Duan is an HHMI pre-doctoral fellow. T.D. Hanks is funded by the National Institutes of Health under a Ruth L. Kirschstein National Research Service Award.

Numerous brain regions have been shown to have neural correlates of gradually accumulating evidence for decision-making, but the causal roles of these regions in decisions driven by accumulation of evidence have yet to be determined. Here, in rats performing a sensory evidence accumulation task, we inactivated the frontal orienting fields (FOF) and posterior parietal cortex (PPC), two rat cortical regions that have neural correlates of accumulating evidence and that have been proposed as central to decision-making. We used a detailed model of the decision process to analyze the effect of inactivations. Inactivation of the FOF induced substantial performance impairments that were quantitatively best described as an impairment in the output pathway of an evidence accumulator with a long integration time constant (>240ms). In contrast, we found a minimal role for PPC in decisions guided by accumulating evidence, even while finding a strong role for PPC in internally-guided decisions.

Gradual accumulation of evidence for or against different choices has been implicated in many types of decision-making, including value-based decisions (Basten et al., 2010; Cavanagh et al., 2011; Milosavljevic et al., 2010; Hunt et al., 2012; Solway and Botvinick, 2012), social decisions (Krajbich and Rangel, 2011), economic decisions (Gluth et al., 2012), gambling decisions (Busemeyer and Townsend, 1993), memory-based decisions (Ratcliff, 1978), numerical comparison decisions (Sigman and Dehaene, 2005), visual search decisions (Purcell et al., 2010; Heitz and Schall, 2012), and perceptual (Gold and Shadlen, 2007; Ratcliff et al., 2007; Mante et al., 2013) decisions. It is therefore considered a core decision-making process. Although neural correlates of evidence accumulation have been reported in several interconnected primate brain regions—such as PPC (Shadlen and Newsome, 2001; Roitman and Shadlen, 2002; Hunt et al., 2012), prefrontal cortex (Hunt et al., 2012) including frontal eye fields (Ding and Gold, 2012; Kim and Shadlen, 1999; Purcell et al., 2010; Heitz and Schall, 2012; Mante et al., 2013), striatum (Ding and Gold, 2010), and superior colliculus (Horwitz and Newsome, 1999; Ratcliff et al., 2007),—the specific roles of these different brain regions in decisions driven by accumulation of evidence have not yet been distinguished.

We recently developed a rat model of gradual accumulation of evidence for decision-making, using a task that allows detailed quantitative modeling of the accumulation and decision processes (“Poisson Clicks” task; Brunton et al., 2013). In separate work from our laboratory using the Poisson Clicks task, electrophysiological recordings in rat PPC and Frontal Orienting Fields (FOF; Erlich et al., 2011) revealed classic neural correlates of evidence accumulation (Figure 1 of T.D. Hanks, C.D. Kopec, B.W.B., C.A.D., J.C.E., C.D.B., *in review*). Specifically, we found neurons in these rat regions that ramp up their activity during the stimulus, and the slope of that ramp is correlated with the strength of the momentary evidence—just as one would expect from neurons whose firing rates represent the accumulation of evidence over time, and just as previously reported in monkey regions that have been suggested as analogous to the rat PPC and FOF (primate PPC: Shadlen and Newsome, 1996; 2001;

Roitman and Shadlen, 2002; and monkey frontal eye field (FEF): Ding and Gold, 2012; Mante et al. 2013; for PPC analogy, see Whitlock et al. 2008 and Reep et al. 2009; for FOF/FEF analogy see Erlich et al. 2011).

