalia: 101,106; Reptilia: 50,769). The
458 distribution of these sequences between classes and loci, and the losses at each curation
459 step are shown in Figure 4. In three of the four classes, there is a clear bias towards *CytB*
460 sequences, with over 50% of sequences derived from this locus. In both Aves and
461 Mammalia, the *16S* and *12S* loci are severely underrepresented at less than 10% each, while
462 for Reptilia, *COI* is the least sequenced locus in the database.

463 The numbers of sequences and rates of loss due to our curation steps varied among
464 taxonomic classes and the four loci, although losses were observed between steps in almost
465 all instances. The most significant losses followed amplicon trimming and removal of non-
466 unique sequences. Amplicon trimming led to especially high losses in Amphibia and *16S*,
467 indicating that data published on GenBank for this class and marker do not generally overlap
468 with our amplicons. Meanwhile, the high level of redundancy in public databases was
469 highlighted by the significant reduction in the number of sequences during the final step of
470 removing redundant sequences – in all cases over 10% of sequences was discarded, with
471 some losses exceeding 50% (Mammalia: *COI*, *CytB*, *16S*; Amphibia: *16S*).

472 Data loss due to apparent mislabelling ranged between 1.9% and 7.4% and was thus
473 generally higher than similar estimates for curated microbial databases [29]. SATIVA flags
474 potential mislabels and suggests an alternative label supported by the phylogenetic
475 placement of the sequences, allowing the user to make an appropriate decision on a case by
476 case basis. The pipeline pauses after this step to allow such manual inspection to take place.
477 However, for the current database, the number of sequences flagged was large (4378 in
478 total), and the required taxonomic expertise was lacking, so all flagged sequences from non-
479 target species were discarded to be conservative. The majority of mislabels were identified
480 at species level (3053), but there were also significant numbers at genus (788), family (364)
481 and order (102) level. Two to three sequences from Bornean mammal species were
482 unflagged in each amplicon to retain the sequences in the database. This was important as
483 in each case these were the only reference sequences available for the species. Additionally,
484 *Muntiacus vaginalis* sequences that were automatically synonymised to *M. muntjak* based
485 on the available information in the Catalogue of Life were revised back to their original
486 identifications to reflect current taxonomic knowledge.

487 *Database composition*

488 The final database was skewed even more strongly towards *CytB* than was the raw
489 database. It was the most abundant locus for each class and represented over 60% of

490 sequences for both Mammalia and Reptilia. In all classes, *16S* made up less than 10% of the
491 final database, with Reptilia *COI* also at less than 10%.

492 Figure 5 shows that most species represented in the curated database for any locus have
493 just one unique haplotype against which HTS reads can be compared; only a few species
494 have many haplotypes. The prevalence of species with 20 or more haplotypes is particularly
495 notable in *CytB* where the four classes have between 25 (Aves) and 265 (Mammalia) species
496 in this category. The coloured circles in Figure 5 also show that the species of the taxonomy
497 are incompletely represented across all loci, and that coverage varies significantly between
498 taxonomic groups. In spite of global initiatives to generate *COI* sequences [53], this marker
499 does not offer the best species-level coverage in any class and is a poor choice for Amphibia
500 and Reptilia (<15% of species included). Even the best performing marker, *CytB*, is not a
501 universally appropriate choice, as Amphibia is better covered by *12S*. These differences in
502 underlying database composition will impact the likelihood of obtaining accurate taxonomic
503 assignment for any one species from any single marker. Further barcoding campaigns are
504 clearly needed to fill gaps in the reference databases for all markers and all classes to
505 increase the power of future e/iDNA studies. As the costs of HTS decrease, we expect that
506 such gap-filling will increasingly shift towards sequencing of whole mitochondrial genomes
507 of specimen obtained from museum collections, trapping campaigns etc. [34], reducing the
508 effect of marker choice on detection likelihood. In the meantime, however, the total
509 number of species covered by the database can be increased by combining multiple loci
510 (here, up to four) and thus the impacts of database gaps on correctly detecting species can
511 be minimized ([54]; Fig. 6).

512 In the present study, the primary target for iDNA sampling was the mammal fauna of
513 Malaysian Borneo, and the 103 species expected in the sampling area represent an
514 informative case study highlighting the deficiencies in existing databases (Fig. 7). Nine
515 species are completely unrepresented while only slightly over half (55 species) have at least
516 one sequence for all of the loci. Individually, each marker covers over half of the target
517 species, but none achieves more than 85% coverage (*12S*: 75 species; *16S*: 68; *CytB*: 88; *COI*:
518 66). Equally striking is the lack of within-species diversity, as most of the incorporated
519 species are represented by only a single haplotype per locus. Some of the species have large
520 distribution ranges, so it is likely that in some cases the populations on Borneo differ
521 genetically from the available reference sequences, possibly limiting assignment success.
522 Only a few expected species have been sequenced extensively, and most are of economic
523 importance to humans (e.g. *Bos taurus*, *Bubalus bubalis*, *Macaca* spp, *Paradoxurus*
524 *hermaphroditus*, *Rattus* spp., *Sus scrofa*), with as many as 100 haplotypes available (*Canis*
525 *lupus*). Other well-represented species (≥20 haplotypes) present in the sampling area
526 include several Muridae (*Chiropodomys gliroides*, *Leopoldamys sabanus*, *Maxomys surifer*,
527 *Maxomys whiteheadi*) and the leopard cat (*Prionailurus bengalensis*).

528 *Laboratory workflow*

529 Shotgun sequencing of a subset of our samples revealed that the median mammalian DNA
530 content was only 0.9%, ranging from 0% to 98%. These estimates are approximate, but with
531 more than 75% of the samples being below 5%, this shows clearly the scarcity of target DNA
532 in bulk iDNA samples. The generally low DNA content and the fact that the target DNA is
533 often degraded make enrichment of the target barcoding loci necessary. We used PCR with
534 high cycle numbers to obtain enough DNA for sequencing. However, this second step
535 increases the risk of PCR error: artificial sequence variation, non-target amplification, and/or
536 raising contaminations up to a detectable level.

537 We addressed these problems by running two *extraction replicates*, two *PCR replicates*, and
538 a multi-marker approach. The need for *PCR replicates* has been acknowledged and
539 addressed extensively in ancient DNA studies [16] and has also been highlighted for
540 metabarcoding studies [19; 20; 55; 56]. Despite this, many e/iDNA studies do not carry out
541 multiple *PCR replicates* to detect and omit potential false sequences. In addition, *extraction*
542 *replicates* are seldom applied, despite the evidence that cross-sample DNA contamination
543 can occur during DNA extraction [57; 58; 59]. We only accepted sequences that appeared in
544 a minimum of two independent PCRs for the lax and for the stringent criterion, where it has
545 to occur in each *extraction replicate A* and *B* (Fig. 1). The latter acceptance criterion is quite
546 conservative and produces higher false negative rates than e.g. accepting occurrence of at
547 least two positives. However, it also reduces the risk of accepting a false positives compared
548 to it (see Supplemental Fig. 1. for a simulation of false positive and false negatives rates
549 within a PCR), especially with increasing risk of false positive occurrence in a PCR for e.g.
550 example due to higher risk of contamination etc.. Metabarcoding studies are very prone to
551 false negatives, and downstream analyses like occupancy models for species distributions
552 can account for imperfect detection and false negatives. However, methods for discounting
553 false positive detections are not well developed [60]. Thus we think it is more important to
554 avoid false positives, especially if the results will be used to make management decisions
555 regarding rare or endangered species. In contrast, it might be acceptable to use a relaxed
556 acceptance criterion for more common species, as long as the rate false-positives/true-
557 positives is small and does not affect species distribution estimates. Employing both of our
558 tested criteria researchers could flag unreliable assignments and management decisions can
559 still use this information, but now in a forewarned way. An alternative to our acceptance
560 criteria could be use the PCR replicates itself to model the detection probability within a
561 sample using an occupancy framework [20; 60; 61].

