Abstract

Background:

We previously found that increasing propulsion demands during split-belt walking (i.e., legs moving at different speeds) facilitates locomotor adaptation. There is a clinical interest to determine if this is also the case in stroke survivors.

Objective:

We investigated the effect of propulsion forces on locomotor adaptation during and after split-belt walking in the asymmetric motor system post-stroke.

Methods:

To test this, 12 chronic stroke subjects experienced a split-belt protocol in a flat and incline session so as to contrast the effects of two different propulsion demands. Step length asymmetry and propulsion forces were used to compare the motor behavior between the two sessions because these are clinically relevant measures that are altered by split-belt walking.

Results:

The incline session resulted in more adaptation (i.e., less limping) during late split-belt walking and larger after-effects following split-belt walking. In both testing sessions, stroke subjects adapted to regain speed and slope-specific leg orientations similarly to

younger adults. These leg orientations achieved during split-belt walking were predictive of the post-adaptation behavior.

Conclusion:

These results indicated that the asymmetric motor system post-stroke can adapt to meet leg-specific kinetic demands. This promising finding suggests that augmenting propulsion demands during split-belt walking could favor symmetric walking in stroke survivors, perhaps making split-belt interventions a more effective gait rehabilitation strategy.

Introduction

Brain lesions, such as stroke, may result in asymmetric gait (i.e., limp). Post-stroke disability is largely due to such gait impairments, which may be why improving walking is the most common goal of stroke survivors (Jørgensen et al., 1995). It is of clinical interest to reduce post-stroke gait asymmetry because it can lead to comorbidities affecting mobility such as musculoskeletal injuries (Jørgensen et al., 2000) and joint pain (Patterson et al., 2012). Promising studies show that split-belt walking, in which the legs move at different speeds, could correct gait asymmetries post-stroke (Reisman et al., 2007, 2009). However, it is not effective in all individuals (Reisman et al., 2013). It has been suggested that each subject's baseline asymmetries are a factor limiting their ability to adjust their gait (Malone and Bastian, 2014), raising the question of whether locomotor adaptation could be increased in this clinical population.

63 Our previous work indicates that locomotor adaptation in young, healthy subjects
64 increases by augmenting propulsion demands during split-belt walking. More
65 specifically, we found that baseline kinetic demands were predictive of step lengths at
66 steady state and after-effects, such that greater propulsion demands led to more
67 adaptation and larger after-effects in every individual (Sombric et al., 2019). It is unclear
68 if the same could be observed post-stroke given their known propulsion deficits
69 (Balasubramanian et al., 2007; Bowden et al., 2006). However, it has been shown that
70 stroke survivors can augment their propulsion forces when required by the task (Awad et
71 al., 2014; Hsiao et al., 2015, 2016; Kesar et al., 2011; Reisman et al., 2013). Thus, we
72 tested whether locomotor adaptation in stroke survivors could be augmented by
73 increasing propulsion demands with inclined split-belt walking.

74 We hypothesized that increasing propulsion demands would lead to more
75 adaptation and after-effects following split-belt walking in stroke survivors. To this end
76 stroke subjects experienced a split-belt adaptation protocol both in a flat and incline
77 environment that had different propulsion demands (Lay et al., 2006, 2007). We
78 expected that stroke subjects' gait adaptation and recalibration would be augmented by
79 incline split-belt walking relative to flat split-belt walking. We also anticipated that that
80 the adaptation and recalibration would be achieved through similar unilateral changes to
81 one step length during adaptation and the other step length following adaptation. These
82 changes in step length were expected to be achieved by recovering speed and slope-
83 specific baseline leg orientations. These anticipated findings would suggest that therapies
84 increasing propulsion demands during walking would be a good strategy for improving
85 post-stroke gait.

Methods

We investigated the effect of augmenting propulsion demands during split-belt walking on gait adaptation under distinct slopes (i.e., flat and incline), which naturally increase propulsion forces (Lay et al., 2006, 2007). To this end, we evaluated the adaptation and after-effects of 12 stroke patients (8 male and 4 female, 61.1 +/- 10.6 years of age) in the chronic phase of recovery (>6 months post-stroke) during separate flat and incline testing sessions. Stroke subjects were eligible if they (1) had only unilateral and supratentorial lesions (i.e., without brainstem or cerebellar lesion) as confirmed by MRI, (2) were able to walk without assistance for 5 minutes at a self-selected pace, (3) were free of orthopedic injury or pain that would interfere with testing, (4) had no other neurological condition other than stroke, (5) had no severe cognitive impairments defined by a mini mental state exam score below 24, (6) could perform moderate intensity exercise, and (7) did not take medications that altered cognitive function. Written and informed consent was obtained from all participants prior to participation. The University of Pittsburgh Institutional Review Board approved the used experimental protocol, which conformed to the standards set by the Declaration of Helsinki except for registration in the database.

106 ***Table 1. Clinical characteristics of stroke survivors***

ID	Age	Gender	Affected Side	Lesion Location	Fugl-Meyer Score	Mid Speed (m/s)	Adapt Strides (flat/ incline)	Post Strides (flat/ incline)	Incline Session Slope (°)

107

2.1 General Paradigm

All subjects experienced a split-belt protocol while either walking flat or incline throughout two separate experimental sessions (Figure 1A). The flat session was always performed first. The protocol was tailored (i.e., slope, duration, and speed) so that each subject could complete both testing sessions at the same walking speed. The subject-specific walking speed on the treadmill was determined by subtracting 0.35 m/s from each subject's overground walking speed during a Six-Minute Walking Test (Rikli and Jones, 1998). We selected this procedure since it leads to treadmill walking speeds that participants of similar age ranges to our population can sustain during long durations of the split-belt walking condition (Iturralde and Torres-Oviedo, 2019). Treadmill walking speed, labeled as Mid speed, for each participant is presented in Table 1. The speeds experienced during split-belt walking were selected based on subject's mid walking speed. The slow speed was defined as 66.6% of the medium speed, and the fast speed as 133.3% of the same. In this way, the average belt-speed during split-belt walking matched that of baseline and washout, and the belt-speed ratio during split-belt walking was 2:1. We selected an inclination of either 5° or 8.5° based on the level of the subject-specific motor impairments to ensure that all participants could complete the incline session.