In addition to having neural correlates of accumulating evidence (T.D.H. et al.), several properties of the rat FOF suggest it as a candidate for a causal role in decisions driven by accumulation of evidence. Accumulation of evidence involves both maintaining a memory of evidence accrued so far and addition of new evidence to the memory, and is therefore linked to short-term memory processes. The rat FOF has delay activity that correlates with short-term memory, and plays a causal role in short-term memory for orienting acts (Erlich et al., 2011). Furthermore, the rat FOF is well-situated to play an important role in perceptual decision-making, since it receives inputs from multiple sensory cortices (Conde et al., 1995), and it projects to the superior colliculus (SC) (Stuesse and Newman, 1990), a subcortical region that, in both rodents and primates, is involved in controlling orienting motions (Isa and Sasaki, 2002; Felsen and Mainen, 2008) and is thought to be involved in decisions reported through such orienting motions. Moreover, the rat FOF is reciprocally connected with the rat PPC (Reep et al., 1987; 1994), which is currently considered a critical, central node in rodent perceptual decision-making (Carandini and Churchland, 2013). The rodent PPC itself also has neural correlates of accumulating evidence (T.D.H. et al.), and it shares with the FOF some of the key properties that suggest a causal role in decisions driven by accumulation of evidence. The rodent PPC has delay activity that correlates with performance on short-term memory tasks (Nakamura, 1999; Harvey et al., 2012), and, as shown through inactivations, plays a causal role in short-term memory for orienting acts (Harvey et al., 2012). For these reasons, the FOF and the PPC are the most prominent candidate regions in rodent association cortex for being important nodes in orienting decisions guided by accumulation of evidence. We focus on these two areas here.

We implanted bilateral cannula in both FOF and PPC of rats trained to perform the Poisson Clicks task, and inactivated these regions with the GABA-A agonist muscimol while the rats performed the task. Consistent with expectations drawn from neural correlates in the rat FOF, inactivation of the FOF

impaired performance in the task. We used a quantitative model to characterize which aspect of the accumulation and decision process was impacted by inactivation of the FOF. The results of this analysis revealed a specific location for the FOF in the causal circuit underlying the Poisson Clicks behavior: the behavioral impairment caused by FOF infusions could be parsimoniously and quantitatively explained as an impairment in the premotor output pathway of an evidence accumulator with a long accumulation time constant (240 ms or more). It is possible that the decision itself — i.e., the categorization of the graded accumulator value into a discrete choice, which is a process subsequent to graded evidence accumulation — could occur in the FOF.

In contrast, we found that PPC inactivation had only minor and inconsistent effects on the task. This was true even while the same PPC inactivations had strong effects on interleaved “free-choice” trials, in which no sensory evidence was provided and rats were rewarded regardless of their choice of response. Our data thus suggest that the PPC plays a minimal causal role in decisions guided by accumulation of evidence, while playing an important role in internally-guided decisions.

Together, our findings from inactivations of the PPC and the FOF provide important constraints on the neural circuitry underlying decisions guided by accumulation of evidence in the rat.

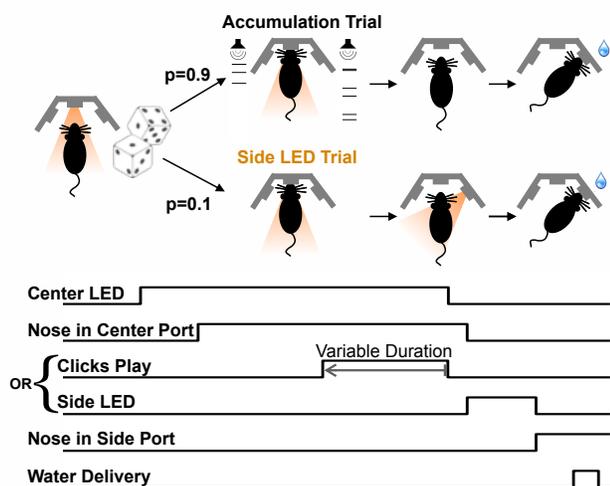

Figure 1. Poisson Clicks accumulation task trials and interleaved Side LED trials. Each accumulation task trial begins with the onset of the center LED, which signals to the rat to enter the center port. The subject holds his nose in the center port for 2 sec, until the center LED offset, which is the go cue. The majority of trials (90%) are accumulation trials. On accumulation trials, clicks play from the right and left speakers (right + left click rate = 40 clicks/sec), terminating with the go cue. After the go cue reward is available at the side port associated with the greater number of clicks. The stimulus duration on each trial is set by the experimenter to be in the range 0.1-1 sec. On Side LED trials, no sound is played during the fixation period and one of the side ports is illuminated once the rat withdraws from the center port to indicate that reward is available there. Accumulation and side LED trials are randomly interleaved, as are left and right trials.

