**Abstract:** Genotype-to-phenotype association studies typically use macroscopic physiological measurements or molecular readouts as quantitative traits. These approaches have been successful for the identification of disease risk loci, and variants that affect gene transcription and regulation. However, there are comparatively few suitable quantitative traits available between cell and tissue length scales, a limitation that hinders our ability to identify variants affecting phenotype at many clinically informative levels. We overcome these limitations by showing that unbiased quantitative image features, automatically extracted from histopathological imaging data, can be used successfully for image Quantitative Trait Loci (iQTL) mapping and disease variant discovery. Using thyroid pathology images, clinical metadata, and genomics data from the Genotype and Tissue Expression project, we establish and validate a quantitative imaging biomarker for thyroid autoimmune disease. A total of 100,215 candidate variants in 1,380 genes differentially expressed in Hashimoto's Thyroiditis cases were selected for iQTL profiling, and tested for genotype-phenotype associations with our quantitative imaging biomarker. Significant associations were found with variants in HDAC9 and TXNDC5, genes not previously associated with thyroid autoimmune disease. We validated our results using GTEx *cis*-expression QTL data, and an independent dataset of 1,213 hypothyroidism cases and 3,789 controls from the Electronic Medical Records and Genomics network.

**One Sentence Summary:** We use a histopathological image QTL analysis to identify genomic variants associated with thyroid autoimmune disease.

## **Introduction**

Modern genomics has had tremendous success in relating genetic variants to a variety of molecular phenotypes. Variants associated with gene expression, so-called expression Quantitative Trait Loci (eQTLs), are enriched for regions of active chromatin, influence gene regulation, and are involved in processes that contribute to disease (1,2). At the macroscopic level, genome-wide association studies (GWAS) that use physiological measurements of organ health have also provided insight into the genetic component of human disease. However, given the immense gap between SNP-level variation and tissue and body function, GWAS results concerning human traits can be challenging to interpret, in part due to the high correlations observed between studies of different traits (3). This is especially true for autoimmune diseases, which have many shared genetic risk factors (4). One way to increase GWAS variant interpretability and to discover new disease variants will be to place more focus on quantitative traits that lie at intermediate cellular and sub-tissue scales.

Histopathology has for decades remained the standard for the diagnosis and grading of many complex diseases. Advances in digital slide imaging have allowed for unprecedented resolution at tissue, cellular, and sub-cellular scales. As such, histopathology could provide the genomics community with a vast resource of quantitative traits for evaluating disease phenotype across a range of mesoscopic scales. Previous histopathological GWA studies have used discrete pathology grading schemes as quantitative traits. While such schemes are highly effective for guiding clinical decisions on the level of individual patients, and can in principle identify disease variants in GWAS (5), they do not scale well to the hundreds or thousands of samples needed due to inter- and intra-observation bias (6-8). When performing millions of statistical tests in GWAS, any source of bias will increase the likelihood of finding spurious associations and negatively affect the replicability of study findings.

Unbiased, automatically extracted, continuous features have been shown to improve the predictive power of survival analyses with pathology data in comparison to discrete grades (9,10). GWA studies using quantitative image features extracted from radiological imaging data have successfully identified COPD-relevant variants using Computed Tomography (11), and variants related to Alzheimer's Disease and Mild Cognitive Impairment using Magnetic Resonance Imaging (12). Thus, genome association studies that leverage automated imaging analysis methodologies can be highly effective. With quantitative image analysis now routinely applied to digital pathology datasets (9,10,13-15), it is clear that unbiased, continuous image features can readily be extracted for histopathological GWAS variant discovery.

Nevertheless, little attention has been paid to the use of cellular imaging to obtain quantitative traits for understanding the connection between genotype and cellular phenotypes. Part of the reason for this may be that there are few available datasets for which both genomic profiling and standardized histopathology data are available for any appreciable number of samples. The Genotype-Tissue Expression (GTEx) resource (16,17) has collected germline genotype data from over 450 autopsy research subjects, as well as standardized histological imaging and RNA-Seq gene expression from approximately 50 different body sites.

One of the tissues for which there is substantial histological imaging data is the thyroid. The thyroid plays a central role in the endocrine system, producing thyroid hormones that influence protein synthesis and metabolism. Hashimoto's Thyroiditis (HT) is an autoimmune disease affecting approximately 5% of the population, in which the thyroid is slowly destroyed,

frequently leading to hypothyroidism, particularly in women (18). Among the GTEx population there are 341 individuals for whom paired thyroid imaging and gene expression data was available; of these 31 had morphological evidence of HT according to GTEx pathology notes. We saw this dataset as an ideal place to test the hypothesis that cellular imaging features could be used to discover disease variants in an image Quantitative Trait Locus (iQTL) analysis.

### **Quantitative image analysis**

Image data was downloaded from the GTEx histological image archive (Materials and Methods), and convolved with a Gaussian filter to smooth out pixel-level variation on a length scale smaller than observed regions of lymphocytic invasion in HT samples. Individual tissue pieces were segmented using adaptive thresholding (Figure 1A), and 117 Haralick image features were extracted for each tissue piece using the Bioconductor image processing package *EImage* (19) (Materials and Methods). Haralick features are widely used for the quantification of image texture, and take into account correlations between neighboring pixels in an image (20). Given that lymphocyte invasion has a profound effect on histological image texture, Haralick features were ideal candidates for capturing HT cellular phenotype. After removing overly small tissue pieces, averaged image feature values were calculated across pieces to give a single value for each sample and feature. In preparation for downstream model fitting, features were  $\log_2$  transformed, and centered and rescaled using a z-score to ensure feature comparability (Figure 1B). A fully worked through image analysis example with the applied segmentation parameters is supplied as part of a supplemental R data package.

To reduce the number of candidate features and to identify the primary directions of variability in our image feature matrix, we performed Principal Component Analysis (PCA), and found that the first two imaging Principal Components (PCs) were sufficient to explain 73% of the variance. By inspection of the images, low values of PC1 were found to be associated with interior holes in the thyroid pieces (Figure S1A), an effect we adjudged to be primarily technical in origin. High values of image PC2 were visually strongly associated with the presence of invading lymphocytes (Figure S1B).

To validate this observation we identified all samples for which HT was indicated in the comments of the original GTEx pathologists (Figure 1C blue points). A ROC curve showed that image PC2 was a highly performant biomarker for HT, with an AUC of 0.84 (Figure 1D). Using logistic regression, we found that HT status was significantly associated with image PC2 (OR=1.3,  $P=1.4 \times 10^{-9}$ ) after correcting for sex and age (Materials and Methods). A higher association with HT status for women was also observed after correcting for age (OR=4.2,  $P=4 \times 10^{-4}$ ), a known clinical characteristic of the disease (18). That image PC2 is a performant HT biomarker likely does not have direct clinical relevance since a pathologist can easily diagnose the disease by inspection of pathology images; we considered its utility to be for downstream integration with genomic data.