Experimental protocols for both sessions consisted of three epochs (i.e., Baseline, Adaptation, and Post-Adaptation). These epochs were used to assess subjects' baseline walking characteristics and subjects' ability to adjust and recalibrate their gait for each

131 session-specific slope. Baseline: Subjects first experienced a baseline epoch, lasting at
132 least 50 strides, was used to characterize their baseline gait at the specific inclination used
133 throughout each session. Subjects walked with both belts moving at the same Mid speed
134 (Table 1). A baseline epoch with the belts moving at the slow walking speed (i.e., 66.6%
135 of the Mid speed) was also measured during the flat session. However, this epoch was
136 removed in the incline session to ensure that all subjects could complete the entire
137 protocol. Adaptation: Next, the Adaptation epoch was used to assess subjects' ability to
138 adjust their locomotor pattern in response to a split-belt perturbation. During this epoch,
139 the non-paretic leg walked twice as fast as the paretic leg. The paretic leg was confirmed
140 with MRI. The speeds for the fast and slow belts and the duration of the Adaptation
141 epoch for each subject are shown in Table 1. Post-Adaptation: Finally, The Post-
142 Adaptation epoch was used to assess the after-effects when the split-belt condition was
143 removed. Both bets moved at the same Mid speed as in the Baseline epoch. We counted
144 the number of strides in real-time to regulate the duration for each epoch, where a stride
145 was defined as the period between two consecutive heel-strikes (i.e., foot landings) of the
146 same leg. All participants took resting breaks as requested. Also, all subjects wore a
147 safety harness attached to a sliding rail in the ceiling to prevent falls. In addition, there
148 was a handrail in front of the treadmill for balance support, but individuals were
149 encouraged to hold on to it only if needed.
150
151 **2.2 Data Collection**
152
153 Kinematic and kinetic data were used to characterize subjects' ability to adapt

their gait during Adaptation, and retain the learned motor pattern during Post-Adaptation. Kinematic Data: Kinematic data were collected with a passive motion analysis system at 100 Hz (Vicon Motion Systems, Oxford, UK). Subjects' behavior was characterized with passive reflective markers placed symmetrically on the ankles (i.e., lateral malleolus) and the hips (i.e., greater trochanter) and asymmetrically on the shanks and thighs (to differentiate the legs). The origin of the kinematic data was rotated with the treadmill in the incline conditions such that the z-axis ('vertical' in the flat condition) was always orthogonal to the surface of the treadmill (Figure 1B). Gaps in raw kinematic data were filled with a quintic spline interpolation (Woltring; Vicon Nexus Software, Oxford Uk). Kinetic Data: Kinetic data were collected with an instrumented split-belt treadmill at 1,000 Hz (Bertec, Columbus, OH). Force plates were zeroed prior to each testing session so that each force plate's weight did not affect the kinetic measurements. In addition, the reference frame was rotated at the inclination of each specific experiment such that the anterior-posterior forces were aligned with the surface on which the subjects walked. A heel-strike was identified in real-time when the raw normal force under each foot reached a threshold of 30 N. This threshold was chosen to ensure accurate counting of strides at all slopes. On the other hand, we used a threshold of 10 N on median filtered data (with a 5 ms window) to detect the timing of heel strikes more precisely for data processing.

2.3 Data Analysis

2.3.1 Kinematic Data Analysis

Kinematic behavior was characterized with step length asymmetry, which exhibits robust adaptation in split-belt paradigms (e.g., Reisman et al., 2005) and is of clinical interest. It is calculated as the difference in step length between the two legs on consecutive steps. Step length (SL) is defined as the distance in millimeters between the ankle markers at heel strike. Therefore, equal step lengths result in zero step length asymmetry. A positive step length asymmetry indicates that the non-paretic leg's step length was longer than the paretic leg's step length. Step length asymmetry was normalized by stride length, which is the sum of two consecutive step lengths, resulting in a unitless parameter that is robust to inter-subject differences in step size.

Each step length was also decomposed into anterior and posterior foot distances relative to the hip position (Figure 1B) as in previous work (Finley et al., 2015). This was done to quantify the leading and trailing legs' positions relative to the body when taking a step because inclination is known to affect these measures (Dewolf et al., 2017; Leroux et al., 2002). The leading leg's position ('α') was computed as the distance in millimeters between the leading leg's ankle and the hip at heel strike; similarly, the trailing leg's position ('X') was computed as the distance in millimeters between the trailing leg's ankle and the hip at heel strike. The hip position, which is a proxy for the body's position, was estimated as the mean instantaneous position across hip markers. By convention

198 positive α values indicate that the foot landed in front of the hips, whereas negative X
199 values indicate that the trailing leg was behind the hips. Note that the magnitudes of α
200 and X summed to the leading leg's step length. As indicated in Figure 1B, α and X were
201 computed aligned to the treadmill's surface in all sloped conditions.
202
203 **2.3.2 Kinetic Data Analysis**
204
205 Kinetic data were used to characterize the adaptation of ground reaction
206 forces. We focused our analysis on the propulsion component of the anterior-posterior
207 ground reaction forces for three reasons: 1) propulsion forces are augmented by incline
208 walking (e.g., Lay et al., 2006, 2007), 2) these are associated with augmented kinematic
209 adaptation during split-belt walking (Sombric et al., 2019), and 3) they are associated
210 with hemiparetic gait pathologies (Balasubramanian et al., 2007; Bowden et al.,
211 2006). The anterior-posterior ground reaction forces (AP forces) were first low-pass
212 filtered with a cutoff frequency of 20 Hz. Then, they were normalized by each subject's
213 body weight to account for inter-subject differences. Similar to our previous work, we
214 computed peak propulsion forces (Sombric et al., 2019) as the maximum AP force ($P_{Paretic}$
215 and $P_{Non\text{-}Paretic}$) excluding the initial positive AP forces following heel strike. Note that we
216 did not remove slope-specific biases due to gravity because we focused on analyzing
217 changes in propulsion forces between epochs of interest.
218

