Title
Experience-dependent plasticity in accessory olfactory bulb interneurons following male-male social interaction

Abbreviated title
Accessory olfactory bulb inhibitory plasticity

Abstract
Chemosensory information processing in the mouse accessory olfactory system (AOS) guides the expression of social behavior. After salient chemosensory encounters, the accessory olfactory bulb (AOB) experiences changes in the balance of excitation and inhibition at reciprocal synapses between mitral cells (MCs) and local interneurons. The mechanisms underlying these changes remain controversial. Moreover, it remains unclear whether MC-interneuron plasticity is unique to specific behaviors, such as mating, or whether it is a more general feature of the AOB circuit. Here, we describe targeted electrophysiological studies of AOB inhibitory internal granule cells (IGCs), many of which upregulate the immediate-early gene Arc after male-male social experience. Following the resident-intruder paradigm, Arc-expressing IGCs in acute AOB slices from resident males displayed stronger excitation than non-expressing neighbors when sensory inputs are stimulated. The increased excitability of Arc-expressing IGCs was not correlated with changes in the strength or number of excitatory synapses with MCs, but was instead associated with increased intrinsic excitability and decreased HCN channel-mediated I_H currents. Consistent with increased inhibition by IGCs, MCs responded to sensory input stimulation with decreased depolarization and spiking following resident-intruder encounters. These results reveal that non-mating behaviors drive AOB inhibitory plasticity, and indicate that increased MC inhibition involves intrinsic excitability changes in Arc-expressing interneurons.
Significance Statement: The accessory olfactory bulb (AOB) is a site of experience-dependent plasticity between excitatory mitral cells (MCs) and inhibitory internal granule cells (IGCs), but the physiological mechanisms and behavioral conditions driving this plasticity remain unclear. Here, we report studies of AOB neuronal plasticity following male-male social chemosensory encounters. We show that the plasticity-associated immediate-early gene Arc is selectively expressed in IGCs from resident males following the resident-intruder assay. After behavior, Arc-expressing IGCs are more strongly excited by sensory input stimulation and MC activation is suppressed. Arc-expressing IGCs do not show increased excitatory synaptic drive, but instead show increased intrinsic excitability. These data indicate that MC-IGC plasticity is induced after male-male social chemosensory encounters, resulting in enhanced MC suppression by Arc-expressing IGCs.
Introduction

A central goal in neuroscience is to understand how sensory processing in the brain guides behavior. The mammalian accessory olfactory system (AOS) is an attractive neural pathway for studying the processes linking sensation and behavior because the AOS has a relatively linear circuit pathway into the brain and drives a variety of social behaviors (reviewed in Liberles, 2014). In the AOS, sensory information is generated in the vomeronasal organ (VNO) and processed by a single dedicated neural circuit, the accessory olfactory bulb (AOB), before being sent to limbic structures including the medial amygdala and bed nucleus of the *striata terminalis* (Scalia and Winans, 1975). Animals lacking proper AOS signaling display a range of atypical behaviors, including deficits in predator avoidance (Papes et al., 2010; Perez-Gomez et al., 2015), courtship (Pankevich et al., 2004; Kimchi et al., 2007; Ferrero et al., 2013), and territorial aggression (Stowers et al., 2002; Chamero et al., 2007; Leinders-Zufall et al., 2014). Though many of these behaviors are considered innate, behavioral and physiological evidence suggests that the AOB is a site of experience-dependent plasticity. This has been best studied in the context of pregnancy block, in which a female forms a chemosensory memory of her recent mate, but remains unexplored in the context of other AOS-mediated social behaviors (Bruce, 1959; Brennan et al., 1990).

There is still much to learn about how the AOB contributes to plasticity in social behaviors. In pregnancy block, one hypothesis proposes that inhibitory gain limits activation of AOB projection neurons, called mitral cells (MCs) to the chemosensory cues of a recent mate (reviewed in Brennan, 2009). Increased inhibition involves changes at reciprocal dendro-dendritic synapses between MCs and AOB interneurons.
(Brennan et al., 1990; Araneda and Firestein, 2006; Larriva-Sahd, 2008; Brennan, 2009; Smith et al., 2009). It remains unclear whether such inhibition is induced by other social chemosensory encounters, and the specific neuronal populations that contribute to these effects are not yet clear.

Immediate early genes (IEGs) are expressed in recently active neurons and can provide extensive information about the cells and networks that participate in sensory and behavioral experiences (Kawashima et al., 2013; Kim et al., 2015; Vousden et al., 2015). The IEG Arc is both an important plasticity-related gene and a useful marker of neuronal populations engaged by experience (reviewed in Shepherd and Bear, 2011). Arc is typically expressed in principal excitatory neurons (e.g., cortical and hippocampal pyramidal neurons), where it mediates many forms of experience-dependent synaptic plasticity (Plath et al., 2006; Vazdarjanova et al., 2006; Jakkamsetti et al., 2013). Studies of Arc expression in the AOB show that it is selectively upregulated in subsets of AOB internal granule cells (IGCs), but not MCs, in male and female rodents after mating (Matsuoka et al., 2002a; Matsuoka et al., 2003). Arc expression by interneurons has also been noted in the main olfactory bulb in several studies (Guthrie et al., 2000; Vazdarjanova et al., 2006; Shakhawat et al., 2014). The selective expression of Arc by interneurons is atypical, and studying these populations is likely to provide new insights into the role of Arc in non-principal neuronal types.