### **Integrated RNA-Seq and image analysis: imaging biomarker validation**

Next we analyzed GTEx gene expression data associated with the 341 thyroid images. After the removal of lowly expressed genes, counts were  $\log_2$  transformed and underwent quantile normalization to ensure comparability of samples (Materials and Methods). To test for

associations between gene expression and image PCs, linear models were used to fit each image PC against normalized gene readouts while correcting for age, sex, sample collection site, tissue autolysis score, and RNA extraction type. To remove bias caused by unknown confounders (Figure S2A) we fitted 20 PEER (Probabilistic Estimation of Expression Residuals) factors (21) to the gene expression data while including the known confounders in the PEER fit; a similar approach was used by the GTEx consortium (16,22). The first PEER factor was not included as a covariate in the linear model fits due to the strength of its correlation with our image PC2 biomarker (Pearson  $r=0.53$ ,  $P<2.2\times 10^{-16}$ ), which indicated that it likely contained valuable biological information. The results from fits correcting for the known confounders as well as the 19 remaining PEER factors revealed that image PC2 was systematically and highly associated with gene expression (Figure 2A), suggesting that lymphocyte infiltration is at least a major, if not the primary source of expression variability in GTEx thyroid tissue. In contrast, image PC1 had comparatively few significant associations with thyroid gene expression (Figure 2A).

To identify which biological pathways may drive the significant image PC2 associations with gene expression we performed gene-set enrichment analysis, choosing as a test set 2,913 genes with  $-\log_{10}(P_G) > 10$  in the gene expression analysis and all other 21,080 genes as a background set (Materials and Methods). Significant enrichment was observed for a number of gene ontology terms related to immune function, and the activation and signaling activity of invading T and B lymphocytes (Table 1).

To confirm the association between image PC2 and the presence of invading immune cells on the level of individual samples, we ran our gene expression data through CIBERSORT, an algorithm designed to deconvolve complex cell mixtures (23). The LM22 leukocyte gene signature matrix supplied by the CIBERSORT team was used to perform the deconvolution as it could in principle detect and distinguish between a number of T and B cell types. As expected, CIBERSORT failed to detect immune cells in the majority of healthy thyroid samples. However, in samples where immune cells were detected (CIBERSORT  $P_C < 0.5$ ), the significance of detection correlated significantly with image PC2 (Figure 2B; Spearman  $\rho=0.67$ ,  $P=3\times 10^{-7}$ ). Figure 2C shows the cell type signature for samples with  $P_C < 0.1$  and cell types with an average CIBERSORT frequency of more than 5% across samples. This analysis confirmed the presence of T-cell CD4 memory resting, T-cell CD8, naïve and memory B cells, as well as other immune cell types, on the level of individual samples.

The CIBERSORT algorithm also detected infiltrating immune cells in several samples for which image PC2 was high but HT was not indicated by GTEx pathologists (Figure 2B grey points), suggesting that our imaging biomarker may be able to detect a broader spectrum of thyroid autoimmune diseases. By inspection, we confirmed that many of these images did show infiltrative phenotypes but did not exhibit the classical HT visual phenotype (for example GTEX-OXRO, GTEX-144FL), suggesting that they were not false negatives for HT. One possible clinical application of our imaging approach would therefore be to automatically flag such samples for rechecking by pathologists.

To demonstrate the advantage of using PCA for the identification of a candidate imaging biomarker, as opposed to directly using the individual Haralick image features, we correlated each of the 117 image features with CIBERSORT significance of detection for immune cells, in the same manner as above. Image PC2 had a higher Spearman correlation coefficient than all image features, with the closest having a coefficient of  $\rho=0.60$  (Figure S2B). Thus, image PC2 combined information from multiple image features to attain a higher overall performance.

## **iQTL identification of Hashimoto's Thyroiditis disease variants**

Based on our analysis of image features and gene expression, we decided to use image PC2 as a quantitative trait capturing the cellular features of HT in an image QTL analysis. Since we did not have sufficient sample size to achieve high power in an iQTL analysis that would include millions of variants, we decided to reduce the search space by asking a more targeted question of the data. We hypothesized that the genotype of differentially expressed genes in GTEx samples with HT, could in part determine thyroid autoimmune disease risk and severity. Therefore, the analysis was further restricted to 100,215 candidate SNPs residing in 1,380 genes that were significantly ( $-\log_{10}(P_{\text{adj}}) > 7$ , Figure S3A) and positively ( $\log_2(\text{Fold-Change}) > 0.5$ ) differentially expressed in 31 HT cases versus 310 controls (Figure 3A blue points) using *DESeq2* (24).

We then limited our analysis to the 292 samples that had both thyroid imaging and genotype information. The genotype data had already undergone rigorous quality control and filtering by the GTEx consortium, including but not limited to Hardy-Weinberg equilibrium and imputation quality criteria. Due to sample size considerations, minor allele frequencies (MAFs) of less than 10% were removed, as well as SNPs with a missingness frequency of more than 10%.

Image QTL linear model fits were implemented using the R package *MatrixEQTL* (25) by treating image PC2 as a pseudo *trans* gene. Fits were corrected for age, sex, race, ancestry, processing center, and tissue autolysis score (Materials and Methods). A QQ plot comparing the distribution of observed p-values to the expected uniform distribution showed that the data was well behaved under the null hypothesis (Figure 3B), with a departure from the dashed line for a group of SNPs with low p-values. Independent Hypothesis Weighting (IHW) (26) using MAF as the independent covariate was used to correct for multiple testing. In a data-driven way, this method assigned different weights to variants based on their MAF (Figure S3B) to maximize the number of null hypothesis rejections while controlling for Type I error. A total of 21 SNPs across 3 haplotype blocks were identified as being significant ( $P_{\text{IHW}} < 0.05$ ; Table S1). As expected, IHW attained higher power as compared to standard, unweighted Benjamini and Hochberg FDR (Table S1).

Strikingly, 20 of the 21 significant SNPs resided in Histone Deacetylase 9 (HDAC9), an enzyme linked to epigenetic control of gene transcription, and previously proposed to be an epigenetic switch for T-cell mediated autoimmunity (27). Histone deacetylase inhibitors have been effective in the treatment of hypothyroidism in mice (28), and autoimmune diseases in general (29). A plot of SNP significance along HDAC9 revealed a sharp peak at 18,301 kb on chromosome 7 (Figure 3C). To our knowledge this is the first reported association between HDAC9 variants and thyroid autoimmune disease. A search of GWAS Central ([www.gwascentral.org](http://www.gwascentral.org) (30)) revealed that modest associations between Ulcerative Colitis (UC) and two of our significant image QTL variants ( $-\log_{10}(P) = 2.3$  for *rs215122*,  $-\log_{10}(P) = 2.7$  for *rs2529749*) have previously been reported (31). While further work will be required to investigate the biological effects of HDAC9 genotype in both UC and HT, a common genetic basis would be consistent with evidence that these conditions present concurrently at higher rates than would be expected in the general population (32).