562 We used three different loci to correct for potential PCR-amplification biases. We were,
563 however, unable to quantify this bias in this study due to the high degradation of the target
564 mammalian DNA, which resulted in much higher overall amplification rates for *16S*, the
565 shortest of our PCR amplicons. For *16S*, 85% of the samples amplified, whereas for *CytB* and
566 *12S*, only 57% and 44% amplified, respectively. Also the read losses due to trimming and
567 quality filtering were significantly lower for the *16S* sequencing runs (1.3% and 5.3% in

568 average, Supplemental Table 3) compared to the sequencing runs for the longer fragments
569 of *12S* and *CytB* (65.3% and 44.3% in average, Supplemental Table 3). Despite the greater
570 taxonomic resolution of the longer *12S* and *CytB* fragments, our poorer amplification and
571 sequencing results for these longer fragments emphasize that e/iDNA studies should
572 generally focus on short PCR fragments to increase the likelihood of positive amplifications
573 of the degraded target DNA. In the case of mammal-focussed e/iDNA studies, developing a
574 shorter (100 bp) *CytB* fragment would likely be very useful.

575 Another major precaution was the use of twin-tagging for both PCRs (Fig. 2). This ensures
576 that unlabelled PCR products are never produced and allows us to multiplex a large number
577 of samples on a single run of Illumina MiSeq run. Just 24 sample *tags 1* and 20 plate *tags 2*
578 allow the differentiation of up to 480 samples with matching tags on both ends. The same
579 number of individual primers would have needed longer tags to maintain enough distance
580 between them and would have resulted in an even longer adapter-tag overhang compared
581 to primer length. This would have most likely resulted in lower binding efficiencies due to
582 steric hindrances of the primers. Furthermore, this would have resulted in increased primer
583 costs. Thus our approach reduced sequencing and primer purchase costs while at the same
584 time largely eliminating sample mis-assignment via tag jumping, because tag-jump
585 sequences have non-matching forward and reverse *tag 1* sequences [43]. We estimated the
586 rate of tag jumps producing non-matching *tag 1* sequences to be 1 to 5%, and these were
587 removed from the dataset (Table 4). For our sequenced PCR plates, the rate of non-
588 matching *tag 2* tags was 2%. These numbers are smaller than data from Zepeda-Mendoza et
589 al. [56] who reported on sequence losses of 19% to 23% due to unused tag combinations
590 when they tested their DAMe pipeline to different datasets built using standard blunt-end
591 ligation technique. Although their numbers might not be one-to-one comparable to our
592 results as they counted unique sequences, and we report on read numbers, our PCR
593 libraries with matching barcodes seem reduce the risk of tag jumping compared to blunt-
594 end ligation techniques. For the second PCR round, we used the same tag pair *tag 2* for all
595 24 samples of a PCR plate. In order to reduce cost we tested pooling these 24 samples prior
596 to the second PCR round, but we detected a very high tag jumping rate of over 40% (Table
597 4), which ultimately would increase cost through reduced sequencing efficiency. Twin-
598 tagging increases costs because of the need to purchase a larger number of primer pairs but
599 at the same time it increases confidence in the results.

600 Tagging primers in the first PCR reduces the risk of cross-contamination via aerosolised PCR
601 products. However, we would not be able to detect a contamination prior the second PCR
602 from one plate to another, as we used the same 24 tags (*tag 1*) for all plates. Nevertheless
603 such a contamination is very unlikely to result in any accepted false positive as it would be
604 improbable to contaminate both the A and B replicates, given the exchange of all reagents
605 and the time gap between the PCRs. Previous studies have shown that unlabelled volatile
606 PCR products pose a great risk of false detections [62], a risk that is greatly increased if a
607 high number of samples are analysed in the laboratories [13]. Also, in laboratories where

608 other research projects are conducted, this approach allows the detection of cross-
609 experiment contamination. Therefore, we see a clear advantage of our approach over
610 ligation techniques when it comes to producing sequencing libraries, as the Illumina tags are
611 only added after the first PCR, and thus the risk of cross contamination with unlabelled PCR
612 amplicons is very low.

613 *Assignment results*

614 A robust assignment of species is an important factor in metabarcoding as an incorrect
615 identification might result incorrect management interventions. The reliability of taxonomic
616 assignments is expected to vary with respect to both marker information content and
617 database completeness, and this is reflected in the probability estimates provided by
618 *PROTAX*. In a recent study, less than 10% of the mammal assignments made at species level
619 against a worldwide reference database were considered reliable with the short *16S*
620 amplicon, but this increased to 46% with full-length *16S* sequences [31]. In contrast, in the
621 same study over 80% of insect assignments at species level were considered reliable with a
622 more complete, geographically restricted database of full-length COI barcodes. A similar
623 pattern was observed in our data during manual curation of the assignment results – there
624 was more ambiguity in the results for the short *16S* amplicon than for other markers.
625 However, due to the limited amount of often degraded target DNA in e/iDNA samples, short
626 amplicons amplify much better. In our case, this had the drawback that some species lacked
627 any interspecific variation, and thus sequencing reads shared 99%-100% identity for several
628 species. For example, our only *16S* reference of *Sus barbatus* was 100% identical to *S.*
629 *scrofa*. But as latter species does not occur in the studied area we could assign all reads
630 manually to *S. barbatus*. In several cases we were able to confirm *S. barbatus* by additional
631 *CytB* results, highlighting the usefulness of multiple markers.

632 Another advantage of multiple markers is the opportunity to fill gaps in the reference
633 database. For example, we lacked *16S* reference sequences for *Hystrix brachyura*, and reads
634 were assigned by *PROTAX* only to the unknown species *Hystrix* sp.. In one sample, however,
635 almost 5000 *CytB* reads could be confidently assigned to *Hystrix brachyura*, and thus we
636 used the *Hystrix* sp. 16S sequences in the same sample to build a consensus *16S* reference
637 sequence for *Hystrix brachyura* for future analyses. In another example we had *CytB* reads
638 assigned to *Mydaus javanicus*, the Sunda stink-badger in one sample but *12S* reads assigned
639 to *Mydaus* sp. in another one. As we lacked a *12S Mydaus* reference and as there is only one
640 *Mydaus* species on Borneo we could assume that this second sample is most likely also
641 *Mydaus javanicus*.

642 We also inferred that PCR and sequencing errors resulted in reads being assigned to sister
643 taxa. We observed that a high number of reads of a true sequence were assigned to a
644 species and a lower number of noise sequences were assigned to a sister taxon. Such a
645 pattern was observed for ungulates, especially deer that showed little variance in *16S*. It is
646 hard to identify and control for such pattern automatically, and it highlights the importance
647 of visual inspection of the results.