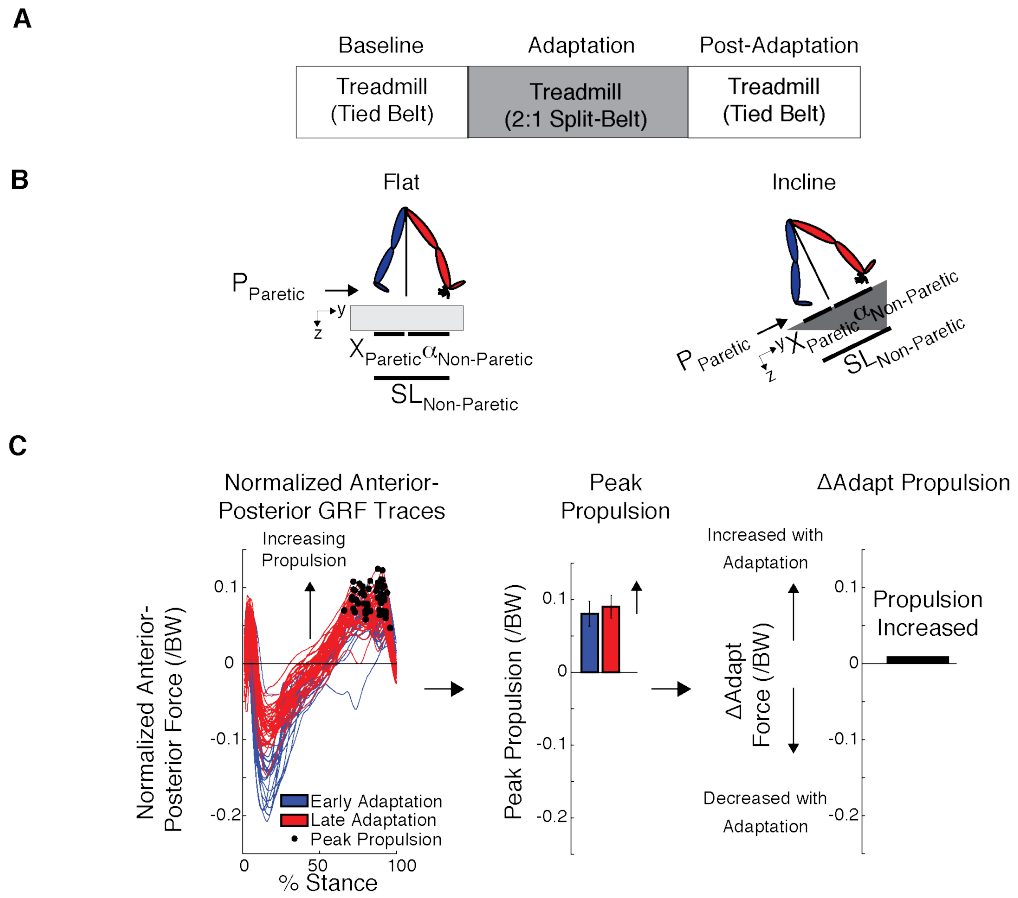

Figure 1: Experimental Paradigm and Kinetic and Kinematic Analysis| (A) Paradigm used for both the flat and incline sessions to assess locomotor adaptation during and after split-belt walking. Subjects walked flat for the entire flat session, and incline (either 5° or 8.5°) for the entire incline session. The walking speeds, duration of epochs, resting breaks and inclination were based on each subject's ability. (B) The decomposition of step length into leading (α) and trailing (X) leg positions with respect to the body is illustrated for each sloped condition. This decomposition was done because it is known that inclination affects these aspects of step length differently (Dewolf et al., 2017, 2018; Leroux et al., 2002). Also note that when taking a step, the step length will depend on the position of the leading and trailing leg, which are generating a braking and propulsion force, respectively. (C) We used the peak propulsion force for each step to compute outcome measures of interest, such as the ΔAdapt measure. This measure was computed to quantify increments or reductions in magnitude within the adaptation epoch of each specific parameter. Note that increases in magnitude were defined as positive changes, whereas decreases in magnitude were defined as negative changes.

2.3.3 Kinetic and Kinematic Outcome Measures

Outcome measures were used to characterize kinematic and kinetic changes during the Adaptation and Post-Adaptation epochs relative to Baseline or within the Adaptation epoch. Outcome measures of interest were Baseline, Late Adaptation, After-Effects, ΔAdapt, and ΔPost. **Baseline** was defined as the average of the last 40 strides of the Baseline epoch for all parameters. This outcome measure characterized subjects' baseline gait characteristics at each sloped environment and was used as a reference for Late Adaptation and After-Effects. **Late Adaptation** was defined as the difference between the average of the last 40 strides of the Adaptation epoch and Baseline for all parameters. This outcome measure indicated the steady state behavior reached at the end of the Adaptation epoch. **After-Effects** were defined as the difference between the average of the first 5 strides of Post-Adaptation and Baseline values (e.g., Post-Adaptation - Baseline). Positive After-Effect values indicated increments in magnitude of a specific parameter during Post-Adaptation relative to Baseline, and vice versa for negative values. We also characterized the behavioral changes within Adaptation and Post-Adaptation with ΔAdapt and ΔPost, respectively. **ΔAdapt** was computed as the difference between Late Adaptation and Early Adaptation values (i.e., average of the first 5 strides during the Adaptation epoch). **ΔPost** was computed as the difference between Baseline and early Post-Adaptation (e.g., Baseline - Post-Adaptation). Baseline was used instead of late Post-Adaptation because the duration of the Post-Adaptation epoch was not sufficiently long enough in all individuals to extinguish split-belt After-Effects. Thus, Baseline behavior was used a proxy for the late Post-Adaptation behavior. ΔAdapt and

ΔPost were calculated such that an increase in the magnitude of a parameter during either Adaptation or Post-Adaptation resulted in positive values and a reduction of a parameter during these epochs resulted in negative values. Figure 1C illustrates an example, to illustrate ΔAdapt for propulsion forces.

2.4 Statistical Analysis

A significance level of α=0.05 was used for all statistical tests. All statistical analyses were performed either with Stata (StataCorp LP, College Station, TX) or with MATLAB (The MathWorks, Inc., Natick, Massachusetts, United States).

2. 4. 1. Group analyses

Session averages were compared to determine the effect of slope on each of our outcome measures using kinetic (e.g., $P_{paretic}$) and kinematic parameters (e.g., step length asymmetry). We considered that slope might influence gait (Baseline), the extent of movement update during Adaptation or Post-Adaptation (ΔAdapt and ΔPost), the final adapted stated reached (Late Adaptation), and/or After-Effects. Thus, the influence of slope was assessed for each of these outcome measures with paired t-tests. A post-hoc, one sample t-test was utilized to determine if ΔPost was significantly different from zero in the flat session.

During baseline walking, it was also of interest to identify differences between the paretic and non-paretic legs in addition to determining the effect of slope on outcome measures. Therefore, we performed ANOVAs with individual subjects as a random factor to account for the paired nature of the data set and slope and leg as fixed, repeated factors. These ANOVAs were performed on the peak propulsion values and the trailing leg's position because our study was focused on the propulsion phase of the gait cycle, which is associated to these two parameters.

The changes of both step lengths during the Adaptation and Post-Adaptation epochs for the flat and incline sessions was also of interest. Therefore, we performed an ANOVA with individual subjects as a random factor to account for the paired nature of the data, and the fixed factors are slope, leg, and epoch. Slope and leg were considered repeated factors in the analysis. Epoch is not repeated and is treated as a between-subject factor given that these epochs are not directly associated (Sombric et al., 2019).

2. 4. 2. Regression analyses

We tested the association between leg positions ('α' and 'X') during speed-specific Baseline and Late Adaptation to determine if Late Adaptation values could be predicted from Baseline values in stroke survivors, as observed in young unimpaired subjects (Sombric et al., 2019). We specifically tested the model $|y| = a*|z|$, where y is the predicted leg position during Late Adaptation and z is the leg position recorded during Baseline. We also tested the ipsilateral association between the leading leg's position

during Late Adaptation and Post-Adaptation and the contralateral association between the trailing leg's position during these two epochs in stroke survivors, since these relations were also observed in young individuals (Sombric et al., 2019). Thus, we tested the model $|y| = a*|z|$, where y is each leg's position during Early Post-Adaptation and z is either the ipsilateral 'α' position recorded during Late Adaptation or the contralateral 'X' position recorded during Late Adaptation. An absolute model was utilized so that the data would not bias the results of the regression to be linear by having a cluster of positive (α) and negative (X) data points.

Results

Adaptation and recalibration of step length asymmetry are augmented when walking incline

Step length asymmetry adaptation and recalibration were augmented by incline walking. Figure 2A illustrates the evolution of step length asymmetry throughout the flat and incline sessions. Figure 2B shows a wide range of baseline step length asymmetries across individuals (colored lines) for each slope condition. On average, these baseline biases were not different between flat and incline walking (p=0.30). During Adaptation, participants exhibited similar changes in step length asymmetry from early to late adaptation (Figure 2D, p=0.75), but they were more symmetric in the incline than the flat session in Late Adaptation (Figure 2C, p=0.004). Furthermore, the incline session had larger magnitudes of After-Effects during early Post-Adaptation relative to the flat

session (Figure 2E, p=0.008). Thus, incline walking augmented the symmetry in step lengths during Late Adaptation and the magnitude of After-Effects.