One variant in the Thioredoxin Domain Containing 5 gene (TXNDC5), *rs11962800*, was found to be significant at the level of  $P_{\text{IHW}} < 0.05$  (Table S1). TXNDC5 expression is induced by hypoxia (33), and variants in this gene have been associated with a number of autoimmune diseases including rheumatoid arthritis (34) and vitiligo (35). As for HDAC9, variants in

TXNDC5 have not previously been associated with thyroid autoimmune disease, again showing that iQTLs can uncover new disease associations. Encouragingly, *rs11962800* was reported as a *cis*-expression QTL in thyroid tissue by the GTEx consortium ( $P=7.7\times 10^{-21}$ ; [www.gtexportal.org](http://www.gtexportal.org) (22)). Since our analysis shows that TXNDC5 expression is associated with lymphocyte invasion in thyroid tissue, it is possible that any expression-based result could be biased by cell-type mixing, as has been highlighted in GTEx lung tissue (36). However, *rs11962800* was also a reported eQTL in 16 other GTEx tissues (22), with thyroid ranked 3/17 in terms of highest significance. Next we relaxed the IHW adjusted p-value cutoff for iQTLs to 0.4, and found that the top five iQTLs in TXNDC5 were also eQTLs (Table 2). Additionally, 12/31 of the GTEx TXNDC5 eQTLs overlapping with our set of tested variants were iQTLs or in linkage disequilibrium with iQTLs (Figure S4 red points). Together, these results offer the mechanistic hypothesis that genetic variation in TXNDC5 affects HT imaging phenotype directly through local regulation of RNA expression levels.

Next we asked how the performance of our imaging biomarker might compare with expression-based biomarkers for disease variant discovery. We chose the first expression PEER factor (PEER1) as a comparative candidate biomarker based on the earlier observation that it was significantly correlated with image PC2. After verifying that PEER1 was performant for predicting HT (AUC 0.88, Figure S5A), we ran another QTL analysis using the same 100,215 variants as for the iQTL analysis, but with PEER1 as the response variable. A QQ plot revealed that PEER1 performed poorly (Figure S5B), with no significant QTL hits. Therefore, image PC2 was in this case a superior choice of biomarker for disease variant discovery.

### **Validation of iQTL results using an independent dataset**

To validate the observed associations between HDAC9 and TXNDC5 genotype, and thyroid autoimmune disease in an independent dataset, we obtained genotype and phenotype data, and clinical metadata from the Electronic Medical Records and Genomics (eMERGE) network (37) (Materials and Methods). This dataset has been used previously for hypothyroidism variant discovery (38). We selected 1,261 chronic autoimmune hypothyroidism (presumptive Hashimoto's hypothyroidism) cases and 4,457 non-hypothyroidism controls (Materials and Methods). As over 96% of the hypothyroidism cases were from the Caucasian cohort, and 250/292 of the GTEx samples used for the image QTL analysis were of European American descent, to simplify the analysis all non-Caucasian cohorts were removed, leaving 1,213 cases and 3,789 controls. For consistency with the image QTL analysis, SNPs with a minor allele frequency of less than 10% and a missingness frequency of more than 10% were removed. One SNP in HDAC9 was removed due to deviation from Hardy-Weinberg equilibrium (Materials and Methods).

We used logistic regression to test for associations between hypothyroidism status, and HDAC9 and TXNDC5 genotype while correcting for patient age (decade of birth), sex, and collection site (Materials and Methods). For both genes, the location of the most significant GTEx image QTL peaks, as determined by their IHW-adjusted p-values, coincided closely with the highest eMERGE peaks (Figure 3C,D vertical lines), and we noted a high degree of similarity between the association profiles. To quantitatively assess the concordance of the association signatures between the GTEx and eMERGE data, we first selected the SNPs common to both datasets, and grouped neighboring SNPs into bins of size 15 SNPs based on their genomic coordinates. The

lowest p-value in each bin was then selected for both datasets. A correlation test revealed that the association signatures between eMERGE and GTEx data were highly concordant across both HDAC9 (Figure S6A1; Spearman  $\rho=0.68$ ,  $P<2.2\times 10^{-16}$ ) and TXNDC5 (Figure S6A2; Spearman  $\rho=0.69$ ,  $P=1.8\times 10^{-4}$ ).

To verify that it was hypothyroidism status driving the concordance, we performed 1,000 permutations of the hypothyroidism case/control labels in the eMERGE dataset and repeated the logistic regression, binning, and correlation analyses between eMERGE and GTEx data. The resulting permutation p-values for both HDAC9 ( $P=0.009$ ) and TXNDC5 ( $P=0.007$ ) demonstrated that it was highly unlikely to obtain the observed concordance between eMERGE and GTEx profiles by chance (Figure S6B1,2).

These validations also showed that image QTL approaches that use continuous phenotypic measurements can attain higher power for the detection of disease-relevant genomic regions as compared to traditional cases versus controls analyses. One explanation for this might be that quantitative histological image analysis captures subclinical, as well as clinical disease phenotype as a smooth function, while binary categorizations of disease status do not take into account informative subclinical disease cases, or the morphological severity of the disease phenotype.

## **Outlook**

Our intuition, along with over a decade of progress in GWAS, tells us that genotype and phenotype are associated in ways that can be quantitatively assessed. The growth of integrated data resources such as GTEx, and the advancement of digital slide imaging technologies, provides the opportunity to explore that association at the cellular level. This study demonstrates the potential of histopathological image-based QTL profiling for *de novo* discovery of disease variants, especially when unbiased, continuous, automatically extracted image features are used as quantitative traits. Our results indicate that iQTLs can identify different disease variants to cases vs controls GWAS, offering a complementary approach that leverages cell-level phenotypes for target discovery. While we applied iQTLs to a thyroid dataset, the method is completely generalizable to other tissues and disease contexts. With larger sample sizes and study designs tailored for specific diseases, iQTL scans can be extended to millions of variants. Ultimately, digital pathology image analysis approaches could revolutionize genome-wide association studies by providing a wealth of unbiased quantitative traits at the cellular level that have high levels of biological interpretability.