Here, we report that Arc is selectively expressed in posterior AOB IGCs of male mice following the resident-intruder territorial aggression assay. Arc upregulation by IGCs required intact vomeronasal signaling, indicating that centrifugal inputs were not sufficient to induce Arc in this behavioral paradigm. Following resident-intruder
behavior, Arc-expressing IGCs in resident males showed enhanced network excitation compared to non-expressing IGCs, while MC activity was suppressed. We investigated the IGC physiological features that underlie their enhanced activity and found no evidence for an increase in excitatory synapse strength or number. Instead, we found that Arc-expressing IGCs display a robust increase in intrinsic excitability compared to other IGCs. Our results show that AOB inhibitory plasticity occurs after non-mating behaviors, and reveal cellular mechanisms underlying MC inhibition after chemosensory social encounters.

**Materials and Methods**

**Mice**

All animal procedures were in compliance with the UT Southwestern Institutional Care and Use Committee. Sexually-naïve adult male mice aged 6-12 weeks were housed on a customized 12/12 light cycle with the lights on from noon until midnight. Food and water were provided *ad libitum*. Arc-d4EGFP-BAC (a kind gift from Pavel Osten via Kimberly Huber; Grinevich et al., 2009) and Arc<sup>Im1St</sup> (“Arc-/-“ or “Arc-d2EGFP”; Jackson Labs Stock # 007662; RRID:IMSR_JAX:007662; Wang et al., 2006) mice were generous gifts from Kimberly Huber. Trpc2<sup>tm1Dlc</sup> (“Trpc2-/-“ Jackson Labs Stock # 021208; RRID:IMSR_JAX:021208; Stowers et al., 2002) and Gt(ROSA)26So<sup>tm9(CAG-tdTomato)Hze</sup> (“Ai9” Jackson Labs Stock # 007905; RRID:IMSR_JAX:007905; Madisen et al., 2010) mice were obtained from Jackson Laboratory. A total of 119 mice were used in this study.
Behavior

Resident male mice were individually housed on corn cob bedding, without cage changes, for one week prior to the experiment. All behavior occurred during the dark phase (Zeitgeber time 20-24 h) in a dimly lit room to facilitate video recording. After a 10-minute habituation period, a BALB/cJ male intruder mouse was introduced to the resident cage for 10-minute encounter. To test the response to soiled bedding alone, a small petri dish was filled with bedding from a cage of 4 BALB/cJ males that had gone without cage changes for one week. This petri dish was introduced to the resident’s cage for 10 minutes instead of an intruder animal.

Live slice preparation

Animals were anesthetized with isofluorane and decapitated 3 hours after the resident-intruder paradigm was completed unless otherwise specified. Brains were dissected and 400 µm parasagittal sections of the AOB were prepared using a Leica VT1200 vibrating microtome in ice-cold, oxygenated artificial cerebrospinal fluid (ACSF). ACSF contained (125 mM NaCl, 2.5 mM KCl, 2 mM CaCl₂, 1 mM MgCl₂, 25 mM NaHCO₃, 1.25 mM NaH₂PO₄, 25 mM glucose, 3 mM myo-inositol, 2 mM Na-pyruvate, 0.4 mM Na-ascorbate) with an additional 9 mM MgCl₂ in the slicing buffer. After slicing, the slices were kept in a recovery chamber at room temperature (22 °C) containing ACSF with 0.5 mM kynureninic acid to prevent potential glutamate excitotoxicity during the recovery/holding period. Just prior to recordings, slices were transferred to a slice chamber (Warner Instruments) mounted on a fluorescence- and differential interference contrast imaging-equipped upright microscope (FN1 Model, Nikon). Oxygenated ACSF
was superfused via a peristaltic pump (Gilson) at a rate of 1-2 mL/min throughout. Slice
temperature was maintained at 32-33 °C via inline and chamber heaters (Warner
Instruments).

2-photon imaging and image analysis

Image stacks up to 200 µm deep were acquired using an excitation wavelength of
890 nm and a 40x (1.0 NA) water-immersion objective (Olympus). Images were
denoised using a 3D median filter and deconvolved using a model point spread function
in ImageJ (RRID:SCR_003070). Fluorescent cells were counted using a 3D object
counting add-on (Bolte and Cordelieres, 2006). Cell counts were normalized to the
volume of the cell layer of interest. $I_{Arc\text{sum}}$ was computed as follows:

$$I_{Arc\text{sum}} = \frac{\sum_{i=1}^{n} I_{Arc(i)}}{x \ \mu m^3}$$

where $I_{Arc(i)}$ is the normalized brightness of each cell ($I_{Arc(i)} = \frac{B_i}{K}$), $B_i$ is the mean pixel
intensity within cellular region of interest $i$, $K$ is the mean pixel intensity within the ICL
but outside cellular regions of interest, and $x$ is the total volume within the imaged
portion of the ICL. This metric combines relative brightness of all identified cells and is
normalized by the imaged volume to facilitate comparisons across experimental
preparations.

Immunohistochemistry

Following behavior, animals were briefly anesthetized with inhaled isofluorane, then
injected with a ketamine/xylazine cocktail (120 mg/kg ketamine/16 mg/kg xylazine dose)
and transcardially perfused with 0.01 M PBS followed by 4% paraformaldehyde in PBS.
Brains were post-fixed in 4% paraformaldehyde in PBS overnight. Brains were then cryoprotected overnight in PBS containing 25% sucrose, embedded in OCT compound (TissueTek), and flash frozen. 30 µm sections were prepared using a Leica CM3050 S cryostat and processed free-floating. Sections were rinsed 4x in 0.01 M PBS, incubated in 0.1% Triton X in PBS for 2 hours, rinsed 3x, incubated in 10% goat serum in PBS for 2 hours, and incubated in primary antibody in primary block (0.1% Triton X, 10% goat serum in PBS) overnight at 4 °C. Sections were then rinsed 3x in PBS and incubated in secondary antibody in secondary block (0.1% Triton X, 5% goat serum) for 2 hours. Sections were rinsed 3x, incubated in 500 nM DAPI in PBS, and rinsed 3x again. Sections were then mounted on slides in Fluoromount-G mounting medium (SouthernBiotech). Anti-Arc primary antibody specificity (Synaptic Systems #156003 rabbit polyclonal, RRID:AB_887694) was verified using Arc−/− mice and was used at 1:1000. Anti-GFP primary (Abcam #ab13970 chicken polyclonal, RRID:AB_300798) was used at 1:500. Goat anti-rabbit AF633 (Molecular Probes Cat# A21070, RRID:AB_2535731) and goat anti-chicken AF488 (Molecular Probes Cat# A11039, RRID:AB_142924) were both used at 1:2000 dilution.