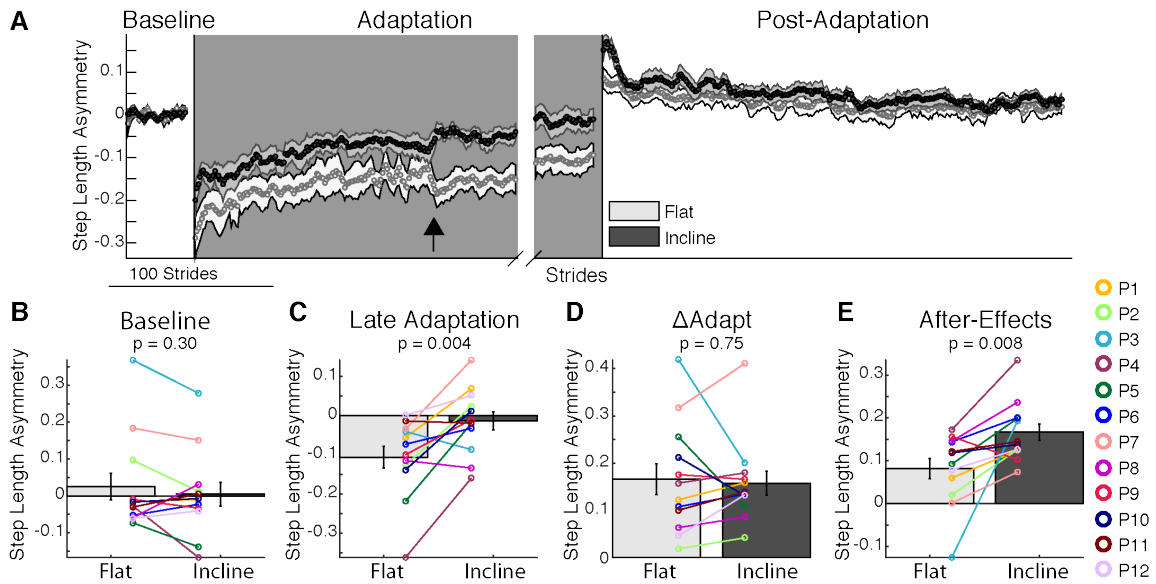

Figure 2: Step Length Asymmetry Adaptation and Recalibration| (A) Stride-by-stride time course of step length asymmetry during Baseline, Adaptation, and Post-Adaptation for each session are shown. Note that each subject's baseline bias has been removed. Each data point represents the average of 5 consecutive strides and shaded regions indicate the standard error for each session. For display purposes only, we include in the time courses stride values that were computed with a minimum of 10 subjects. The black arrow indicates a discontinuity in the data caused by many subjects taking a resting break at the same time. **(B-E)** The height of the bars indicates group average step length asymmetry ± standard errors. Individual subjects are represented with colored dots connected with lines. **(B)** Baseline: Baseline step length asymmetry is not influenced by slope. **(C)** Late Adaptation: Note that each session plateaued at different step length asymmetry values during the Adaptation epoch such that subjects reached more symmetric step lengths in the incline session than the flat session **(D)** ΔAdapt: Participants changed their gait by similar amounts during the Adaptation epoch in both sessions. **(E)** After-effects: Subjects had larger After-Effects during early Post-Adaptation in the incline session than the flat session, which is consistent with the Late Adaptation differences across sessions.

Both step lengths contribute to step length asymmetry adaptation and after-effects during incline walking in the asymmetric motor system

Stroke subjects adjusted both step lengths during split-belt walking. Stroke subjects modulate both their slow (paretic) and fast (non-paretic) step lengths during Adaptation and have After-Effects during Post-Adaptation (Figure 3A). The change of each step length during the Adaptation and Post-Adaptation epochs are quantified in Figure 3B. There was a significant effect of epoch (p_{epoch}=0.001) and interaction between leg and epoch ($p_{leg\#epoch}$<0.001) indicating that the step length with the paretic leg is reduced during Adaptation, but increased during Post-Adaptation and vice versa for the non-paretic leg. Overall, slope did not alter step length changes (p_{slope}=0.16, $p_{slope\#leg}$=0.18, $p_{slope\#epoch}$=0.17), except for the paretic leg's de-adaptation quantified by ΔPost ($p_{leg\#epoch\#slope}$=0.016). More specifically, the paretic step lengths did not exhibit de-adaptation in the flat session (i.e., ΔPost is not different from zero, p=0.38), whereas step lengths for both legs had significant de-adaptation in the incline session (i.e., non-zero ΔPost, p<0.001). Stroke subjects use both their paretic and non-paretic leg to counteract the split-belt perturbation and both legs are recalibrated following incline adaptation.

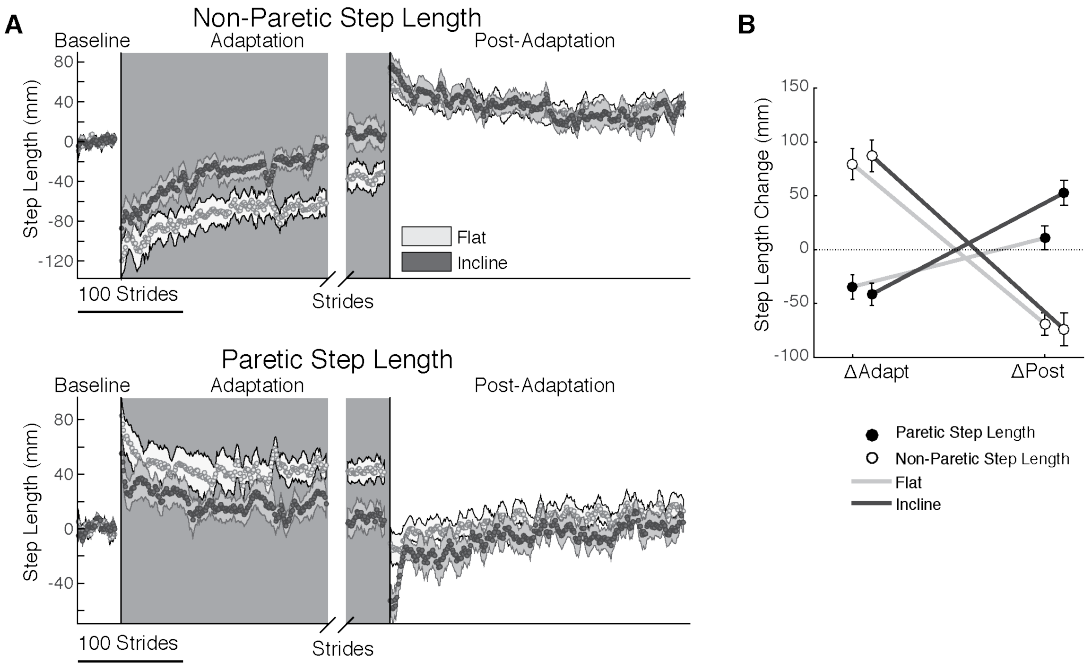

Figure 3: Step length Adaptation and After-Effects.| (A) Stride-by-stride time courses of step lengths when either the non-paretic leg (top panel, fast leg during Adaptation) or the paretic leg is leading (bottom panel, slow leg during Adaptation) are shown during Baseline, Adaptation, and Post-Adaptation. Each data point represents the average of 5 consecutive strides and shaded regions indicate the standard error for each group. For display purposes only, we include stride values during Post-Adaptation that were computed with a minimum of 10 subjects. **(B)** The effect of slope on each leg's change during Adaptation (ΔAdapt) and Post-Adaptation (ΔPost) is illustrated. Note that both the paretic and non-paretic leg adapted similarly. While the non-paretic leg has recalibrated (ΔPost≠0) following both the flat and incline session, the paretic leg is only recalibrated following incline Adaptation.