**Notes:** Code and analysis reproducing paper figures, as well as reported image and statistical analyses performed on non-protected data, are supplied as part of an R package that will be made available upon publication.

**Author Contributions:** JDB, HJWLA and JQ conceived of the project. JDB performed all image and data analysis, with input from MF (CIBERSORT analysis), JNP (statistical analysis), and JP (QTL pipeline). JDB wrote the paper with input from all authors.

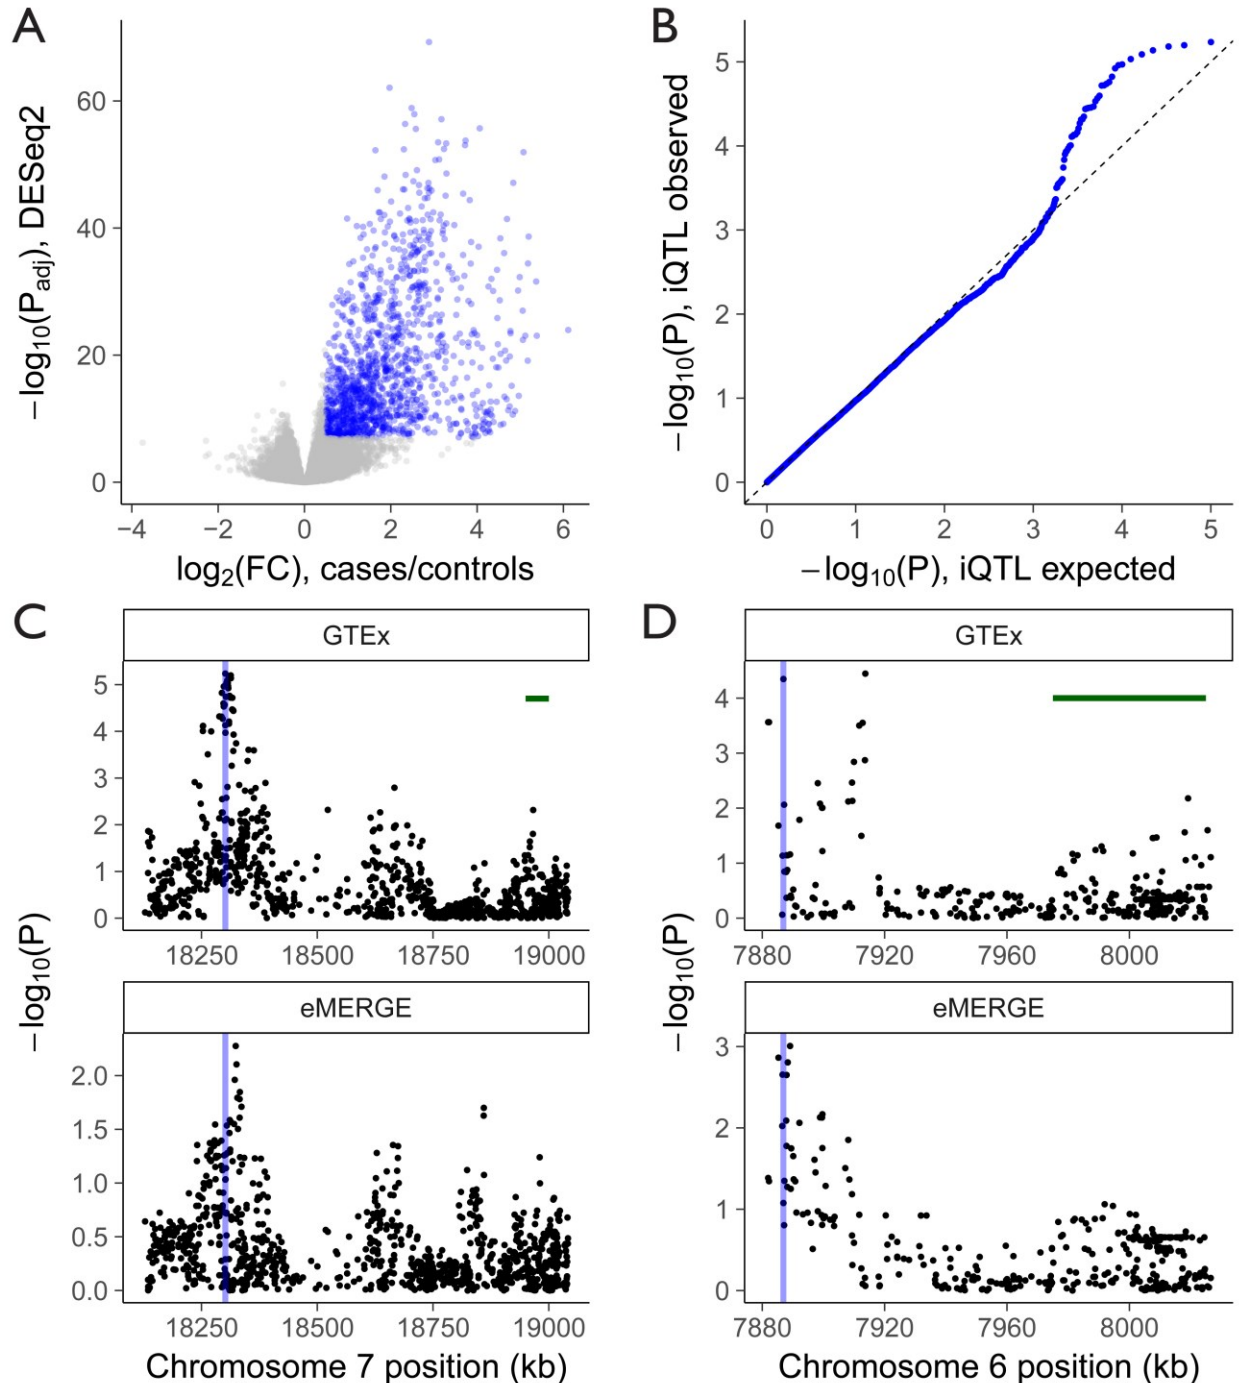

**Acknowledgements:** This work was supported by grants from the US National Institutes of Health, including 5U01CA190234 and 5U24CA194354 (JDB, HJWLA, JQ), 5R01AI099204 (JP, JQ); 5R01HL111759 (JQ, JNP), and 5P50CA127003 (JQ). This work was conducted under dbGaP approved protocols #9112 and #13896.

**Figure 1.** Thyroid image processing and establishment of a quantitative imaging biomarker for Hashimoto's Thyroiditis (HT). **(A)** Digital pathology slide for thyroid sample GTEX-11NV4. Raw: pre image processing. Blurred: post Gaussian convolution. Segmented: tissue piece masks after adaptive thresholding. **(B)** Heatmap of 117  $\log_2$  transformed and standardized Haralick image features against 341 thyroid samples. **(C)** PC1 versus PC2 from a PCA of the image feature matrix. Blue points indicate patients with HT, as identified from pathology notes. Circles indicate females, and triangles males. **(D)** ROC curve showing biomarker performance of PC2 for predicting HT.