Biocytin amplification of filled neurons was achieved using streptavidin-Alexa Fluor 568 (ThermoFisher #S11226, RRID:AB_2315774). Slices were washed in PBS 3x for 30 minutes each. Slices were then incubated in a blocking solution containing 0.5% TritonX and 10% goat serum in PBS for 2 hours, followed by the same blocking solution containing streptavidin-AF568 at 0.01mg/mL for 4 hours. Slices were then rinsed 3x for 30 min each, and mounted on slides in Fluoromount-G mounting medium.
For the experiments in Figs. 2 and 5, immunostained sections were imaged with a 40x (1.3 NA) oil immersion objective on an LSM 510 inverted confocal microscope (Zeiss). For the experiments in Fig. 1, immunostained sections were imaged with a Zeiss Axioscan.Z1 using a 20x (0.8 NA) air objective. Cells were counted manually using ImageJ by a scorer blinded to the experimental condition. Anterior-posterior index was calculated using custom MATLAB software. Spines were counted and morphological analysis performed using the Simple Neuron Tracer plugin for ImageJ (Longair et al., 2011) by a scorer blinded to experimental conditions. Spines were counted on the 100 µm of primary dendrite in the external cellular layer (ECL) starting at the edge of the lateral olfactory tract.

**Electrophysiology**

Whole cell patch-clamp recordings were made on d4EGFP+ and d4EGFP- IGCs during a window spanning 4-8 hours following behavior. Thin wall borosilicate glass electrodes with a tip resistance between 4 and 12 MΩ were filled with internal solution containing (in mM) 115 K-gluconate, 20 KCl, 10 HEPES, 2 EGTA, 2 MgATP, 0.3 Na₂GTP, 10 Na phosphocreatine at pH 7.37. All recordings were amplified using a MultiClamp 700B amplifier (Molecular Devices) at 20 kHz and were digitized by a DigiData 1440 analog-digital converter controlled via pClamp 10.5 software (Molecular Devices, RRID:SCR_011323). Data were analyzed by Clampex 10.5 (Molecular Devices) and custom software written in MATLAB.

For glomerular stimulation experiments, a theta glass stimulating electrode was placed in the glomerular layer while recordings were made from IGCs. A series of 0.3
11 ms single pulses was used to construct input-output curves (Stimulus Isolator A365RC, World Precision Instruments), and the stimulation intensity for 20 Hz trains was the highest sub-saturating value from the input-output analysis. One d4EGFP+ and one d4EGFP– neuron were recorded per slice (one at a time). The d4EGFP+ neuron was recorded first in 6/10 pairs. Input-output curves were generated for each neuron, but the stimulation intensity used for both was chosen based on the first neuron recorded. Prior to MC recordings, we confirmed that stimulus conditions effectively recruited IGCs through direct IGC patch clamp recordings (23/24 recordings).

For mEPSC recordings, 5 minutes of baseline activity was recorded, then 1µM TTX was washed on for 5 minutes, and 5 minutes of post-drug activity was recorded. Biocytin (3 mg/mL) and/or AlexaFluor568 (166 µM) was added to the internal solution to visualize dendritic arbors and spines. After filling, slices were fixed in 4% PFA in PBS for one hour, and then stored in PBS at 4°C.

To assess intrinsic electrophysiological features, we subjected patched AOB neurons to a series of current clamp and voltage clamp challenges. Immediately after achieving the whole cell configuration, each cell’s resting membrane potential (V_{rest}) was measured in current clamp mode. To standardize measurements across cells with different V_{rest}, we injected steady-state currents to maintain each cell’s membrane potential (V_m) between -70 and -75 mV. Based on initial measurements of input resistance (R_{input}), we empirically determined the amplitude of hyperpolarizing current that adjusted V_m by -50 mV (to ~-125 mV). After determining this initial current injection amplitude, we generated a cell-specific 10-sweep Clampex protocol that applied increasingly depolarizing 0.5 s square current pulses, starting with the initial injection
amplitude. For example, if the initial current injection was determined to be -100 pA, the 10-sweep protocol would have current injection increments of +20 pA (i.e., -100 pA, -80 pA, -60 pA, ..., +80 pA). If the initial depolarization was determined to be -125 pA, the protocol would include increments of +25 pA, etc. This strategy allowed us to objectively challenge cells with widely varying $V_{rest}$ and $R_{input}$. In voltage clamp, cells were initially held at -70 mV, and a series of 12 voltage command steps (0.5 s in duration) were applied that spanned -100 mV to +10 mV.