Slope and speed-specific walking demands determine the distinct step length asymmetries across inclination conditions

Speed and slope-specific leg orientations mediated the distinct step length asymmetries selected during Late Adaptation and early Post-Adaptation. Figure 4A illustrates a top-down view of the baseline leg orientations that contribute to each step length relative to the hips. The stroke subjects' leg positions are diverse across subjects

388 (colored lines, $p_{Individual}$=0.002), but the trailing leg position, X, is increased in both legs
389 during incline walking (p_{Slope}=0.042, p_{Leg}=0.22, $p_{Slope\#Leg}$=0.76). The schematic in figure
390 4B illustrates how young subjects are able to recover speed-specific leg orientations
391 (Sombric et al 2019). Figure 4C indicates that this is also true for stroke individuals
392 based on the paretic leg's leg orientation during slow baseline walking and late
393 adaptation (solid cyan line; |y|=a*|x|; 95% confidence interval of a=[0.92, 1.13], R^2=0.76,
394 p<0.001). We also show as a reference, the relation between (recorded) Baseline and
395 (predicted) Late Adaptation leg orientation values for both legs and inclinations in young
396 unimpaired individuals (magenta dashed line; (|y|=a*|x|; 95% confidence interval of
397 a=[0.91, 0.96], R^2=0.89, p<0.001). Note the similarity between the intact and lesioned
398 behavior (cyan vs. magenta lines). The leg orientations selected during Late Adaptation
399 influence Post-Adaptation behavior as is illustrated in Figure 4D. Specifically, the
400 leading leg's orientations were similar before and after removal of the split-belt
401 perturbation (i.e., Late Adaptation $\alpha_{Paretic}$=Post-Adaptation $\alpha_{Paretic}$ and vice versa)
402 whereas the trailing legs' orientations were swapped between the legs (i.e. Late
403 Adaptation $X_{Paretic}$ = Post-Adaptation $X_{Non\text{-}Paretic}$ and vice versa). This is supported by the
404 significant relationship between Late Adaptation and Post-Adaptation leg orientations
405 observed when individual subjects' values for each leg and both sloped sessions are
406 regressed (Figure 4E; solid cyan line; |y|=a*|x|; 95% confidence interval of a=[0.94,
407 1.02], R^2=0.79, p<0.001). We also show as a reference, the relation between (recorded)
408 Late Adaptation and (predicted) Post-Adaptation leg orientation values for both legs and
409 both sloped conditions in young unimpaired individuals (magenta dashed line; (|y|=a*|x|;
410 95% confidence interval of a=[0.95, 1.03], R^2=0.78, p<0.001). Note the similarity

between the intact and lesioned behavior (cyan vs. magenta lines). Similar to the intact motor system, the lesioned motor system is able to recover speed and slope-specific leg orientations during Late Adaptation, which propagate to Post-Adaptation in a predictable way.

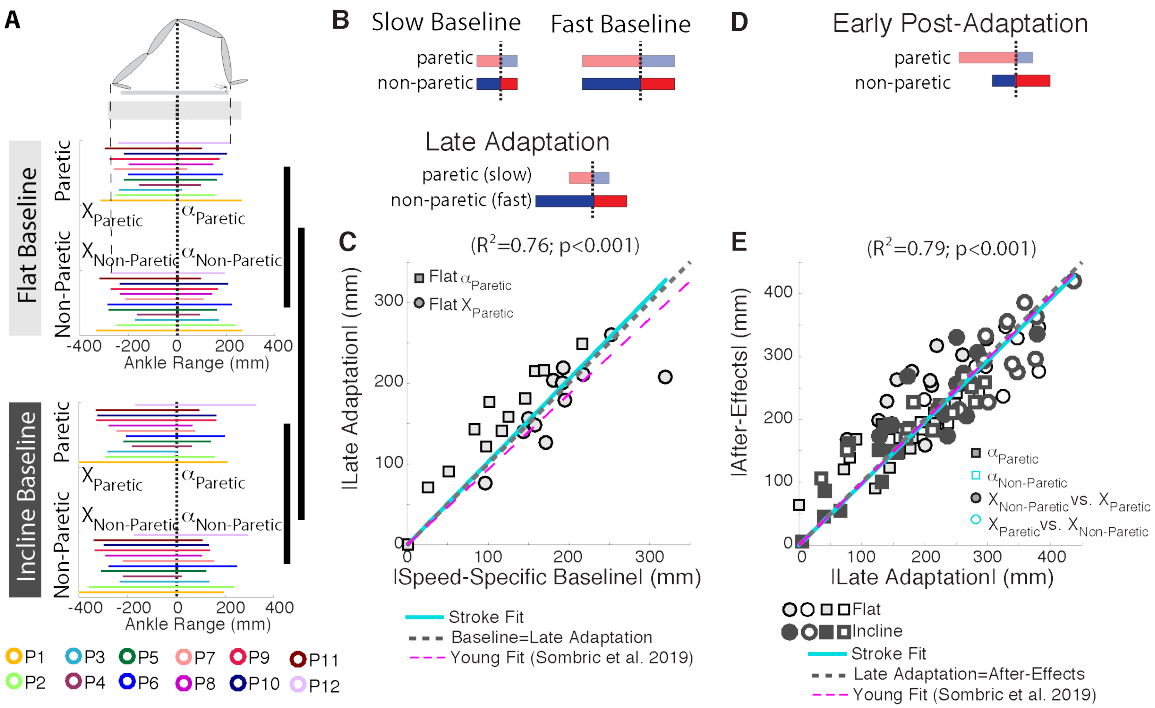

Figure 4: Leg orientation Adaptation and After-Effects. | (A) Leg orientations are depicted for individual subjects (as indicated with different colors) in both the flat and incline conditions. Note that subjects orient their legs about their bodies differently and that subjects alter their leg orientation based on slope. Thick vertical black lines indicated that there is a significant effect of leg (i.e., paretic or non-paretic) and slope (i.e., flat or incline) on trailing leg positions. **(B)** Schematic of the slow and fast (predicted) baseline behavior for the paretic and non-paretic leg orientations, respectively. The speed-specific leg orientations were regained during Late Adaptation. **(C)** The similarity between leg orientations across the speed-specific Baseline and Late Adaptation epochs is illustrated by the significant regression (solid cyan line; $|y| = a*|x|$, 95% Confidence interval for a = [0.92, 1.13]). Recall that a slow Baseline was only collected in the flat session, thus only the slow Baseline and Late Adaptation for the paretic leg (which walked slow during Adaptation) are shown. Note that the regression line closely overlaps with the idealized situation in which baseline and late adaptation values are identical (dashed gray line; slope of one, i.e., $y = x$) and the behavior of young, healthy adults (sombric et al. 2019,

dashed magenta line). **(D)** Schematic of the leg orientations during early Post-Adaptation. The forward leg positions are ipsilaterally and the trailing leg positions are contralaterally maintained from split-to-tied walking. **(E)** The ipsilateral and contralateral similarity between α and X, respectively, across the Late Adaptation and early Post-Adaptation epochs is quantified with a significant correlation (solid cyan line; $|y| = a*|x|$, 95% Confidence interval for a = [0.94, 1.02]). The idealized situation in which Late Adaptation and early Post-Adaptation values are identical (dashed gray line; slope of one, i.e., $y = x$) and the behavior of young, healthy adults (Sombric et al. 2019, dashed magenta line) are presented as a reference.