**Figure 2.** Integration of imaging data with gene expression analyses verifies that image PC2 is highly associated with autoimmune response. **(A)** A QQ plot of p-values ( $P_G$ ) from the regression analysis of image PC1 and PC2 against thyroid gene expression for 23,993 genes. **(B)** Correlation of image PC2 with  $-\log_{10}(P_C)$  from the CIBERSORT analysis for samples with  $P_C < 0.5$ . Blue points are samples for which Hashimoto's Thyroiditis was indicated in GTEx pathology notes. **(C)** Frequencies of immune cell types reported from CIBERSORT for samples with  $P_C < 0.1$ . Cell types with an average frequency of 5% or more are shown.

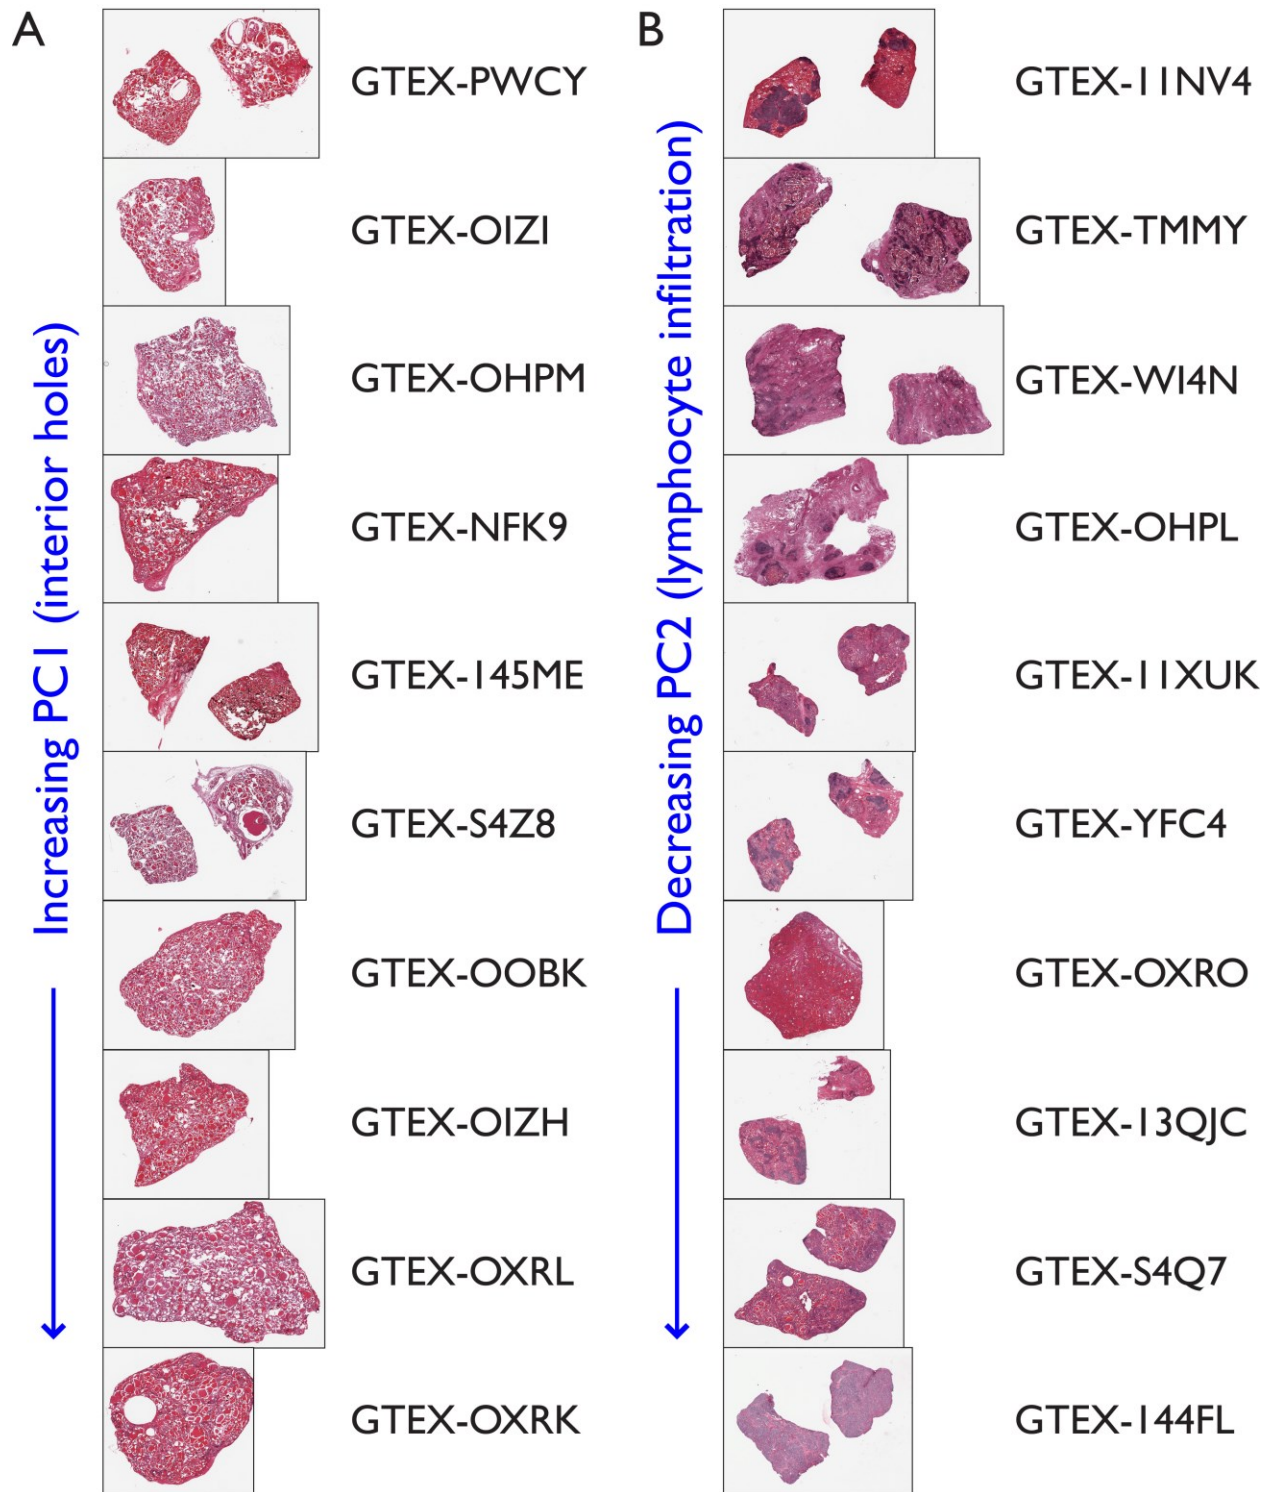

**Figure 3.** An image QTL analysis finds associations between genomic variants and our image PC2 biomarker for thyroid autoimmune disease. **(A)** Selection of 1,380 candidate genes (blue points) based on their positive fold-change ( $\log_2(\text{FC}) > 0.5$ ) and significant differential expression ( $-\log_{10}(P_{adj}) > 7$ ) in GTEx Hashimoto's Thyroiditis (HT) cases. **(B)** A QQ plot showing expected vs observed p-values from image QTL fits of 100,215 candidate SNPs residing in the selected genes highlighted blue in panel A. **(C-D)** A plot of  $-\log_{10}(P)$  for GTEx iQTLs (top panels) and eMERGE variant association with HT (bottom panels) for all tested SNPs in HDAC9 (C) and

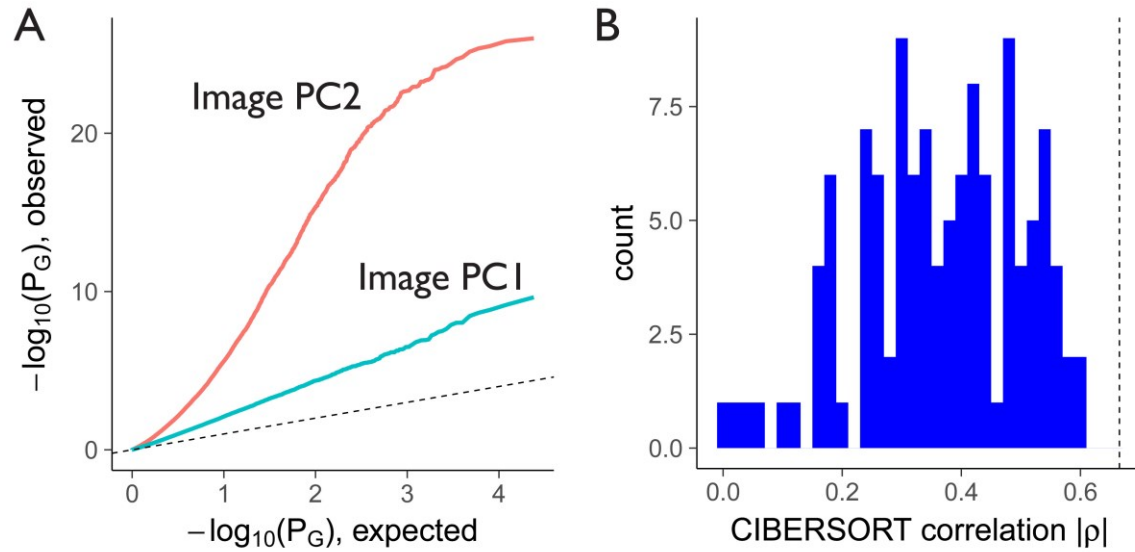