For each cell, both current clamp and voltage clamp protocols were applied up to 4 times, and all reported quantities represent the mean responses across repeated trials. Twenty-six specific intrinsic parameters were extracted from each cell using custom software written in MATLAB. A description of the parameters in Figure 6A and the formulas used to calculate them is presented in Table 1. $I_H$ current ratio (Fig. 6G) was calculated using the formula

$$\frac{I_{init} - I_{ss}}{I_{init}}$$

where $I_{init}$ is the mean initial current (measured between 10 and 160 ms following the voltage pulse) and $I_{ss}$ is the mean steady-state current (measured between 420 and 470 ms after the voltage pulse) generated by a voltage command step from -70 mV to -100 mV. EPSCs were automatically detected and later separated from noise using a custom computer assisted waveform-based event sorting program written in MATLAB (Hendrickson et al., 2008). EPSC decay was measured by calculating the best fit exponentially-decaying line for the decay period of the EPSC. Initial action potential rising slope was calculated by measuring the peak of the first derivative of voltage with respect to time (dV/dt). Threshold was defined as $V_m$ at the time the dV/dt voltage
reached 10% of its peak value (similar to Meeks et al., 2005). Membrane capacitance and input resistance were calculated according to current clamp-based multi-compartmental algorithms (Golowasch et al., 2009). Briefly, the voltage response of each cell to a hyperpolarizing current step was fit with a series of multi-exponential curves, and the best fit determined by identifying the solution with the lowest value of the Bayesian Information Criterion (to avoid over-fitting).
Results

Arc expression is upregulated in posterior AOB IGCs following resident-intruder encounters

Arc is expressed in IGCs in rodents shortly after mating, an AOS-mediated behavior that induces pheromonal memory formation in females (Bruce and Parrott, 1960; Brennan et al., 1995; Matsuoka et al., 2002a; Matsuoka et al., 2003). If experience-dependent plasticity in the AOB is a more general response to chemosensory social events, we hypothesized that the social chemosensory encounters associated with male-male territorial aggression, which is AOS-mediated, would induce AOB plasticity. We used the resident-intruder paradigm, known to encourage AOS-dependent territorial aggression between males, as our behavioral challenge (Maruniak et al., 1986; Stowers et al., 2002). Adult male wild-type C57BL/6J residents were housed individually for one week and then exposed to adult male BALB/cJ intruders for 10 minutes. Arc protein expression was significantly increased 90 minutes after the behavior in AOB IGCs of resident males compared to controls (Wilcoxon-Mann-Whitney test, p<0.0001, Fig. 1A-D). Previous studies indicated that male-male resident-intruder encounters increase Fos expression in the posterior AOB (pAOB), which is selectively innervated by vomeronasal sensory neurons (VSNs) that express members of the V2R subfamily of vomeronasal receptors (Belluscio et al., 1999; Kumar et al., 1999; Rodriguez et al., 1999; Chamero et al., 2007). Consistent with these results, Arc protein expression after the resident-intruder paradigm was selectively upregulated in pAOB IGCs (Wilcoxon-Mann-Whitney test, p<0.001, Fig. 1E). These initial results show that Arc expression in IGCs following resident-intruder behavior is similar to Arc expression following mating.
behavior, and suggest that Arc expression occurs in an interneuron population that might increase MC inhibition after resident-intruder encounters.

*Arc-d4EGFP-BAC tools mark Arc-expressing IGCs in a time- and chemosignal-dependent manner*

To identify Arc-expressing IGCs in live tissue, we utilized Arc-d4EGFP-BAC reporter mice (Grinevich et al., 2009). In these mice, a destabilized form of EGFP with a 4-hour half-life (d4EGFP) is expressed under control of the Arc promoter on a bacterial artificial chromosome, leaving endogenous Arc unperturbed. To assess the Arc-d4EGFP-BAC reporter, we used Arc-d4EGFP-BAC male mice as residents in the resident-intruder paradigm. We sacrificed animals at various time points following behavior (Fig. 2A) and compared Arc protein and d4EGFP immunostaining levels to controls (no intruder, BALB/cJ male soiled bedding only, Fig. 2A-D). Arc protein expression began rising by 30 minutes post-behavior, peaked 1-2 hours post-behavior and returned to baseline by 4 hours post-behavior (one-way ANOVA, F(7,11)=18.64, p<0.0001, n = 1-2 mice and 2-3 sections per condition, 11 mice and 19 sections overall, Fig. 2A, C). d4EGFP levels increased significantly by 1 hour post-behavior and remained elevated at 4 hours post-behavior (one-way ANOVA, F(7,11)=13.07, p=0.0002, Fig. 2 A, D). We observed strong colocalization between the Arc protein and d4EGFP signals, while some cells showed d4EGFP signal but no Arc protein in the cell soma. This effect could be explained by the fact that Arc protein is often localized to the dendrites (Shepherd and Bear, 2011), and that low levels of d4EGFP expression (indicating low level Arc transcription) were boosted by immunostaining.
Because d4EGFP immunostaining boosts very weak signals, we wanted to test whether d4EGFP expression alone was sufficient to identify Arc-expressing cells in living tissue. Live 2-photon imaging of acute AOB slices from Arc-d4EGFP-BAC residents revealed robust d4EGFP expression starting at 3 hours post-behavior and remaining strong until 6 hours post-behavior (Fig. 2E). Thus, unamplified d4EGFP signals lag behind the immunostaining time course, which is likely due to differences in antibody-amplified versus native d4EGFP signal. Importantly, the time window including the strongest behaviorally-driven d4EGFP expression was well-aligned with the time course of acute slice electrophysiological experiments, making the Arc-d4EGFP-BAC mice a strong tool for investigating the physiological properties of Arc-expressing IGCs.