RESULTS

Behavior

We trained male Long-Evans rats ($n = 14$ rats) on the Poisson Clicks accumulation task (**Figure 1**, Brunton et al., 2013). On each trial of this task, illumination of the center LED indicated that the rat should place its nose in the center port and remain there while click trains with Poisson-generated inter-click-intervals were played from the left and right speakers. The rats learned to report which side had played the greater total number of clicks by nose-poking into the corresponding side port (**Figure 2a**). We refer to these trials as “accumulation trials”.

In order to control for motor effects of inactivations, the accumulation trials were randomly interleaved, in most sessions, with trials that we refer to as “side LED” trials. On side LED trials no sounds were played during fixation. Immediately after the end of fixation, one of the two side ports was illuminated, indicating availability of reward at the lit

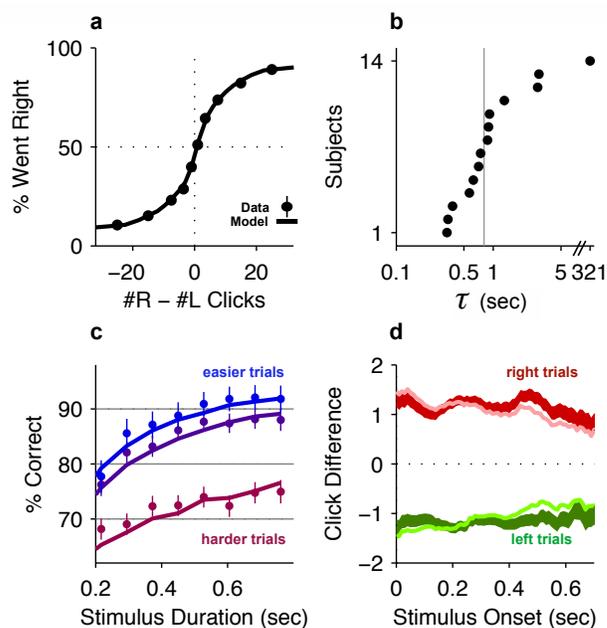

Figure 2. Behavioral evidence of accumulation, following and consistent with Brunton et al. 2013. **(a)** Behavior as a function of total right minus total left clicks. For very easy trials (large click differences) performance is $\sim 90\%$ correct. The circles (with very small error bars) are the mean \pm 95% binomial confidence intervals across trials for all accumulator trials from all rats one day before an infusion session ($n=47580$ trials across 14 rats). The thick line is the psychometric curve predicted by the accumulator model. **(b)** The time-constant of accumulation as fit by the model for each rat in the experiment. The median (810 ms) is marked by a thin gray line. **(c)** Chronometric plot generated using the same data as in panel (a). The rats’ performance increases with longer duration stimuli, consistent with an accumulation strategy. The circles and error bars are the mean \pm 95% binomial confidence intervals across trials on the easiest (blue), middle (purple) and hardest (magenta) thirds of trials defined by the absolute value of the ratios of left vs. right click rates. The thick lines are the model-predicted chronometric curves. **(d)** Reverse correlation analyses showing that clicks throughout the stimulus were used in the rats’ decision process, supporting the long accumulation time constants in (b). The thick dark red and green lines are the means \pm std. err. across trials for where the rats went right and left. Thin light red and green lines are the model-predicted reverse correlation.

port (**Figure 1**). The right and left side LED trials, together, comprised ~10% of the total trials.

To demonstrate that subjects accumulated the sensory evidence provided by the auditory clicks, we fit an accumulator model using the individual click times and the rats' choices on each trial (**Figure S1**; see also Brunton et al., 2013). Different parameter value regimes of this model can implement many different strategies, such as responding based on the first few clicks, or last few clicks, or to a burst of clicks, and many others. Consistent with previous results, maximum likelihood fits resulted in best-fit parameters associated with a gradual evidence accumulation strategy. Most importantly for this study, this strategy was characterized by a long accumulator time-constant, just under 1 second (**Figure 2b**, Table S1), which is the duration of the longest stimuli used here. As expected for a gradual accumulation strategy in which clicks from the entire stimulus are weighted equally, performance improved for longer stimuli with the same underlying click rates (**Figure 2c**; Ratcliff et al. 1998, Usher et al. 2001, Brunton et al. 2013), and a psychophysical reverse correlation analysis (Kiani et al., 2008; Raposo et al., 2012; Brunton et al., 2013) indicates that rats used clicks from all times of the stimuli to make their decision (**Figure 2d**).