TXNDC5 (D). Blue vertical lines indicate the locations of the most significant SNP for each gene after multiple testing correction using the IHW method described in the main text. Plot ranges are mapped to the start and end positions of the genes, as defined by GTEx-consortium transcript data. Horizontal green bars are of length 50kb.

**Table 1.** Significant gene ontology terms for genes highly associated with image PC2 ( $-\log_{10}(P_G) > 10$ , see Figure 2A) in the gene expression regression analysis. All terms with an odds ratio of greater than 5 and an adjusted p-value of less than 0.01 are shown. BP: Biological Process, CC: Cellular Component.

**Figure S1.** Examples of phenotypes associated with image PC1 and PC2. (A) Images with the 10 lowest values of PC1. Interior holes were observed, many of which were likely associated with tissue damage incurred during sample preparation. (B) Images with the 10 highest values of PC2. Lymphocyte invasion phenotypes were apparent.

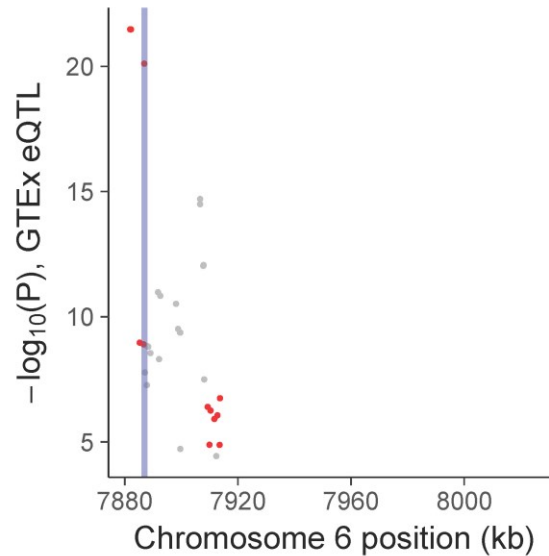

**Figure S2.** (A) QQ plot showing deviation from the dashed line (of slope 1) when fitting image PCs against gene expression while only correcting for the known confounders listed in the main text. Additionally including PEER factors as covariates removed the observed bias (Figure 2A). (B) Histogram of the absolute value of Spearman correlation coefficients between all 117 Haralick image features, and CIBERSORT significance of detection for immune cells. Dashed line indicates the Spearman correlation coefficient for image PC2 ( $\rho=0.67$ ).