Before we tested Arc-expressing IGC physiology, we wanted to determine whether d4EGFP expression required AOS sensory activation. This was important because different salient behaviors can activate centrifugal input into the entire olfactory bulb (Shipley et al., 1985; Brennan et al., 1990; Nunez-Parra et al., 2013; Rothermel et al., 2014; Oettl et al., 2016). Previous studies of AOB IEG expression indicated that chemosensory stimulation alone (soiled bedding) is sufficient to induce Arc expression and that social interaction increases this effect (Matsuoka et al., 2002b). Having confirmed that AOS chemosensory stimulation alone was sufficient to induce robust Arc expression (Fig. 2B-D), we wanted to next determine whether AOS activation was necessary for Arc expression. To accomplish this, we backcrossed Arc-d4EGFP-BAC reporter mice into a Trpc2−/− background. Trpc2, which is expressed in all vomeronasal sensory neurons and a small percentage of main olfactory sensory neurons, is required for proper chemosensory transduction (Omura and Mombaerts, 2014). Thus, Trpc2−/−
mice have severely disrupted vomeronasal chemosensory transduction and profound changes to AOS-mediated behaviors while retaining most main olfactory function (Stowers et al., 2002; Kimchi et al., 2007; Papes et al., 2010). We introduced Arc-d4EGFP-BAC, Trpc2\(^{-/-}\) resident males to BALB/cJ male intruders and imaged acutely-prepared live AOB slices using 2-photon microscopy 4 hours post-behavior, a time of robust d4EGFP expression after resident-intruder behaviors (Fig. 3). We quantified d4EGFP expression in the posterior ICL for \(\text{Trpc2}^{+/+}\), \(\text{Trpc2}^{+/–}\), and \(\text{Trpc2}^{-/-}\) animals exposed to intruders, as well as \(\text{Trpc2}^{+/+}\) residents that were left alone in an empty cage (no intruder) for 10 minutes (Fig. 3 A-F). Compared to the \(\text{Trpc2}\) wild-type, all other groups showed significantly reduced \(d4EGFP\) expression (one-way ANOVA F(3,26)=22.75, \(p<0.0001\), Fig. 3F). This reduction occurred despite the fact that \(\text{Trpc}^{-/-}\) animals do not display deficits in olfactory social investigation (Stowers et al., 2002).

Total d4EGFP intensity in \(\text{Trpc2}^{-/-}\) animals exposed to intruders matched that of \(\text{Trpc2}^{+/+}\) animals left alone in an empty cage, indicating that sensory input from VSNs is necessary for the elevated \(\text{Arc}\) expression in AOB IGCs (Fig. 3F). These results show that \(\text{Arc-d4EGFP-BAC}\) reporter mice label \(\text{Arc}\)-expressing IGCs in living AOB tissue, and show that VSN activation is both necessary and sufficient to induce AOB \(\text{Arc}\) expression after resident-intruder encounters.

\textit{Arc-expressing IGCs respond strongly to glomerular stimulation}

Previous work showed experience-dependent increases in inhibitory tone in the AOB following salient social behavior, suggesting that IGCs increase their inhibitory influence on MC output (Brennan et al., 1990; Brennan et al., 1995). If the IGCs expressing \(\text{Arc}\)
after social chemosensory interactions contribute to AOB experience-dependent plasticity, we hypothesized that Arc-expressing IGCs would respond differently to AOB sensory input than non-expressing IGCs. To test this hypothesis, we made targeted whole cell patch clamp recordings from Arc-expressing (d4EGFP+) and non-expressing (d4EGFP−) IGCs in acute slices 4-8 hours after resident-intruder experiments (Fig. 4). To simulate sensory activity, we electrically stimulated VSN fibers in the AOB glomerular layer using theta-glass electrodes. Stimulating the glomerular layer induces glutamate release from VSN terminals and activates downstream MCs, which in turn activate IGCs at dendro-dendritic synapses (Fig. 4A). Thus, IGC activation resulting from VSN terminal stimulation is a di-synaptic effect. In voltage clamp, Arc-expressing IGCs showed increased single pulse EPSC charge transfer and peak current amplitude compared to non-expressing IGCs across stimulus intensities (paired, 2-tailed Student’s t-test, p<0.05, n=10 slices across 7 mice Fig. 4B-F). d4EGFP+ IGCs were recorded first in 6/10 experiments, so we investigated possible order effects by comparing these same responses based on the recording order (Fig. 4D, F). We found no differences in this comparison (paired, 2-tailed Student’s t-test, p>0.05), indicating that order effects cannot explain the increased excitability of d4EGFP+ IGCs. In order to evaluate the physiological relevance of these responses, we approximated strong MC activation by delivering a 3 s, 20 Hz train of stimuli to glomerular layer (matching MC firing rates measured during direct chemosensory stimulation of the VNO; Meeks et al., 2010). In current clamp, d4EGFP+ IGCs responded to trains with increased peak amplitudes, which were also sustained throughout the 3 second stimulus (repeated measures ANOVA, main effect of group F(1,18)=4.51, p=0.048, Fig. 4G-H). This effect was
eliminated when the same data was organized based on recording order (repeated measures ANOVA, no main effect of group F(1,18)=0.03, p=0.87, Fig. 4I). In voltage clamp, the same d4EGFP+ IGCs responded to stimulus trains with significantly greater charge transfer than d4EGFP− IGCs and sustained this increase throughout the 3 seconds of stimulation (repeated measures ANOVA, main effect of group F(1,18)=5.52, p=0.03, Fig. 4J). As before, this effect was not due to an effect of recording order (repeated measures ANOVA, no main effect of group F(1,18)=0.07, p=0.79, Fig. 4K). These data indicate that Arc-expressing IGCs are more engaged by sensory input stimulation, which may reflect enhanced MC-IGC synaptic communication or increased IGC intrinsic excitability. These data also suggest that Arc-expressing IGCs may contribute to experience-dependent MC inhibition.