Inactivations

We report the results of five different types of inactivations: unilateral FOF, bilateral FOF, unilateral PPC, bilateral PPC, and combined bilateral FOF + unilateral PPC inactivations, for a total of 26521 trials from 161 infusions into the FOF and PPC of 14 rats (**Figure 3a**). We initially performed muscimol inactivations of the FOF and PPC in 6 rats performing

the Poisson Clicks Task (group 1). In order to verify the results and perform control experiments, we performed inactivations in two further groups (group 2, n=4; group 3, n=4). The specific order and outcome of the infusions in each rat is shown in **Figure S4**.

FOF inactivations

We placed cannulae in the center of the location currently identified as FOF (+2.0 mm AP, +/- 1.3 mm ML from Bregma, **Figure S2A**). These are the same coordinates used by Erlich et al. (2011), and are also the coordinates at which neural correlates of accumulation of evidence were observed in the Poisson Clicks task (T.D.H. et al.). For the first bilateral FOF inactivation session we infused 300 ng of muscimol per side, for a total of 600 ng. After these infusions rats did not perform the task. We subsequently used a smaller dose of 75 ng per side (Note: this is half the dose used in the bilateral PPC experiment described below). This resulted in a significant 10.3% decrement on performance on accumulation trials ($p=0.018$, GLMM test; **Figure 3b**, **S6A**). The effect was individually significant in 3/4 rats. Side LED trials were unimpaired ($p>0.5$; **Figure 3b**), indicating that the impairment on accumulation trials was not simply a motor effect.

Unilateral infusions of muscimol into the FOF resulted in a profound bias towards ipsilateral responses in the Poisson Clicks task (**Figure 3c**). Averaged across all unilateral FOF infusion sessions, the ipsilateral bias (defined as ipsilateral % correct - contralateral % correct), was $52 \pm 7\%$ (mean \pm s.e.) for accumulation trials (t -test across 12 rats $t_{11}=7.27$, $p<10^{-4}$; two rats in group 3 failed to perform sufficient numbers of trials during FOF inactivations to be included in this analysis). Unilateral FOF