648 For the more lax criterion (two positive *PCR replicates*) we accepted 196 species
649 assignments out of 109 leech samples. Under the stringent criterion (i.e. having positive
650 detections in both *extraction replicates A* and *B*) we accepted about 14% assignments less;
651 in total 170 vertebrate detections within 97 bulk samples (Table 5). For 65% of the species
652 frequencies did not change and almost half of the not accepted assignments were from the
653 most frequent species *Rusa unicolor* and *Sus barbatus*. However, with the more stringent
654 criterion we did not accept two species (1x *Macaca fascicularis* & 2x *Mydaus javanensis*). In
655 five cases the stringent criterion would not accept assignments that could be made only to
656 unknown species (1x *Hystrix* sp., 3x *Macaca* sp., 1x *Tragulus* sp.) (Table 5). For the all these
657 gernera we have two occurring species in the area. As the true occurrence of species within
658 our leeches was unknown we cannot evaluate how many of the additional 27 detections in
659 the lax criterion are false positives and how many might be false negatives for the stricter
660 criterion. However, by accepting only positive *AB* assignment results, we increase the
661 confidence of species detection, even if the total number of reads for that species was low.
662 When it comes to rare or threated species this outweighs the risk of reporting false positives
663 to our opinion. 48% of the assignments with the stringent criterion were present in all four
664 *A1*, *A2*, *B1* and *B2*. 35% were present in at least three replicates (e.g. A1, A2, B1).

665 The mean number of reads per sample used for the taxomomic assignment varied from
666 162,487 *16S* reads for SeqRun01 to 7,638 *CytB* reads for SeqRun05 (Supplemental Table 4).
667 In almost all cases, however, the number of reads of an accepted assignment was high
668 (median= 52,386; mean= 300,996; SD= 326,883). PCR stochasticity, primer biases, multiple
669 species in individual samples, and pooling of samples exert too many uncertainties that
670 could bias the sequencing results [63; 64]. Thus we do not believe that raw read numbers
671 are the most reliable indicators of tetrapod DNA quantity in iDNA samples. Replication of
672 detection is inherently more reliable. In contrast to our expectation that higher cycle
673 number might be necessary to amplify even the lowest amounts of target DNA, our data do
674 not support this hypothesis. Although we observed an increase in positive PCRs for A2/B2
675 (the 40-cycle PCR replicates), the total number of accepted assignments in *A1/B1* and *A2/B2*
676 samples did not differ. This indicates first that high PCR cycle numbers mainly increased the
677 risk of false positives and second that our multiple precautions successfully minimized the
678 acceptance of false detections.

679 Conclusion

680 Metabarcoding of e/iDNA samples will certainly become a very valuable tool in assessing
681 biodiversity, as it allows to detect species non-invasively without the need to capture and
682 handle the animals [65] and because sampling effort can often be greatly reduced.
683 However, the technical and analytical challenges linked to sample types (low quantity and
684 quality DNA) and poor reference databases have so far been insufficiently recognized. In
685 contrast to ancient DNA studies where standardized laboratory procedures and specialized
686 bioinformatics pipelines have been established and are followed in most cases, there is
687 limited methodological consensus in e/iDNA studies, which reduces rigour. In this study, we

688 present a robust metabarcoding workflow for e/iDNA studies. We hope that the provided
689 scripts and protocols facilitate further technical and analytical developments. The use of
690 e/iDNA metabarcoding to study the rarest and most endangered species such as the Saola is
691 exciting, but geneticists bear the heavy responsibility of providing correct answers to
692 conservationists.

693 Acknowledgements

694 All authors thank the German Federal Ministry of Education and Research (BMBF FKZ:
695 01LN1301A) and the Leibniz-IZW for funding this study. We also thank the Sabah Forestry
696 Department, especially Johnny Kissing, Peter Lagan and Datuk Sam Mannan for supporting
697 the fieldwork and the Sabah Biodiversity Council for providing research, collection and
698 export permits for this work. We are grateful to John Mathai, Seth Timothy Wong for
699 conducting the field work and collecting the leeches. We are also grateful to Jörns Fickel,
700 head of the Department Evolutionary Genetics of the Leibniz-IZW for continuous support
701 and collaboration. Furthermore we would like to thank Sebastian Wieser for lab-support,
702 Dorina Lenz and Anke Schmidt for their help and fruitful discussions. D.W. Yu and C.C.Y. Xu

873 **Table 2:** Main steps undertaken by each module of the database curation script.

MODULE	STEPS
Module 1	Extract subset of raw Midori database for query taxon and loci.
	Remove sequences with non-binomial species names, reduce subspecies to species labels
	Add local sequences (optional)
	Check for relevant new sequences for list of query species on NCBI (GenBank and RefSeq) (optional)
	Select amplicon region and remove primers
	Remove sequences with ambiguous bases
	Align
	End of module: Optional check of alignments
Module 2	Compare sequence species labels with taxonomy
	Non-matching labels queried against Catalogue of Life to check for known synonyms
	Remaining mismatches kept if genus already exists in taxonomy, otherwise flagged for removal
	End of module: Optional check of flagged species labels
Module 3	Discard flagged sequences
	Update taxonomy key file for sequences found to be incorrectly labelled in Module 2
	Run SATIVA
	End of module: Optional check of putatively mislabelled sequences
Module 4	Discard flagged sequences
	Finalise consensus taxonomy and relabel sequences with correct species label and accession number
	Select one representative sequence per haplotype per species

Trichys fasciculata	4	4	0
Viverra tangalunga	12	12	0
total accepted assignments	170	197	+27