Arc-expressing IGCs do not possess increased synapse strength or density

We hypothesized that the increased activation of Arc-expressing IGCs was due to a change in the number of MC-IGC synapses or a change in MC-IGC synaptic strength. To test these hypotheses, we recorded spontaneous and miniature EPSCs (sEPSCs and mEPSCs, respectively) from d4EGFP+ and d4EGFP− IGCs (Fig. 5). Arc-expressing IGCs did not exhibit a significant difference in sEPSC or mEPSC amplitude or frequency (Wilcoxon-Mann-Whitney test, p>0.05, Fig. 5A-C). In these experiments, biocytin was included in the recording pipette to allow post hoc analysis of dendrite morphology and dendritic spine density. Analysis of IGC dendrites showed a trend towards slightly lower spine densities in Arc-expressing IGCs compared to non-expressing IGCs (Wilcoxon-Mann-Whitney test, p=0.0556, Fig. 5D-E). Similarly there were no differences in
average dendritic branch length (d4EGFP+: 485.3 ± 115.7 µm n=6, d4EGFP-: 365.5 ± 57.2 µm n=8, Wilcoxon-Mann-Whitney test, p=0.57), maximum dendritic branch length (d4EGFP+: 1813 ± 149.4 µm n=6, d4EGFP-: 1548 ± 231.4 µm n=8, Wilcoxon-Mann-Whitney test, p=0.41), or number of branches (d4EGFP+: 17.5 ± 4.75 branches n=6, d4EGFP-: 14.3 ± 1.89 branches n=8, Wilcoxon-Mann-Whitney test, p=0.59). Taken together, these results indicate that changes in IGC synaptic strength or number cannot explain the increased responses to glomerular stimulation in Arc-expressing IGCs.

Arc-expressing IGCs possess enhanced intrinsic excitability

Lacking support for our initial hypothesis, we turned to an alternative, which was that Arc-expressing IGCs respond more strongly to VSN input stimulation due to changes in intrinsic properties. We utilized a systematic approach in order to assess possible intrinsic physiological differences in an unbiased way. We targeted whole-cell patch-clamp recordings to Arc-expressing and non-expressing IGCs 4-8 hours post-behavior and delivered a series of electrophysiological challenges in current and voltage clamp. Using automated algorithms (See Experimental Procedures), we quantified 26 physiological characteristics covering a variety of intrinsic properties (Table 1). To capture the differences between Arc-expressing and non-expressing IGCs, we performed cluster analysis on the 26-dimensional array of characteristics from 100 neurons that had undergone the same electrophysiological challenges (Fig. 6A-B). This collection of cells contained 26 d4EGFP+ and 23 d4EGFP- cells, along with 39 control IGCs from mice that had not undergone behavioral challenges and 12 MCs (used as a control population; Fig. 6A-B). 4 clusters were identified by this analysis. 69.2% of all
d4EGFP+ IGCs were assigned to Cluster 3, where neurons exhibited sustained strong spiking activity in response to depolarization and lower levels of spike accommodation. Other intrinsic characteristics, including input resistance, resting membrane potential and action potential threshold, were highly variable across cells in this cluster, indicating that increased IGC firing frequency was not associated with a systematic change in these other properties.

In assessing individual intrinsic properties, few differed significantly between d4EGFP+ and d4EGFP– IGCs (Fig. 6C-H). The most noteworthy individual characteristic was an increase in spiking frequency in response to strong somatic depolarization in Arc-expressing IGCs (Wilcoxon-Mann-Whitney test, p<0.0001, Fig. 6D). d4EGFP+ IGCs demonstrated an increase in the maximal slope of initial action potentials (Wilcoxon-Mann-Whitney test, p<0.05, Fig. 6E), which was not a result of increased sodium current peak amplitudes (d4EGFP+: 2.33 ± 0.22 nA, d4EGFP–: 2.02 ± 0.14 nA, Wilcoxon-Mann-Whitney test, p=0.49) or spike threshold (d4EGFP+: -23.5 ± 1.5 mV, d4EGFP–: -23.0 ± 1.3 mV, Wilcoxon-Mann-Whitney test, p=0.53).

Arc-expressing IGCs also exhibited a slight decrease in hyperpolarization-activated cation (I_H) currents (Fig. 6G), which we confirmed by measuring the currents blocked by the HCN channel antagonist ZD7288 (10 µM; Wilcoxon-Mann-Whitney test, p<0.05, Fig. 6H). Because IGCs have high input resistance (1.0 ± 0.17 GΩ, n = 54 IGCs), small amplitude I_H currents resulted in prominent depolarization (“sag” potential) measured at the soma (d4EGFP+: 5.81 ± 0.62 mV, d4EGFP–: 8.37 ± 0.90 mV, Wilcoxon-Mann-Whitney test, p=0.11). These basic I_H measurements were made after step hyperpolarization from a steady-state membrane potential near -70 mV, which may
have obscured $I_H$ conductances open near IGC resting potential. To measure the contributions of such conductances, we subtracted $I_H$ sag potentials (reflecting conductances activated by the transition from $\approx -70$ to $\approx -125$ mV) from rebound depolarizations that occurred after the hyperpolarizing pulses (reflecting all $I_H$ conductances). This analysis revealed a larger relative contribution of $I_H$ conductances near resting potential in d4EGFP+ IGCs compared to d4EGFP– IGCs, suggesting a slight shift in the voltage-dependence of activation of HCN channels (d4EGFP+: 1.33 ± 0.57 mV, d4EGFP–: 0.23 ± 0.47 mV; Mann-Whitney-Wilcoxon test, $p = 0.059$). At face value, these $I_H$ results were somewhat surprising. However, modulation of $I_H$ has been reported in Arc-dependent plasticity elsewhere in the brain (Shah, 2014). In many cases downregulation of $I_H$ has been associated with increased neuronal excitability (Poolos et al., 2002; Brager and Johnston, 2007; Campanac et al., 2008; Yi et al., 2016).