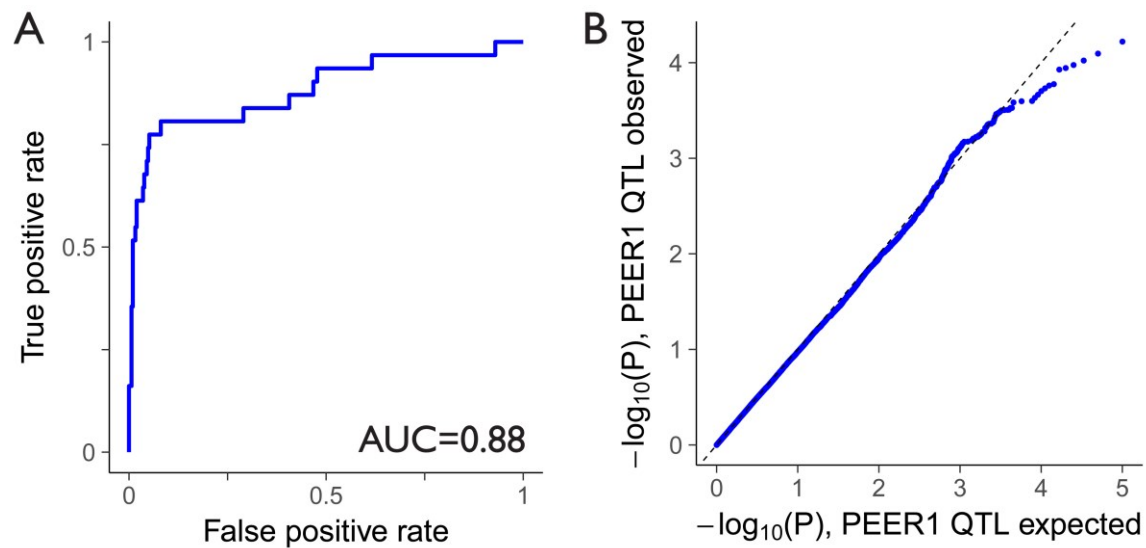

**Figure S3.** (A) Gene expression vs fold-change (FC) between GTEx Hashimoto's Thyroiditis cases and controls. Genes with an adjusted p-value of less than  $10^{-7}$  are colored red. (B) Independent Hypothesis Weighting (IHW) weights as a function of minor allele frequency bin. Each bin corresponds to a change of 0.01 in minor allele frequency between 0.1 and 0.5. Similar profiles for each fold demonstrate the robustness of the IHW fitting procedure.

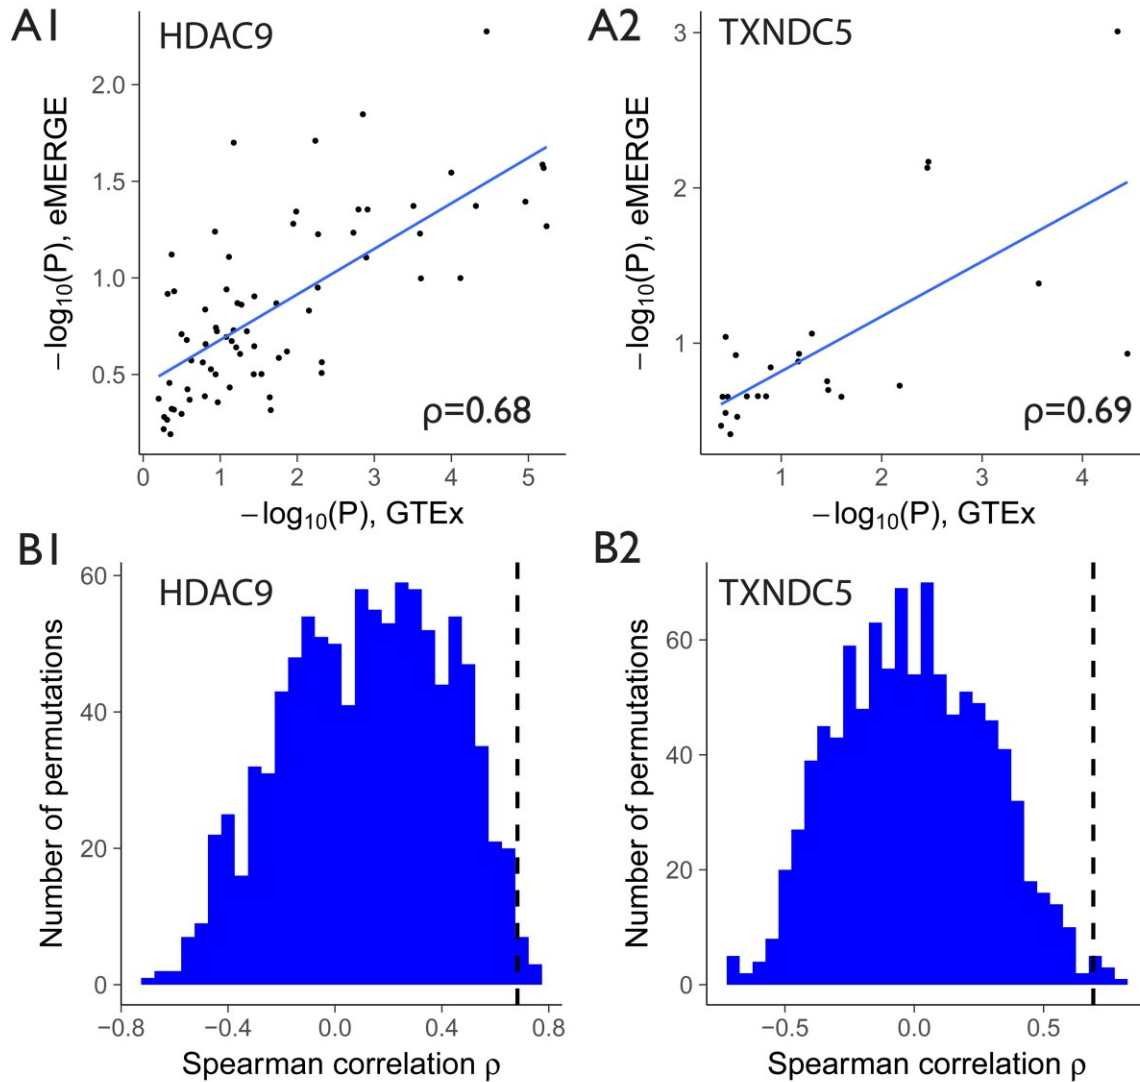

**Figure S4.** Significance of GTEx consortium v6p *cis*-expression QTLs for TXNDC5. Vertical blue line indicates the position of the top iQTL variant, *rs11962800*. Red points are eQTLs that are also iQTLs, or in linkage disequilibrium with iQTLs, as defined by a significance level of  $P_{IHW} < 0.4$  (see Table S2). All significant eQTLs that were also tested in our iQTL analysis are shown. Genomic range is the same as in Figure 3D for comparison.

**Figure S5.** (A) ROC curve showing biomarker performance of the first expression PEER factor (PEER1) for predicting Hashimoto's Thyroiditis. (B) A QQ plot showing expected vs observed p-values from PEER1 QTL fits of 100,215 candidate SNPs residing in the selected genes highlighted blue in Figure 3A.

**Figure S6. (A1-2)** Concordance of the association signature between the GTEx and eMERGE data for HDAC9 (A1) and TXNDC5 (A2). Each point represents the minimum p-value in each bin of size 15 SNPs for each dataset. **(B1-2)** Histograms of GTEx vs eMERGE correlation coefficients after 1,000 logistic regression analyses with permutations of the eMERGE hypothyroidism case/control labels. Dashed lines indicate Spearman correlation coefficients for the non-permuted data displayed in panels A1-2. Permutation p-values are 0.009 for HDAC9, and 0.007 for TXNDC5.