884

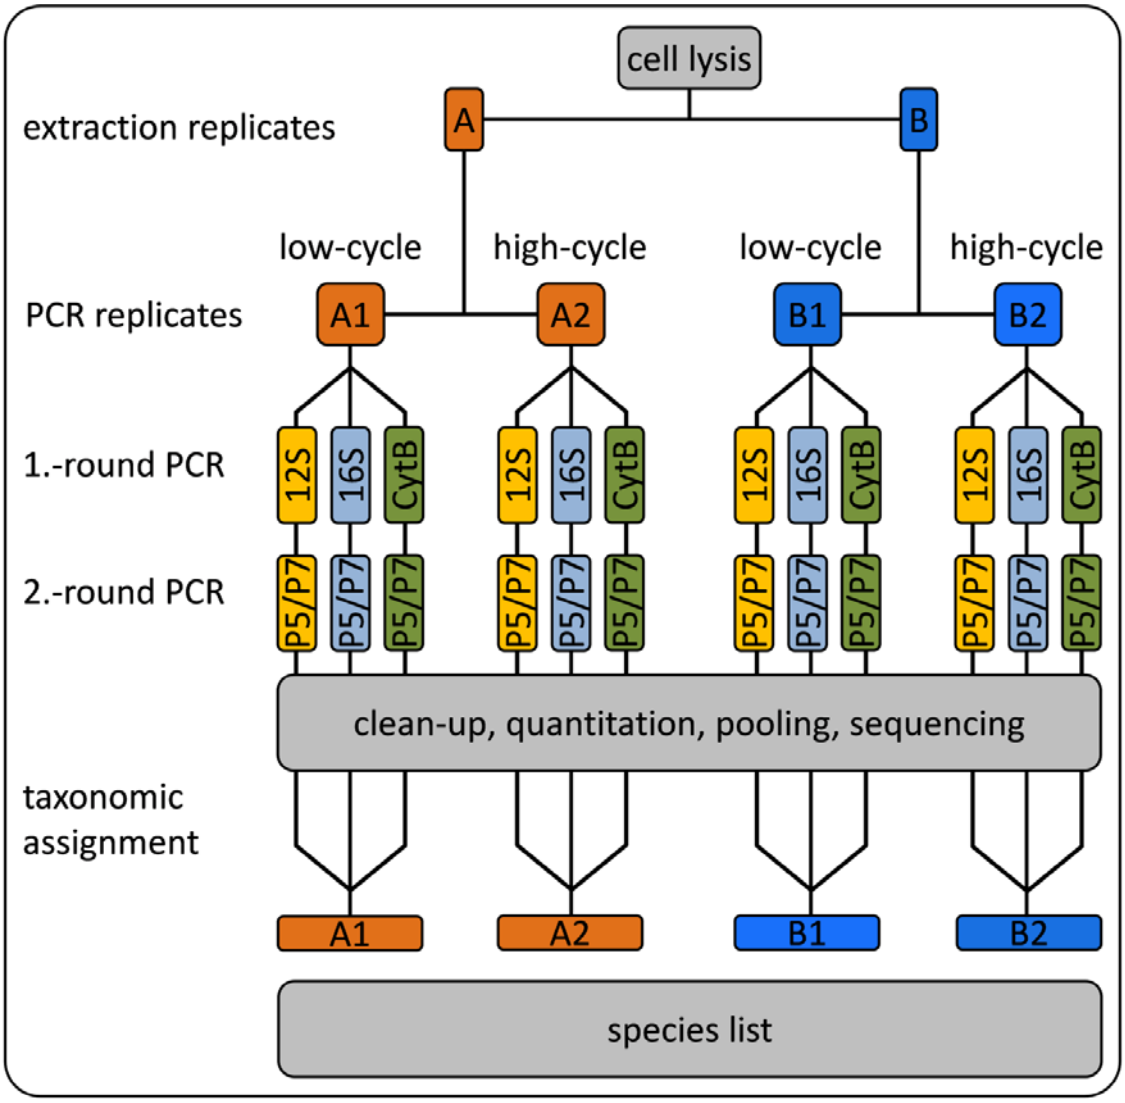

Figure 1: laboratory scheme; during DNA extraction the sample is split into two extraction replicates A & B. Our Protocol consists of two rounds of PCR that were the sample tags, the necessary sequencing primer and sequencing adapters are added to the the amplicons. For each extraction replicate we ran a low cycle PCR and a high cycle PCR for each marker that we have twelve independent PCR replicates per sample. All PCR products were sequenced and the obtained reads were taxonomically identified with PROTAX.

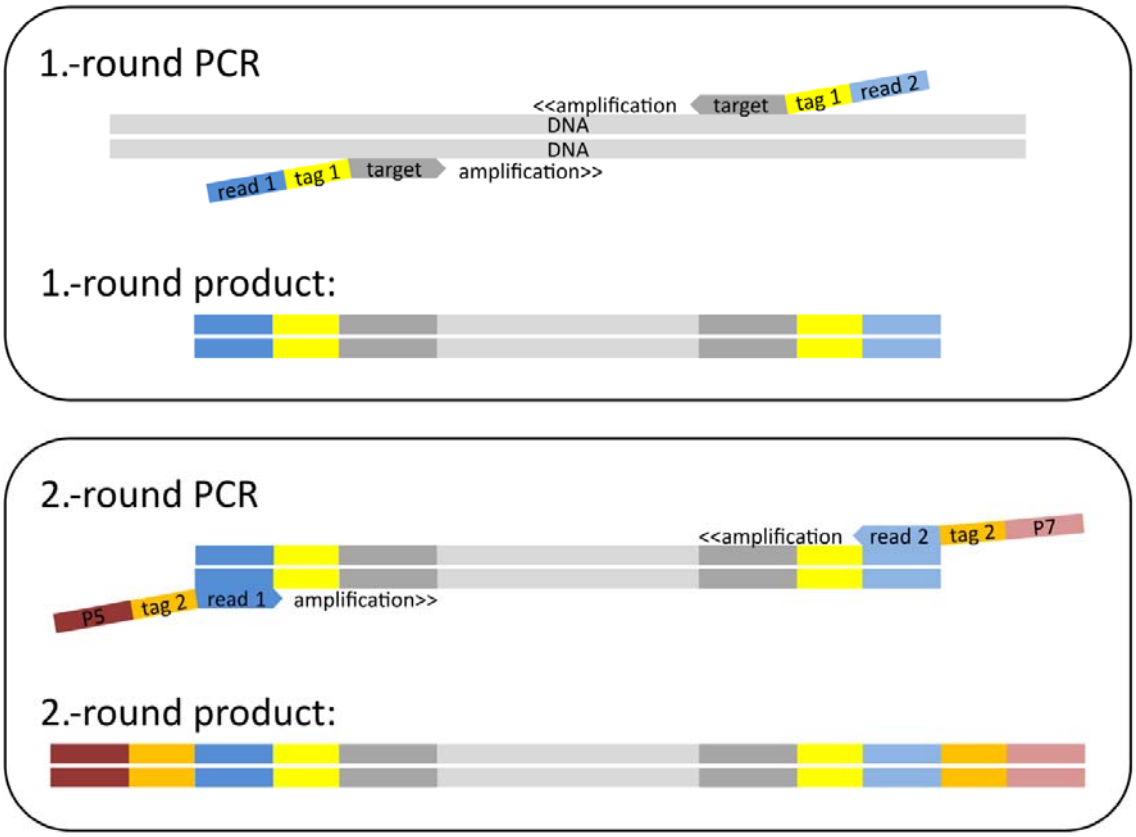

Figure 2: Scheme to build double 'twin-tagged' PCR libraries. The first round of PCR uses target-specific primers (*12S*, *16S*, or *CytB*, dark grey) that have both been extended with the same (i.e. 'twin') sample-identifying *tag* sequences *tag 1* (yellow) and then with the different *read 1* (dark blue) and *read 2* (light blue) sequence primers. The second round of PCR uses the priming sites of the *read 1* and *read 2* sequencing primers to add twin plate-identifying *tag* sequences *tag 2* (orange) and the P5 (dark red) and P7 (light red) Illumina adapters.

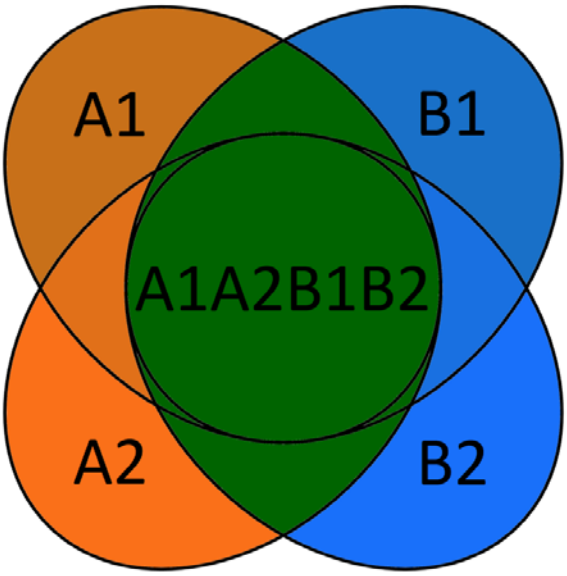

Figure 3: For the stringent acceptance criterion we only accepted taxonomic assignments that were positively detected in both *extraction replicates* A and B (green colour). The numbers (1 & 2) refer to the two PCR replicates for each extraction replicate.