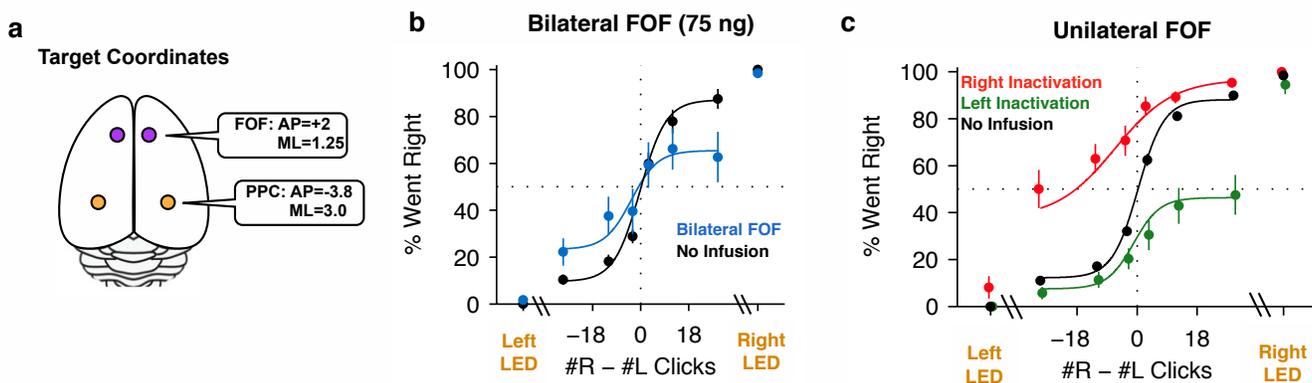

Figure 3. FOF Infusions. (a) Top-down view of rat cortex with the locations of the FOF and the PPC, into which cannulae were implanted. (b) Bilateral infusion of muscimol into the FOF results in a substantial impairment on accumulation trials but has no effect on side LED trials. In black are data from control sessions one day before an infusion (n=8 sessions, 4 rats). In blue are data from bilateral FOF infusions (n=8 sessions, 4 rats, 75 ng per side). The circles with error bars indicate the mean \pm s.e. across sessions. Accumulation trials are binned by #R-#L clicks, spaced so there are equal number of trials in each bin. The lines are a 4-parameter sigmoid fit to the data. As described in Figure 1, side LED trials did not require evidence accumulation. (c) Unilateral infusion of muscimol into the FOF results in a profound ipsilateral bias on accumulation trials but has no effect on side LED trials. In black are data from control sessions one day before an infusion (n=34 sessions, 12 rats). In red are data from right FOF infusions (n=17 sessions, 12 rats, 150 or 300 ng). In green are data from left FOF infusions (n=17 sessions, 12 rats, 150 or 300 ng).

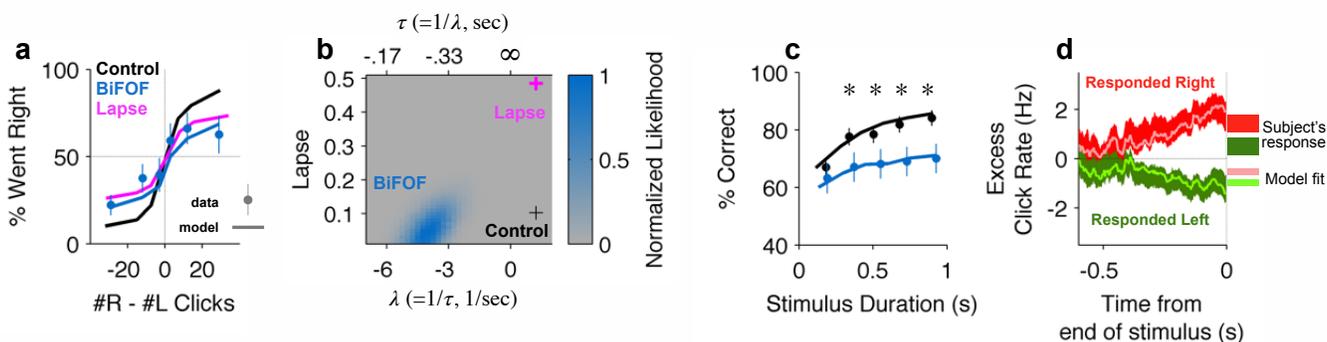

Figure 4. Detailed accumulator model reveals that behavior after bilateral FOF inactivation is best fit as a reduction in the time-constant of accumulation. (a) When analyzed in terms of the psychometric function, changes to either lapse rate alone or accumulation time constant alone can match the bilateral FOF inactivation data. The black line shows the psychometric curve from control data, collected one day before bilateral FOF sessions ($n=1526$ trials). Blue dots with error bars show the experimental data from bilateral FOF inactivation sessions ($n=1809$ trials). The magenta line is the psychometric curve obtained by fitting only the lapse rate parameter to the inactivation data, while keeping all other parameters at their control values (corresponds to magenta cross in panel b). The blue line shows the psychometric curve from the accumulator model fit to the inactivation data (corresponds to peak of blue likelihood surface in panel b), which has a change w.r.t. control in accumulation time constant $\tau (= 1/\lambda)$, but no change in lapse rate. (b) Fitting the detailed click-by-click, trial-by-trial accumulator model (Brunton et al. 2013) to the inactivation data clearly distinguishes between lapse and λ . The panel shows the normalized likelihood surface, indicating quality of the model fit to the inactivation data as a function of the lapse and the $\lambda (=1/\tau)$ parameters. The black cross shows parameter values for the control data. The best fit to the inactivation data is at the peak of the blue likelihood surface ($\lambda = -4.11$, lapse = 0.048), significantly different from control for λ , but not different from control for lapse. This best-fit lambda corresponds to $\tau = -0.243$ s, a substantially leaky integrator. (c) Performance as a function of stimulus duration for bilateral FOF sessions (blue, mean \pm std. err.) and the control sessions one day before (black, mean \pm std. err.). The lines are the chronometric curves predicted by the accumulator model (for inactivation data, parameter values at peak of blue likelihood surface in panel b). (d) Reverse correlation showing the relative contribution of clicks from different times to the rats' decisions for data from bilateral FOF inactivation sessions. Compare to Figure 2d. The thick dark shading shows the mean \pm std. err. across trials based on the rats' choices. The thin bright lines are the reverse correlation traces predicted by the accumulator model (parameter values at peak of blue likelihood surface in panel b).