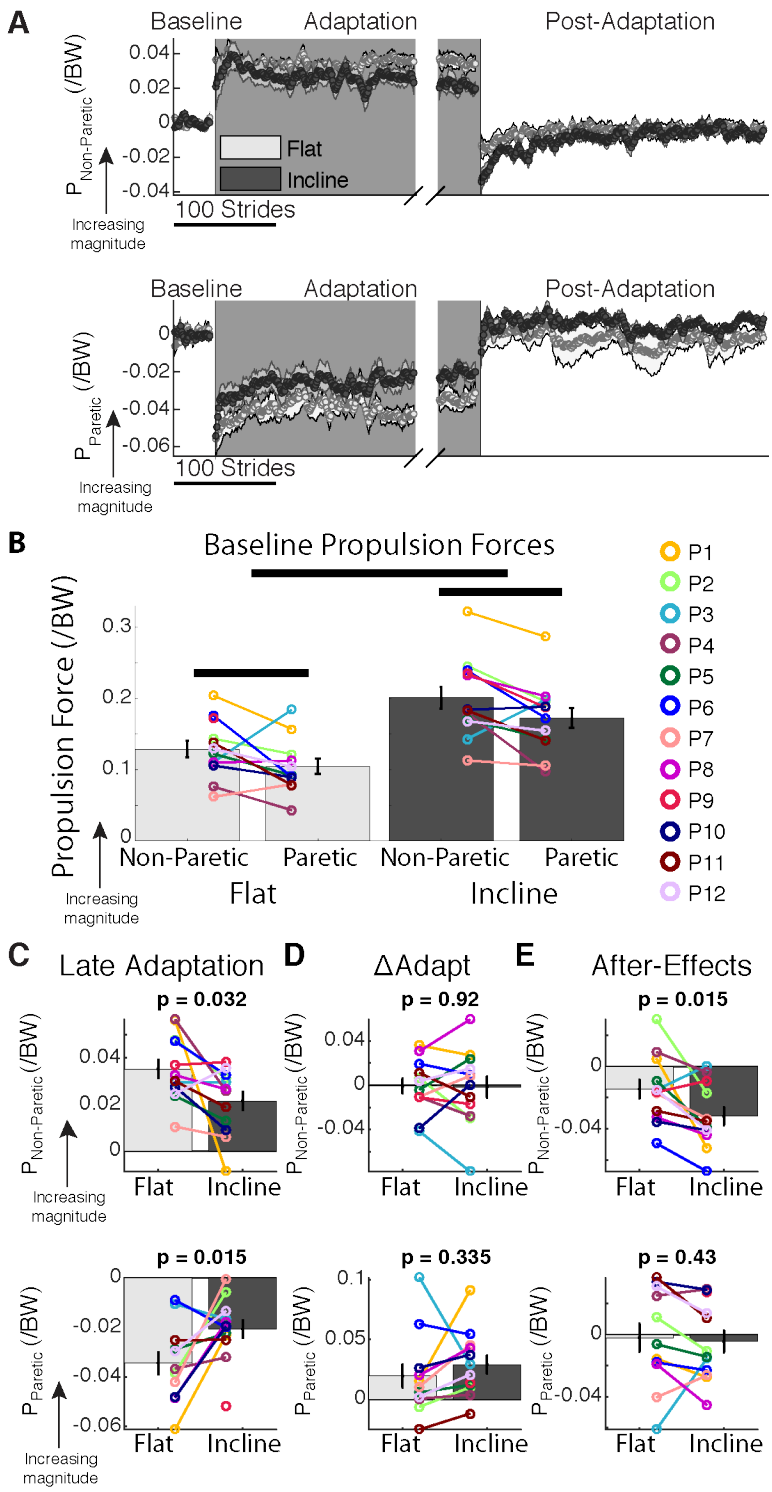

Figure 5: Propulsion force Adaptation and After-Effects.| (A) Stride-by-stride time courses of propulsion forces of the non-paretic (top panel) and paretic leg (bottom panel) are shown during self-selected Baseline, Adaptation, and Post-Adaptation. Each data point represents the average of 5 consecutive strides and shaded regions indicate the standard error for each group. For display purposes only, we include stride values during

Post-Adaptation that were computed with a minimum of 10 subjects. **(B-E)** We display group average values for propulsion force outcome measures ± standard errors. Individual subjects are represented with colored dots connected with lines. **(B)** Baseline: Thick horizontal black lines indicated that there is a significant effect of leg (i.e., paretic or non-paretic) and slope (i.e., flat or incline) on propulsion forces. On average, stroke subjects generate larger propulsion forces with their non-paretic leg, and they generate larger propulsion forces with both legs when walking incline. However, some individual stroke subjects generate larger propulsion forces with their paretic than their non-paretic leg. **(C)** ΔAdapt: Propulsion forces were similarly modulated during the Adaptation epoch for both sloped conditions. **(D)** Late Adaptation: Stroke subjects were closer to their baseline propulsion forces in the incline than the flat sessions. Moreover, baseline propulsion forces in the incline session were larger than the flat session (Figure 2C). Taken together, these results suggest that stroke subjects are forced to propel more during incline split-belt walking with both legs compared to flat split-belt walking. **(E)** After-Effects: Even though both sloped sessions did not change the extent of propulsion force adaptation (ΔAdapt), slope influenced the After-Effects for the non-paretic leg, but not the paretic leg.

Larger after-effects of propulsion forces split-belt incline walking

Sloped walking influenced the extent of recalibration of the non-paretic propulsion forces. It can be seen in Figure 5A that propulsion forces were altered during the Adaptation epochs. These data are plotted relative to baseline propulsion forces, which were larger in the incline condition and the non-paretic leg for both sloped conditions (Figure 5B: $p_{Individual}=0.007$, $p_{Slope}<0.0001$, $p_{Leg}=0.040$, $p_{Slope\#Leg}=0.43$). Note that subjects approached better the larger baseline propulsion values in the incline than flat session for both legs. In the case of the paretic side, this indicates that subjects were generating larger propulsion forces in the incline compared to flat during Late Adaptation (Figure 5C). Even though the Late Adaptation behavior was different across sessions (Figure 5C; non-paretic propulsion: p=0.032, paretic propulsion: p=0.015), the changes in propulsion forces from early to late Adaptation were similar across sloped conditions

(Figure 5D; non-paretic propulsion: p=0.92, paretic propulsion: p=0.33). While paretic propulsion After-Effects are similar in either sloped conditions (Figure 5E, p=0.43), the non-paretic After-Effects are larger in magnitude following incline adaptation (p=0.015). Note that the paretic propulsion forces change the most during Adaptation (Figure 5C), whereas the non-paretic propulsion forces are the ones exhibiting after-effects during Post-Adaptation (Figure 5E). In summary, incline walking demands greater propulsion forces in general, which lead to larger paretic propulsion during split-belt walking and after-effects that reduce the non-paretic propulsion.