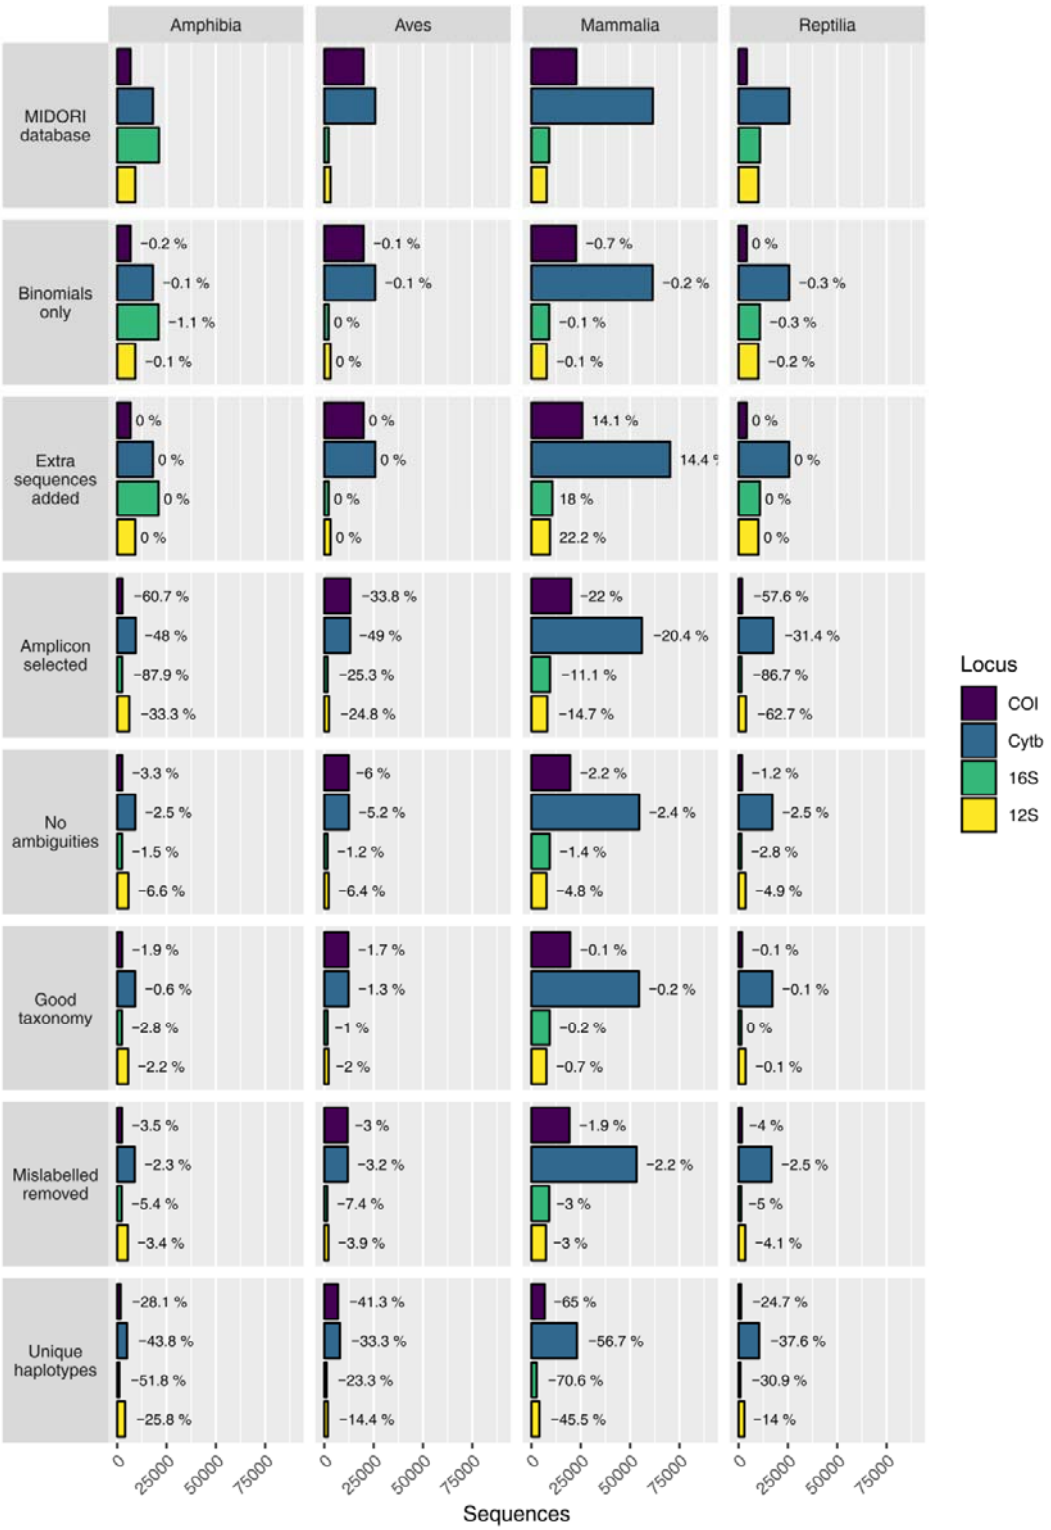

Figure 4: Data availability and percentage loss at each major step in the database curation procedure for each target amplicon and class of Tetrapoda. The number of sequences decreases between steps except "Extra sequences added" where additional target sequences are included for Mammalia and there is no change for the other three classes.