infusions reduced performance to chance on even the easiest contralateral accumulation trials (Figure 3c; green data points for $\#R - \#L \gg 0$, and red data points for $\#R - \#L \ll 0$). The ipsilateral bias induced by FOF inactivation was highly reproducible: 87% (26/30) of individual infusion sessions resulted in a positive ipsilateral bias (sign-test, $p < 0.001$), and in every single rat there were more rightward responses after rightward infusions than leftward infusions (Figure S5A).

Importantly, as in the bilateral inactivations, there was no significant effect on side LED trials (t-test $t(5)=1.55$, $p > 0.15$; Figure 3c, side LED Trials), nor did unilateral FOF inactivations have an effect on the response time on side LED trials (repeated-measures ANOVA, $F(1,3)=0.65$, $p > 0.4$). This indicates that the effect of FOF inactivation was not simply an overall motor effect. Furthermore, the inactivations produced no observable effects outside of the behavioral task. Infused animals appeared normal in their home cages both immediately after the infusion and after the behavioral session. Our localized inactivations thus contrast with previous literature, in which large permanent unilateral lesions of the rat prefrontal cortex (including but extending well beyond the

FOF), produced persistent, ipsiversive circling in the lesioned animals (Crowne and Pathria, 1982).

Bilateral FOF inactivations reduce the subjects' accumulation time constant

Which specific aspects of the evidence accumulation and decision process were impaired by the FOF inactivations? To address this question, we took advantage of the accumulator model of Brunton et al., (2013), which uses the knowledge the precise time of each click in each individual trial, as well as the rat's decision on each trial, to estimate 9 parameters that characterize the accumulation and decision processes (Figure S1). Each parameter quantifies a specific aspect of the decision process. For example, τ , the time constant of the accumulator (also described by the parameter $\lambda = 1/\tau$), characterizes the time period over which the subject accumulates evidence. A negative value of τ indicates a leaky accumulator, a positive value of τ indicates an unstable accumulator, and perfect accumulation would have $\tau = \infty$ (i.e., $\lambda = 0$). Another example parameter is the lapse rate, which quantifies the