Discussion

We investigated the influence of propulsion demands of walking on locomotor adaptation and recalibration in the asymmetric motor system post-stroke. We find that subjects adapt more during incline than flat split-belt walking. We also find that leg orientations during Adaptation are predictive of those Post-Adaptation, leading to greater step length asymmetry after-effects in the incline than flat sessions. Lastly, the larger after-effects in step length asymmetry result from shorter paretic step lengths and lower non-paretic propulsion forces during Post-Adaptation compared to Baseline walking in the incline session. In summary, the ability to control leg orientation to meet speed and force demands during split-belt walking is maintained post-stroke, which can be exploited for designing effective gait rehabilitation interventions in this clinical population.

502 **Post-stroke gait adapts more in response to larger propulsion demands**

503

504 We find that stroke subjects behave similarly to young, healthy adults in their
505 response to sloped split-belt walking. Specifically, stroke subjects are able to augment
506 their propulsion forces and adjust their leg orientations in response to incline split-belt
507 walking as observed in young, healthy adults (Sombric et al., 2019). This is consistent
508 with previous literature indicating that post-stroke patients at the chronic stage can
509 modulate their gait in response to task demands (Awad et al., 2014; Hsiao et al., 2015,
510 2016; Kesar et al., 2011, 2014; Reisman et al., 2013). Additionally, we observe that
511 stroke survivors recover speed and slope-specific leg orientations in the paretic leg for the
512 flat session. We speculate that the same would have been observed in both slope
513 conditions and both legs, as observed in young individuals (Sombric et al., 2019). We
514 think that this is a reasonable expectation given that stroke survivors exhibit similar
515 control of leg orientations to young adults during Late Adaptation and early Post-
516 Adaptation for both legs and sloped conditions. Thus, our results provide further evidence
517 that steady state in the split-belt walking task can be predicted from baseline walking.

518

519 It has been previously suggested that baseline gait asymmetries determine the
520 patients motor behavior at steady state split-belt walking (Malone and Bastian, 2014;
521 Reisman et al., 2007). Our results provide new insights into the influence of baseline
522 walking on adaptation. Specifically, we find that stroke survivors recover their baseline
523 asymmetry in the incline, but not in the flat condition. Thus, it is not baseline gait
524 asymmetry, but kinetic demands that seem to govern patients' motor patterns. More

525 specifically, our results suggest that that post-stroke survivors aim to recover the baseline
526 leg orientations for the specific kinetic demands for each leg in the split condition, as
527 observed in young adults (Sombric et al., 2019). Further, the forward leg orientation in
528 the split condition might be adjusted to harness energy from the treadmill (Sánchez et al.,
529 2019). However, the trailing leg orientation does not match the behavior predicted from
530 an objective function solely based on minimizing work (Supplementary Figure 1). Thus,
531 there might be some other factors such as stability (Buurke et al., 2018) or metabolic
532 energy (Gordon et al., 2009) regulating leg orientation in walking. In summary, the forces
533 generated to propel one's body forward constitute an important control variable
534 regulating the adaptation of movements in the intact and asymmetric motor systems.
535
536 **Bilateral adaptation in stroke survivors contrasts unilateral adaptation in young**
537 **adults**
538
539 Stroke subjects recruit both legs in order to adapt their gait, whereas young adults
540 primarily adapt one leg. Notably, our results show that stroke survivors adjusted the step
541 lengths taken with the paretic and non-paretic legs walking on the slow and fast belts,
542 respectively. In contrast, we have previously observed that young individuals mostly
543 adjusted the step length of the leg walking on the fast belt (Sombric et al., 2019). This
544 could be because stroke survivors may require more repetitions in the altered
545 environment to recover their baseline leg orientation with their paretic leg, whereas intact
546 subjects can do so immediately after the split condition is introduced. Alternatively, it
547 could be that the larger neural coupling post-stroke (Kloter et al., 2011) enhances

548 bilateral adaptation. Regarding post-adaptation, after-effects are only observed in the
549 paretic leg in the incline condition. More specifically, paretic step lengths become longer
550 than in baseline walking, which is beneficial for stroke survivors regularly taking short
551 paretic step lengths (Balasubramanian et al., 2007). On the other hand, after-effects are
552 observed in the non-paretic leg, regardless of the sloped condition. This is atypical since
553 the non-paretic leg walked fast in the split condition and young adults only exhibit after-
554 effects in the leg that walked slow (Sombric et al., 2019). This atypical behavior consists
555 of shortening step lengths compared to baseline walking and might be a strategy to
556 recover balance (e.g., Eng et al., 1994), which is challenged upon removal of the split
557 condition (Buurke et al., 2018; Iturralde and Torres-Oviedo, 2019). In summary, stroke
558 subjects adapt both legs during split-belt walking, but the paretic step lengths only change
559 after the incline split condition.
560
561 **Neurorehabilitation through reinforcement of a corrective pattern during**
562 **adaptation, rather than short-lived after-effects post-adaptation.**
563
564 The long-term therapeutic effect of locomotor adaptation with split-belt treadmills
565 may be due to walking with the motor demands of the split-belt task, rather than the
566 After-Effects. Split-belt walking has been shown to reduce step length asymmetries
567 (Lewek et al., 2018; Reisman et al., 2013). However, it remains an open question what
568 aspects of the split-belt walking underlie these long term changes. Aftereffects could lead
569 to motor improvements (Bastian, 2008). Namely, some patients exhibit reduced gait
570 asymmetry immediately after split-belt walking (Choi et al., 2009; Reisman et al., 2007).

571 However, these after-effects are short lived and decrease as individuals experience
572 multiple days of practicing the split-belt condition (Larish et al., 1988; Leech et al., 2018;
573 Sombric et al., 2017). It is known that regular treadmill walking cannot modify gait
574 asymmetries post-stroke (Kautz et al., 2005; Den Otter et al., 2006; Silver et al., 2000),
575 suggesting that the specific motor demands of the split-belt task might be important for
576 neurorehabilitation. For example, we observe that the split condition forces post-stroke
577 individuals to take longer paretic step lengths and generate greater paretic propulsion.
578 Perhaps practice of these gait features through multiple exposure to the split situation
579 might lead to long term changes in gait symmetry. It is also possible that the strenuous
580 nature of split-belt walking increases neural plasticity, as shown with other high-intensity
581 exercises (Andrews et al., 2019). Thus, incline split-belt walking may be beneficial not
582 only for inducing greater paretic propulsion, but also because it is more demanding than
583 level walking (Johnson et al., 2002). Lastly, it is also possible that the initial disruption of
584 step length asymmetry, which is experienced multiple times during split-belt training, is
585 fundamental for individuals to start exploring new patterns that could converge to more
586 metabolically efficient gait than their baseline walking pattern (Sánchez et al., 2019;
587 Selinger et al., 2015). In summary, the long term benefit of split-belt walking may
588 originate from practicing motor patterns specific to split-belt walking, rather than
589 reinforcement of those observed during post-adaptation.
590