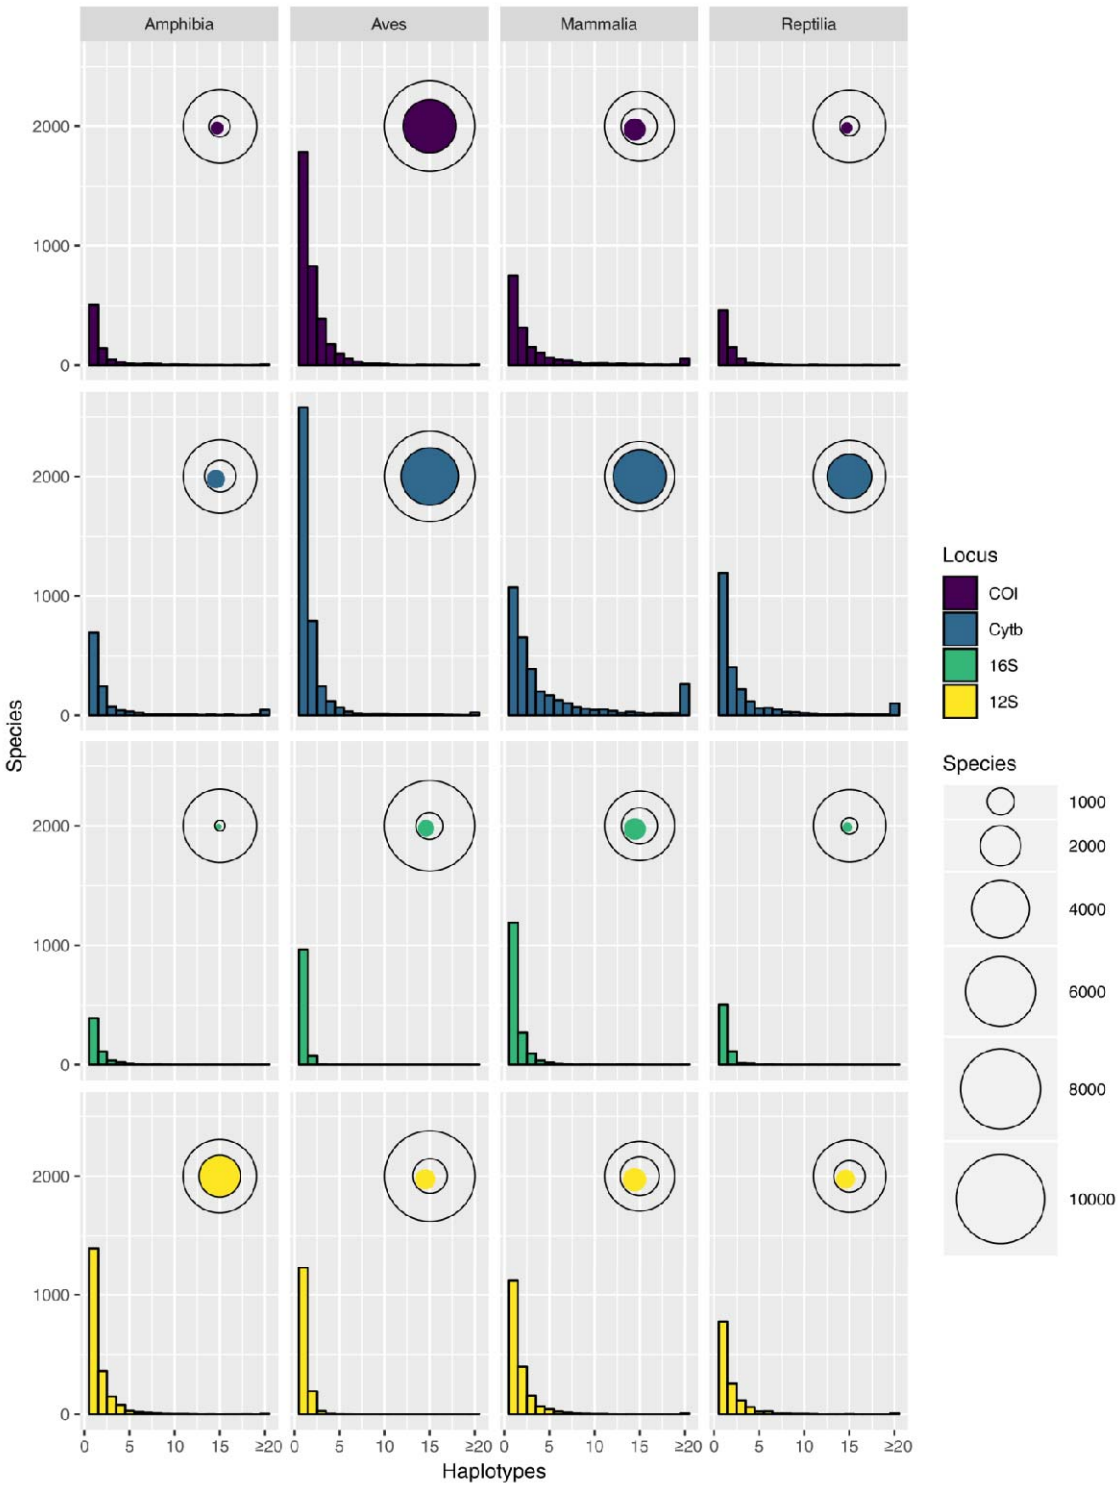

Figure 5: Haplotype number by species (frequency distribution) and the total number of species with at least one haplotype, shown relative to the total number of species in the taxonomy for that category (bubbles), shown for each marker and class of Tetrapoda. The proportion of species covered by the database varies between categories but in all cases a majority of recovered species are represented by a single unique haplotype.

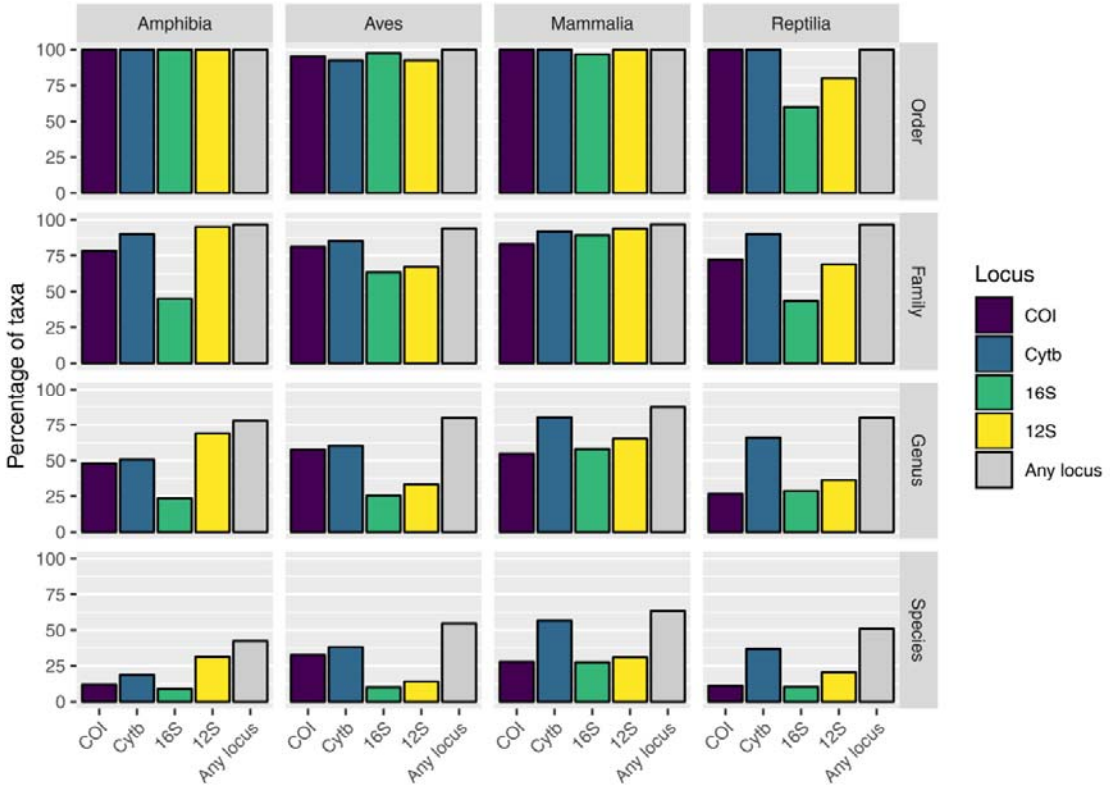

Figure 6: The percentage of the full taxonomy covered by the final database at each taxonomic level for each class of Tetrapoda. Includes the percentage of taxa represented by each marker and all markers combined. In all cases taking all four markers together increases the proportion of species, genera and families covered by the database, but it remains incomplete when compared with the full taxonomy.