It may be possible that Arc is required for the expression of experience-dependent increases in IGC excitability. To investigate this hypothesis, we utilized Arc-d2EGFP knock-in/knock-out animals (Wang et al., 2006). In Arc$^{-/-}$ animals, d2EGFP is expressed in neurons that would normally express Arc. We repeated our intrinsic electrophysiological assay in acute slices taken from Arc$^{-/-}$ male residents. d2EGFP+ IGCs in Arc$^{-/-}$ mice showed no differences in maximum spiking frequency (d2EGFP+: 34.34 ± 4.64 Hz, $n=16$, d2EGFP–: 27.25 ± 4.38 Hz, $n=12$, $p=0.30$ Wilcoxon-Mann-Whitney test), $I_H$ sag potential (d2EGFP+: 7.15 ± 0.71 mV, $n=20$, d2EGFP–: 7.80 ± 1.31 mV, $n=14$, Wilcoxon-Mann-Whitney test, $p=0.45$), or $I_H$ currents ($I_H$ current ratio d2EGFP+: 0.173 ± 0.025, $n=17$, d2EGFP–: 0.155 ± 0.029, $n=14$, Wilcoxon-Mann-Whitney test, $p=0.80$) compared to d2EGFP– IGCs from the same slices. These results
suggest that Arc is required for the observed differences in excitability between Arc-expressing and non-expressing IGCs following male-male social interaction.

**MC responses to glomerular stimulation are suppressed following behavior**

The increased excitability of Arc-expressing IGCs suggests that AOB MCs may experience stimulus-associated suppression following resident-intruder encounters. To test this hypothesis, we measured the responses of posterior AOB MCs to glomerular layer stimulation during the same 4-8 hour post-behavior time window used in IGC recordings (Fig. 7). MCs in current clamp were depolarized via steady-state current injections to -55 mV (just below action potential threshold), and exposed to 3 second, 20 Hz glomerular layer stimulation (Fig. 7B-C). We observed less evoked spiking activity in MCs in AOB slices taken from post-behavior resident males than no-intruder controls (repeated measures ANOVA, interaction between group and stimulus, F(59,1298)=2.45, p<0.0001, n=13 cells, 4 mice for “intruder” group; n=9 cells, 4 mice for “no intruder” group, Fig. 7B-C). Voltage clamp experiments from these same cells held at -40 mV revealed suppressed net inward current during the stimulus trains (repeated measures ANOVA, main effect of group, F(1,22)=8.49, p=0.008, Fig. 7D). We observed no differences in net inward current when cells were held at -50 mV (nearer Cl⁻ reversal potential), indicating that the results at -40 mV reflect the influence of increased outward currents (repeated measures ANOVA, no main effect of group F(1,22)=0.07, p=0.80).

We did not observe increased MC intrinsic excitability post-behavior (MC max spiking frequency: 48.1 ± 2.5 Hz post-behavior, 40.2 ± 2.1 Hz control, Wilcoxon-Mann-Whitney test, p=0.13), but did involve a small decrease in I_{H} currents (normalized I_{H} current ratio
0.0342 ± 0.003 post-behavior, 0.047 ± 0.005, Wilcoxon-Mann-Whitney test, p=0.035). Importantly, these currents are much smaller than those observed in IGCs, consistent with recent observations in mitral cells (Gorin et al., 2016). These results confirm that male-male social chemosensory encounters are associated with subsequent MC suppression, consistent with an experience-dependent increase in IGC-MC inhibition.

**Discussion**

The AOB remains a mysterious sensory circuit. It is often considered to be a relay station for information about environmental pheromones and kairomones, but there is ample evidence that the AOB also participates in experience-dependent plasticity (Brennan, 2009). Experience-dependent plasticity in the AOB has almost exclusively been studied in the female rodent AOB in the context of mating (Binns and Brennan, 2005; Brennan and Kendrick, 2006), but there are many other rodent behaviors that are strongly influenced by the AOS (Maruniak et al., 1986; Wysocki and Lepri, 1991; Stowers et al., 2002; Kimchi et al., 2007; Papes et al., 2010). The principal motivation for this work was a desire to learn more about experience-dependent AOB plasticity in the context of non-mating AOS-mediated behaviors.

We specifically chose to study the resident-intruder territorial aggression paradigm because it is a male-typical AOS-dependent behavior that induces robust IEG activation in the AOB (Maruniak et al., 1986; Wysocki and Lepri, 1991; Kumar et al., 1999; Stowers et al., 2002). Arc is upregulated in male and female rodent AOB IGCs following mating (Matsuoka et al., 2002a; Matsuoka et al., 2002b; Matsuoka et al., 2003), suggesting that Arc-expressing IGCs may underlie the increased AOB inhibition...
observed in this context (Kaba and Keverne, 1988; Brennan et al., 1990). Our results show that Arc is selectively transcribed and translated in posterior AOB IGCs of male mice following male-male social chemosensory encounters (Figs. 1-2). Arc upregulation in AOB IGCs after the resident-intruder assay requires AOS chemosensory signaling, indicating that this effect is not caused by brain processes (e.g., centrifugal neuromodulation) associated with other sensory systems (Figs. 2-3).

The specific neurophysiological changes reported in Arc-expressing neurons in other brain regions vary widely and are often subtle (Wang et al., 2006; Ploski et al., 2008; Shepherd and Bear, 2011; Jakkamsetti et al., 2013). For example, Arc-deficient pyramidal neurons in visual cortex have an overall reduction in their orientation selectivity, but retain experience-dependent refinement of this selectivity (Wang et al., 2006). In the context of novel environment exploration, Arc-expressing hippocampal pyramidal neurons do not show outright synaptic depression, but instead are primed for mGluR-dependent LTD (Jakkamsetti et al., 2013). In the AOB, Arc upregulation is conspicuously absent in projecting MCs (Figs. 1-3). IGCs are physiologically and morphologically different than most of the principal cell types in which Arc has been studied. Specifically, IGCs are axonless and use reciprocal dendro-dendritic synapses to communicate with MCs (Jia et al., 1999; Taniguchi and Kaba, 2001). IGCs also experience significant cellular turnover in adulthood, and are replenished by adult-born neurons that migrate via the rostral migratory stream (Alvarez-Buylla and Garcia-Verdugo, 2002). The selective capacity of IGCs to upregulate Arc in response to social chemosensory experience suggests these interneurons may be primary drivers of AOB experience-dependent plasticity.
There are several genetic tools for labeling and manipulating Arc-expressing cells in living mouse brain tissue (Wang et al., 2006; Grinevich et al., 2009; Guenthner et al., 2013; Kawashima et al., 2014). We specifically chose Arc-d4EGFP-BAC reporter mice for our initial physiological experiments for two reasons. Firstly, endogenous Arc expression in these mice is unperturbed. Secondly, the half-life of the d4EGFP reporter allowed us to visualize Arc-expressing cells in acute slices for several hours following behavior. Arc-d2EGFP knock-in/knock-out mice remain a helpful tool for exploring the Arc-dependence of various forms of neuronal plasticity. However, experiments involving these mice use Arc-positive controls that are haploinsufficient for Arc and limit targeted physiology experiments to shorter time windows.