591 **Clinical implications**

592

593 Split-belt walking has been shown to induce long term changes that could
594 improve the mobility of stroke survivors (Betschart et al., 2018; Lewek et al., 2018;
595 Reisman et al., 2013). However, there is little understanding for what leg should walk on
596 the slow or the fast belt during the split condition (Finley et al., 2015; Malone and
597 Bastian, 2014; Reisman et al., 2007, 2009). For instance, one may consider that the
598 paretic leg should walk on the slow belt to force stroke survivors to use it more, as a form
599 of "constrained use therapy" (e.g., Kwakkel et al., 2015). On the other hand, our results
600 here and in a previous study (Sombric et al., 2019) indicate that placing the paretic leg on
601 the fast leg would force subjects to augment their paretic propulsion and lengthen their
602 paretic steps during split-belt walking, which would be beneficial if these were the
603 patterns that one would like to reinforce. Future studies are needed to determine if stroke
604 survivors could actually augment their paretic propulsion forces during split-belt walking,
605 as observed in the fast leg of young adults (Sombric et al., 2019). This remains an open
606 question given that we observed limited changes in paretic propulsion post-adaptation
607 compared to those reported in controls (Sombric et al., 2019). In sum, our study provides
608 greater understanding of the motor demands associated to the split-belt task, which could
609 be harnessed for gait neurorehabilitation.

610

611 The ability to augment locomotor adaptation and recalibration in the lesioned
612 motor system with incline split-belt training is promising, but future studies are needed to
613 determine if this will be a more effective intervention than flat split-belt walking. Notably

614 not all stroke survivors re-learn to walk symmetrically following several training weeks
615 of flat split-belt walking (Betschart et al., 2018; Lewek et al., 2018; Reisman et al., 2013).
616 Thus, it is clinically relevant to explore alternative strategies to augment adaptation in
617 stroke survivors other than increasing the speed difference (Yokoyama et al., 2018) since
618 not all patients can walk with large speed differences. This work supports that the extent
619 of adaptation in the split condition can be augmented by increasing the propulsion
620 demands required by the task, which in turn would possibly make split-belt walking more
621 effective to more patients. Previous research, however, indicates that overground walking
622 post-stroke is most improved following decline, rather than incline, interventions due to
623 greater similarity in motor patterns between the flat and decline conditions (Carda et al.,
624 2013). Thus, the augmented adaptation in the incline environment may not transfer to
625 overground walking. Therefore, the efficacy of our protocol as an intervention will
626 depend on future work assessing its generalization to level walking.
627

628 ## Competing interests:

629 The authors have no conflicts of interest to report.

630 ## Author Contributions

631 All experiments were performed in the Sensorimotor Learning Laboratory. G.T. and C.S. were
632 involved with the conception and design of the work. C.S. collected and analyzed the data. C.S
633 and G.T. interpreted the results. C. S. drafted the manuscript, which was carefully revised by all
634 authors. The final version of the manuscript has been approved by all the authors who agree to
635 be accountable for all aspects of the work in ensuring that questions related to the accuracy or

integrity of any part of the work are appropriately investigated and resolved. All authors qualify for authorship and all those who qualify for authorship are listed.

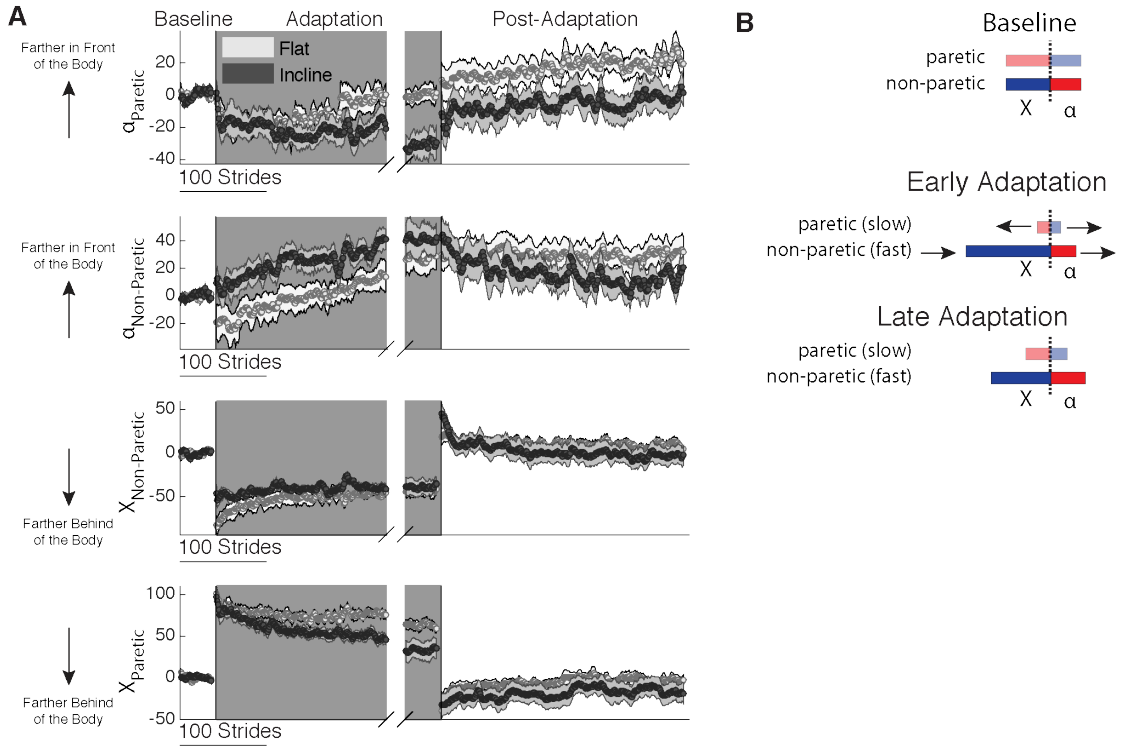
Funding

C.S. is funded by a fellowship from the National Science Foundation (NSF-GRFP); CRDF 4.30204; NSF1535036; AHA 15SDG25710041

Acknowledgements

The authors acknowledge the valuable input from Pablo Iturralde and Digna de Kam.

Supplementary Material



Supplementary Figure 1: Leg Position Adaptation and After-Effects in the Asymmetric Motor System| (A) Stride-by-stride time courses of leg positions (α and X) for the non-paretic and paretic leg are shown during self-selected Baseline, Adaptation, and Post-Adaptation. Each data point represents the average of 5 consecutive strides and

shaded regions indicate the standard error for each group. The beginning and Late Adaptation group average behavior are shown for the Adaptation epoch. For display purposes only, we include stride values during Post-Adaptation that were computed with a minimum of 10 subjects. **(B)** Schematic of the self-selected Baseline, early Adaptation, and late Adaptation behavior for the paretic and non-paretic leg orientations, respectively. Note that there is a general forward movement of the leg position of the non-paretic leg, but the paretic leg increases both the leading and trailing positions.