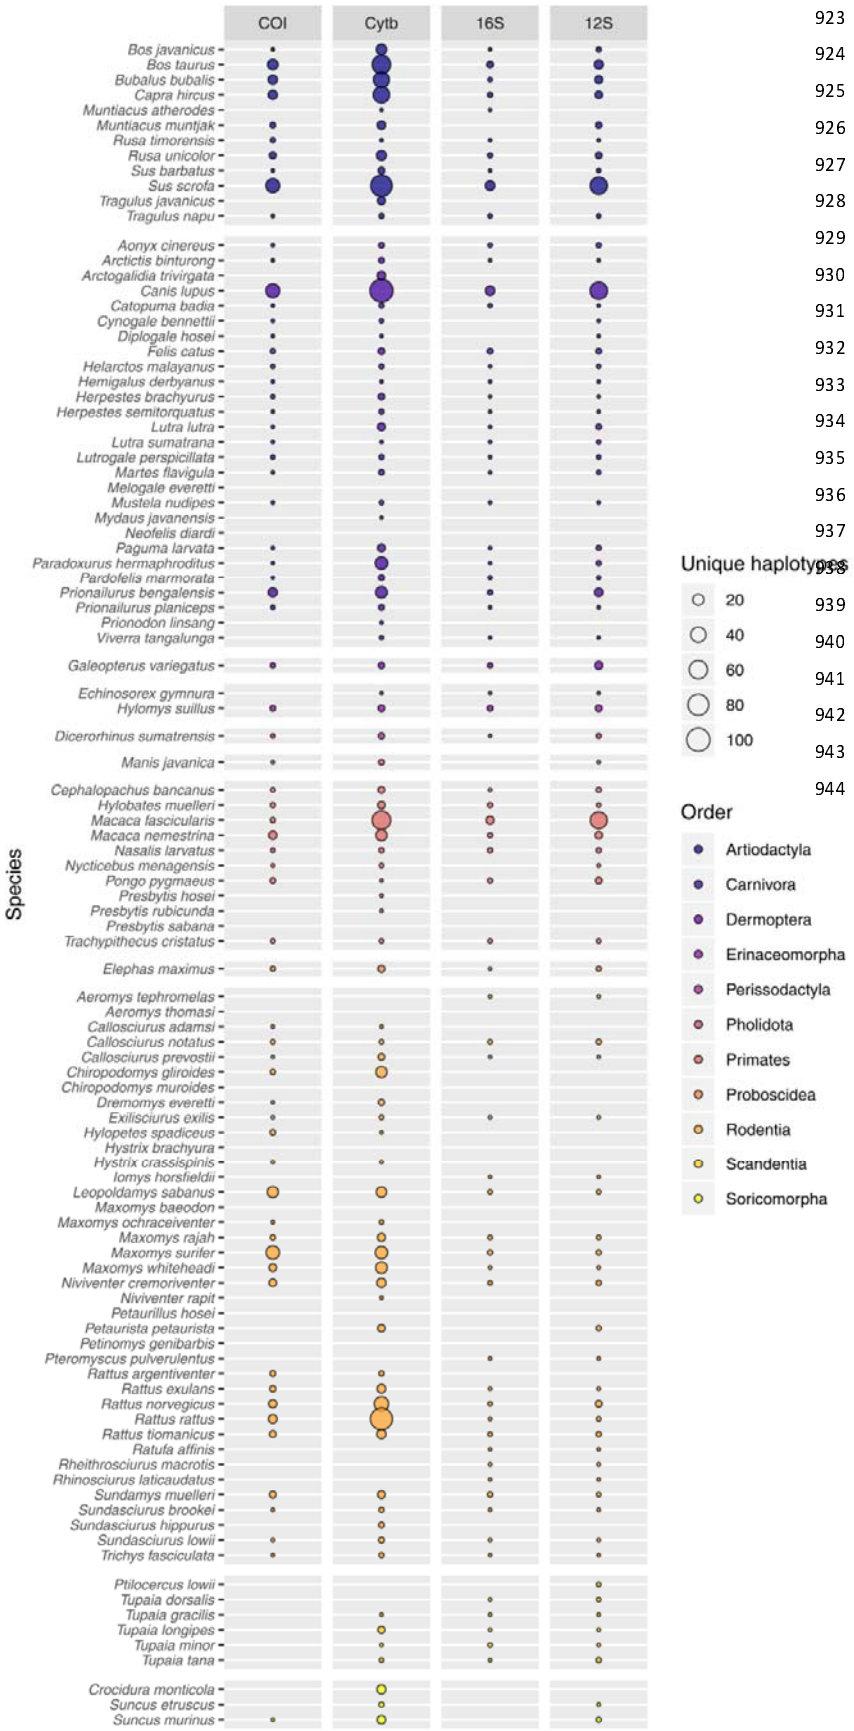

Figure 7: The number of unique haplotypes per marker for each of the 103 mammal species expected in the study area. Bubble size is proportional to the number of haplotypes and varies between 0 and 100. Only 55 species have at least one sequence per marker and nine species are completely unrepresented in the current database.