**Table S1.** Image QTLs with significant associations ( $P_{IHW} < 0.05$ ) with our quantitative imaging biomarker for thyroid autoimmune disease.

## Materials and Methods:

**Image Processing:** 341 publicly available GTEx histopathological thyroid images were downloaded from the Biospecimen Research Database (<http://brd.nci.nih.gov/image-search/searchhome>). For the purpose of segmenting individual tissue pieces only, the average intensity across color channels was calculated, and adaptive thresholding was performed to distinguish tissue from background. Interior holes in the tissue piece masks were filled using the *fillHull* function from the Bioconductor package *EBImage* (19). In preparation for feature extraction, Gaussian blurring was used on each color channel to smooth out pixel-level variation on a length scale smaller than the observed lymphocyte invasion phenotypes. 117 textural Haralick features were then extracted using *EBImage* by calculating 13 base Haralick features for each of the three RGB color channels, and across 3 Haralick scales by sampling every 1, 10, or 100 pixels. Image metadata was extracted to verify identical pixel dimensions and scanning instrumentation across the dataset.

**Image Data Analysis:** 702 thyroid pieces were identified from the image segmentation. 49 pieces with overly small areas were removed. Averaged Haralick feature values were then calculated across tissue pieces for each sample. In preparation for downstream model fitting, each distribution was  $\log_2$  transformed and rescaled using a z-score. Five NA feature values were set to zero to avoid technical issues with the PCA fit.

**Gene Expression Analysis:** GTEx v6 RNA-Seq data was downloaded from dbGaP (phs000424.v6.p1, 2015-10-05 release) under approved protocol #9112. Lowly expressed genes were defined as those which had a read count of less than 1 CPM in more than half of the samples, and were removed. Counts were  $\log_2$  transformed after adding 1 to the counts to avoid the problem of taking the logarithm of zero. Quantile normalization was performed using the R package *limma*. Prior to running the gene expression data through CIBERSORT, RNA extraction batch was corrected for using *limma*. PEER factors were calculated using the R package *peer* (github: PMBio/peer). The fitting of image PCs against gene expression was performed using linear models in R with the formula  $PC = \alpha + \beta gene + \sum_k \gamma_k covariate_k + \epsilon$  where covariates included the known confounders and PEER factors, as discussed in the main text. For each gene, p-values were extracted from *t*-statistics associated with the gene expression coefficient  $\beta$ . Differential expression analysis using *DESeq2* (24) was performed using the raw count data, with RNA extraction batch included as a technical covariate. As biological replicates were not available across samples, *DESeq2* estimated dispersion by pooling all samples.

**Genotype Analysis:** GTEx genotype data was downloaded from dbGaP (phs000424.v6.p1, 2015-10-05 release) under approved protocol #9112. A total of 292 genotyped samples overlapped with the thyroid imaging samples. Minor allele frequency and missingness frequency filtering was performed using PLINK. QTL fits were performed using *MatrixEQTL*, which used the following model:  $PC2 = \alpha + \beta genotype + \sum_k \gamma_k covariate_k + \epsilon$ . Genotype could take on the values 0/1/2/NA, and covariates were as described in the main text. QTL significance was extracted from the *t*-statistics associated with the genotype coefficient  $\beta$ . The correction for ancestry was performed by including as covariates the first 3 PCs of a PCA on the genotype matrix computed from the full set of 450 GTEx patients. Haplotypes were identified using PLINK, with a maximum block size of 5,000 kb. The haplotype identification utilized the full set of 450 GTEx samples. Reported genomic coordinates are for human genome build GRCh37/hg19.

eMERGE data was obtained from the study “eMERGE Network Imputed GWAS for 41 Phenotypes” (dbGaP study accession phs000888.v1.p1) under approved protocol #13896 for the consent cohorts Health/Medical/Biomedical (N=18,621) and Health/Medical/Biomedical-Genetic Studies Only-No Insurance Companies (N=15,911). Chromosome 7 genotype data from both cohorts was merged and 5,718 samples were selected based on their status as Chronic Autoimmune Hypothyroidism (accession phd004989.1) cases or controls. Inclusion criteria for hypothyroidism cases (C99269) included, but were not limited to, abnormal TSH/FT4 levels and the use of thyroid replacement medication. Exclusion criteria for hypothyroidism cases included secondary causes of hypothyroidism, hypothyroidism induced by surgery or radiation treatment, evidence of other thyroid diseases, or the use of thyroid-altering medication. Inclusion criteria for hypothyroidism controls (C99270) included no billing codes for hypothyroidism, no use of thyroid replacement medication, and normal TSH/FT4 levels. Exclusion criteria for controls included any evidence of hypo- or hyper-thyroidism, as well as other thyroid diseases, or the use of thyroid-altering medication. The Caucasian cohort was selected for further analysis, as described in the main text. Tests for Hardy-Weinberg Equilibrium (HWE) were performed using PLINK on the Caucasian cohort. One SNP in HDAC9 (*rs2058074*) had a HWE p-value less than  $10^{-6}$  and was removed. Logistic regression models were fitted with the *glm* function in R using the following model:  $\text{logit}(Y) = \alpha + \beta \text{genotype} + \sum_k \gamma_k \text{covariate}_k$ .  $Y$  indicated the binary case/control disease status, genotype could take on the values 0/1/2/NA, and covariates were as described in the main text. Significance was extracted from the  $z$ -statistics associated with the genotype coefficient  $\beta$ . Reported genomic coordinates are for human genome build GRCh37/hg19.

**Statistical Analysis:** To test for associations between HT status and image PC2, we used the following logistic regression model:  $\text{logit}(Y) = \alpha + \beta_1 \text{PC2} + \beta_2 \text{sex} + \beta_3 \text{age}$  where  $Y$  indicated the HT status according to GTEx pathology notes. The significance of association was extracted from the  $z$ -statistics associated with the beta coefficients. Due to co-linearity between sex and image PC2, associations between HT status and sex were assessed using a reduced model without the image PC2 term. Gene-set enrichment tests were performed using a Fisher’s Exact Test for each Gene Ontology term. Multiple-testing correction across terms was performed using the method of Benjamini and Hochberg. Independent Weighting Hypothesis p-value correction on the image QTL results was performed using the Bioconductor software *IHW* (26). The permutation p-values reported for the eMERGE validations were estimated using the formula  $(M + 1)/(N + 1)$  where  $M$  is the number of permutations with a correlation coefficient exceeding that of the non-permuted data, and  $N$  is the total number of permutations.