Previous studies of AOB IGC function used pharmacology to approximate the conditions present during salient social events (Araneda and Firestein, 2006; Smith et al., 2009; Taniguchi et al., 2012; Smith et al., 2015). These studies revealed important features of IGC neuromodulation, but did not investigate the cellular and synaptic changes that occur in IGCs activated by bona fide social behaviors. In Arc-d4EGFP-BAC mice, Arc expression in IGCs after resident-intruder encounters correlates with increased activation by sensory input (Fig. 4) and increased intrinsic excitability (Fig. 6). Arc expression has been associated with glutamate receptor trafficking in other contexts (Chowdhury et al., 2006; Shepherd et al., 2006; Waung et al., 2008). However, our data show that the increased network excitability of Arc-expressing IGCs is not related to an increase in EPSC frequency or amplitude, nor is there evidence of significant upregulation in the number of dendritic spines (Fig. 5). These results were somewhat surprising in light of previous work showing increased size of the postsynaptic density.
on IGC dendrites in female mice one day after mating, suggesting increased excitatory drive on IGCs (Matsuoka et al., 2004). However, our experiments took place both in a different behavioral context and at an earlier time point, which could indicate that different mechanisms or time courses are present following male-male social encounters. The increased excitability seen in Arc-expressing cells in d4EGFP mice was not observed in Arc−/− mice from the Arc-d2EGFP strain. This indicates that Arc participates in the intrinsic differences in AOB IGCs seen after resident-intruder encounters. Collectively, these data suggest that Arc expression in IGCs contributes to an increased intrinsic capacity to respond to sensory input.

IGCs do not receive direct excitation from VSN terminals in the AOB glomerular layer, but are instead activated by glutamate release from MCs at reciprocal dendro-dendritic synapses (Jia et al., 1999; Taniguchi and Kaba, 2001). MCs do not demonstrate experience-dependent increases in intrinsic excitability following resident-intruder encounters, suggesting that the increased IGC activation is specific to the IGC postsynaptic response. However, it is also possible that a change in presynaptic function in the MCs providing input to Arc-expressing IGCs contributes to this effect. To approach this question will require tools that label both Arc-expressing IGCs and their connected MCs in living tissue.

In our investigation of the intrinsic differences between Arc-expressing and non-expressing cells, we employed methods aimed at objectively classifying cells based on the expression of 26 specific characteristics. Arc-expressing and non-expressing cells were segregated into clusters that differed in their capacity to sustain high frequency spiking (Fig. 6). The increase in excitability was not a result of changes to voltage gated
sodium channel threshold, sodium current amplitudes, or macroscopic changes to voltage gated potassium currents. However, this analysis did reveal a trend for Arc-expressing IGCs to possess smaller \( I_H \) currents, which we confirmed pharmacologically (Fig. 6). HCN channel expression has been noted in the AOB, and in IGCs, but their specific role in AOB circuit function has not yet been determined (Hu et al., 2016). \( I_H \) is active at resting membrane potential and gives rise to rebound depolarization after relief from transient hyperpolarization (Robinson and Siegelbaum, 2003; Biel et al., 2009). At face value, the observed decrease in \( I_H \) is at odds with the increase in intrinsic excitability seen in Arc-expressing IGCs. However, several other studies have shown that plasticity-induced decreases in \( I_H \) are associated with increases in excitability (Poolos et al., 2002; Brager and Johnston, 2007; Campanac et al., 2008; Yi et al., 2016). One potential factor in the apparent excitatory influence of decreased \( I_H \) could be a shift in the voltage dependence of HCN channel activation, leading to an increased number of HCN channels open at rest. Overall, our results suggest that experience-dependent plasticity modulates IGC \( I_H \) currents, perhaps selectively in postsynaptic/dendritic structures. (Lorincz et al., 2002; Yi et al., 2016).

We confirmed that posterior MC activity is suppressed in AOB slices from resident mice following the resident-intruder assay (Fig. 7). This observation supports the hypothesis that experience-dependent upregulation of IGC excitability in Arc-expressing cells contributes to MC suppression. The effects were relatively modest, but were achieved despite lacking an experience-dependent marker to select for MCs that were active during the resident-intruder encounter. It is possible that this limitation precluded
us from identifying other physiological changes in MCs that are induced following male-male social interaction.

The observed increases in IGC intrinsic excitability and MC suppression are present for at least 8 hours following behavior. This suggests that MC activation upon re-exposure to the same male during this time window would be decreased, which may result in a change in male-male social interactions. In the context of the Bruce Effect, pheromonal learning is AOB-dependent and can persist for many weeks (Brennan and Keverne, 1997). It may be the case that the AOS refines male-male social interactions over similar time courses, but the specific behavioral impacts and time courses of any effects remain to be elucidated. In sum, these data reveal that AOB experience-dependent plasticity involves Arc upregulation in IGCs, which results in increased MC inhibition through upregulation of IGC intrinsic excitability. Furthermore, our data show that inhibitory plasticity in the AOB occurs across social contexts and is a general feature of the AOS.