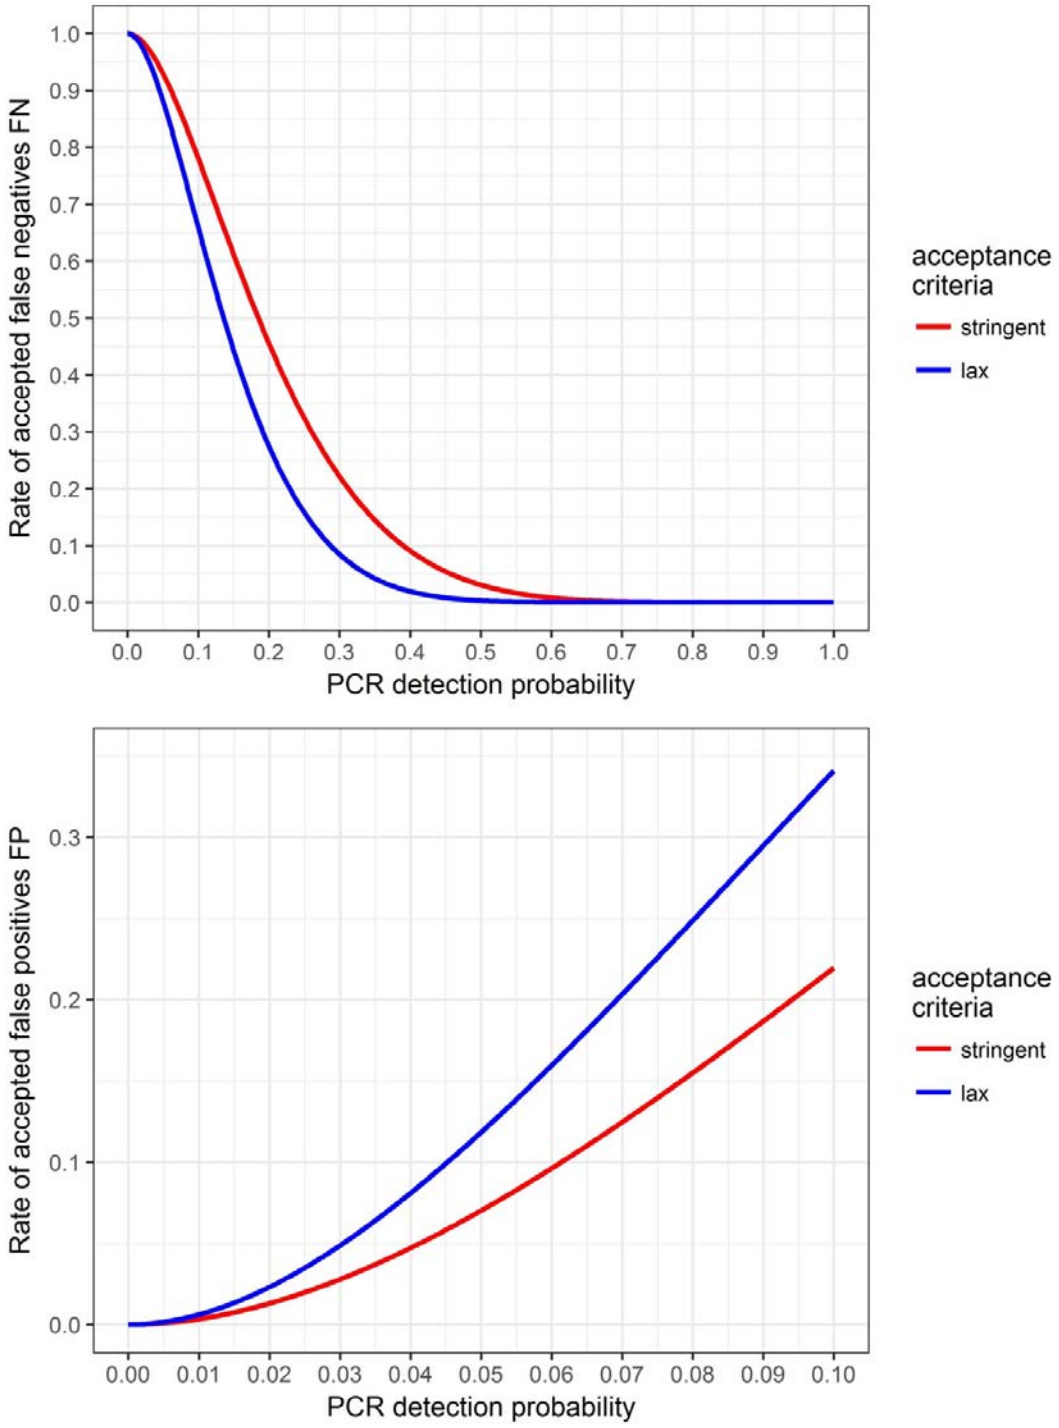

Supplemental Figure 1: The rates of accepted false negatives (upper graph) and false positives (lower graph) for both our used acceptance criteria for varying PCR detection probabilities. The red line always denotes the stringent acceptance criterion that a positive is only accepted if it is present in at least one A and one B replicate. The lax criterion (blue) accepted at any two positives out of the twelve replicates. The stringent criterion poses a higher risk of accepting a false negative but it reduces clearly the risk of false positives, especially with increasing detection probability due to higher risk of contamination.

Supplemental table 1: Complete list of all used primer sequences in 5'-3' direction.

Supplemental table 2: List of Bornean species that were weighted in the PROTAX assignment.

Species	Species	Species
Bos,javanicus	*Arctictis,binturong*	*Chiropodomys,muroides*
Bos,taurus	*Arctogalidia,trivirgata*	*Leopoldamys,sabanus*
Bubalus,bubalis	*Cynogale,bennettii*	*Maxomys,baeodon*
Capra,hircus	*Diplogale,hosei*	*Maxomys,ochraceiventer*
Muntiacus,atherodes	*Hemigalus,derbyanus*	*Maxomys,rajah*
Muntiacus,muntjak	*Paguma,larvata*	*Maxomys,surifer*
Rusa,timorensis	*Paradoxurus,hermaphroditus*	*Maxomys,whiteheadi*
Rusa,unicolor	*Prionodon,linsang*	*Niviventer,cremoriventer*
Sus,barbatus	*Viverra,tangalunga*	*Niviventer,rapit*
Sus,scrofa	*Galeopterus,variegatus*	*Rattus,argentiventer*
Tragulus,javanicus	*Echinosorex,gymnura*	*Rattus,exulans*
Tragulus,napu	*Hylomys,suillus*	*Rattus,norvegicus*
Canis,lupus	*Dicerorhinus,sumatrensis*	*Rattus,rattus*
Catopuma,badia	*Manis,javanica*	*Rattus,tiomanicus*
Felis,catus	*Macaca,fascicularis*	*Sundamys,muelleri*
Neofelis,diardi	*Macaca,nemestrina*	*Aeromys,tephromelas*
Pardofelis,marmorata	*Nasalis,larvatus*	*Aeromys,thomasi*
Prionailurus,bengalensis	*Presbytis,hosei*	*Callosciurus,adamsi*
Prionailurus,planiceps	*Presbytis,rubicunda*	*Callosciurus,notatus*
Herpestes,brachyurus	*Presbytis,sabana*	*Callosciurus,prevostii*
Herpestes,semitorquatus	*Trachypithecus,cristatus*	*Dremomys,everetti*
Mydaus,javanensis	*Pongo,pygmaeus*	*Exilisciurus,exilis*
Aonyx,cinereus	*Hylobates,muelleri*	*Hylopetes,spadiceus*
Lutra,lutra	*Nycticebus,menagensis*	*Iomys,horsfieldii*
Lutra,sumatrana	*Cephalopachus,bancanus*	*Petaurillus,hosei*
Lutrogale,perspicillata	*Elephas,maximus*	*Petaurista,petaurista*
Martes,flavigula	*Hystrix,brachyura*	*Petinomys,genibarbis*
Melogale,everetti	*Hystrix,crassispinis*	*Pteromyscus,pulverulentus*
Mustela,nudipes	*Trichys,fasciculata*	*Ratufa,affinis*
Helarctos,malayanus	*Chiropodomys,gliroides*	*Rheithrosciurus,macrotis*
Rhinosciurus,laticaudatus	*Tupaia,dorsalis*	*Crocidura,monticola*
Sundasciurus,brookei	*Tupaia,gracilis*	*Suncus,etruscus*

Species	Species	Species
Sundasciurus,hippurus	*Tupaia,longipes*	*Suncus,murinus*
Sundasciurus,lowii	*Tupaia,minor*	
Ptilocercus,lowii	*Tupaia,tana*	

955

Supplemental table 3: Summary of the read losses of each sample during the read processing steps for each sequencing run seperately. The first line gives the raw read number per sample. The losses are given as percentage of each step; 1. merging of the R1/R2 reads of the Illumina sequencing done by *usearch* [43; 44], 2. clipping of primers and trimming of reads using *cutadapt* [45], 3. quality filtering and 4. dereplication, both using usearch.

	Step	Mean	SD	Median	Min	Max

Supplemental table 4: Number of merged R1/R2 reads per sample that were used for the taxonomic assignment for each of the eight sequencing runs. Displayed are the median, minimum, maximum read numbers per PCR replicate, the mean and its standard deviation as well as the number of PCR replicates with less than 500 reads.

		SeqRun01	SeqRun02	SeqRun03	SeqRun04	SeqRun05	SeqRun06	SeqRun07	SeqRun08