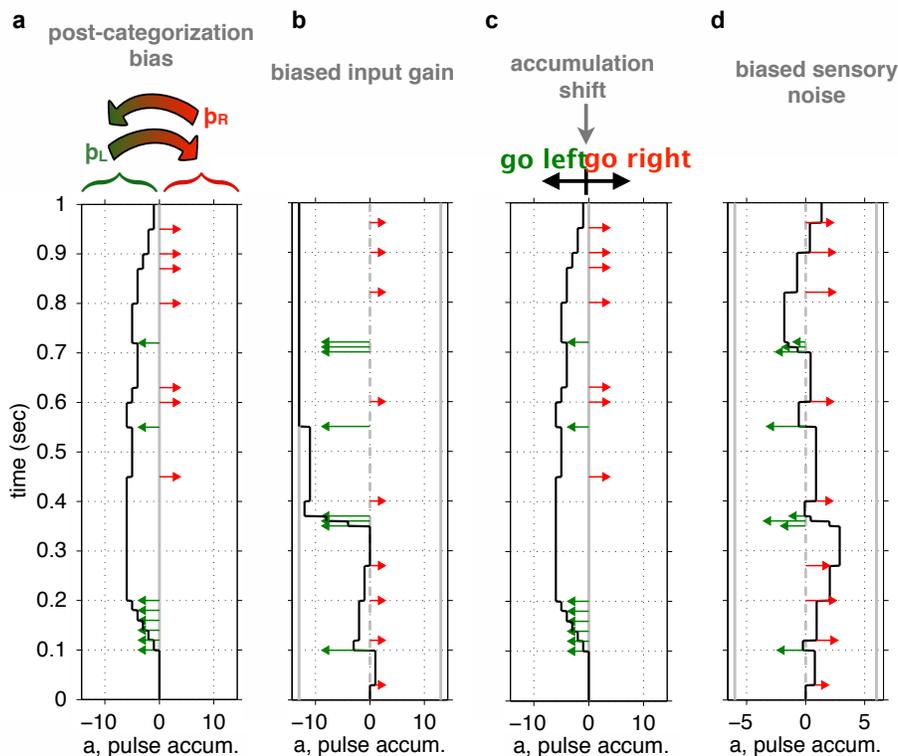

Figure 5. Conceptual illustration of four model parameters, used to quantify different sources of a lateralized bias (a). Post-categorization bias: after categorizing the accumulator value into “Go Left” or “Go Right” decisions, a fraction p_L of Left decisions is reversed into Right decisions, and a fraction p_R is reversed from Right to Left. **(b)** Biased input gain, which can be thought of as a form of sensory neglect: Left and Right clicks have different impact magnitudes on the value of the accumulator. In this illustration left clicks have a much stronger impact, and decisions will consequently be biased to the left. **(c)** Accumulation shift: before categorizing the accumulator into “Go Left” versus “Go Right” decisions (by comparing the accumulator’s value to 0), a constant is added to the value of the accumulator. **(d)** Biased sensory noise, which by differentially affecting signal-to-noise ratios from the two sides, can be thought of as a form of sensory neglect distinct from biased input gain: Left and Right clicks have different magnitudes of noise in their impact. In this illustration, left clicks are more variable than right clicks, which biases decisions to the right.

fraction of trials in which the subject behaves as if it had ignored the clicks that were played and had instead made its decision randomly. Deviations from the perfect values ($\lambda=0$, $\text{lapse}=0$) in either of these parameters can give rise to psychometric curves with shallow slopes, and both types of imperfections can produce curves qualitatively similar to the experimental curve obtained after bilateral FOF inactivation (**Figure 4a**). But the similarity between the psychometric curves for the two imperfections is partly due to the fact that these psychometric curves ignore the specific timing of individual clicks. In contrast, because the two imperfections would have very different signatures in terms of how clicks at different times affect the rats’ decisions, and click timing is fully taken into account in the behavioral model, the model can clearly distinguish the two imperfections. Using the control data, the best-fitting parameter values for the behavioral model had $\tau \sim 0.8\text{s}$ —indicating that subjects accumulated information over almost the entire stimulus duration but were on average slightly unstable,—and a lapse rate of ~ 0.1 (black cross, **Figure 4b**). For data from bilateral inactivation sessions, the maximum likelihood parameter values (center of blue likelihood peak, **Figure 4b**) changed significantly. The inactivation data now had a dramatically different and much shorter accumulation time constant of the opposite sign to the control data, $\tau \sim -0.24\text{s}$ (leaky accumulation over only a quarter of a second). In contrast, the best-fitting lapse rate remained essentially unchanged from control. As described

above, attempting to fit the inactivation data by keeping the time constant unchanged and increasing the lapse rate could qualitatively match the psychometric curve (magenta line, **Figure 4a**), but it produced an extremely poor fit in the full behavioral model (magenta cross in low likelihood region, **Figure 4b**). Thus, after bilateral FOF inactivation, the subjects behaved as if their lapse rate was unchanged, and their accumulator had become much leakier. Accumulator noise and sensory noise also increased significantly after bilateral FOF inactivation (**Table S1**).

To probe the conclusions derived from the trial-by-trial model fit, we used model-free analyses of the data (Brunton et al., 2013). Leaky accumulation with a time constant $\tau \sim -0.24\text{s}$ would predict that trials with a stimulus duration less than a quarter of a second would be essentially unimpaired, while long duration trials would be more strongly impaired. This was indeed observed in the data, with a tight correspondence between quantitative model predictions and experimental data (chronometric curves, shown in **Figure 4c**). A further prediction from a leaky accumulator is that the more recent the clicks are, with respect to the end of the stimulus, the bigger their impact on the subject’s decision. This prediction was also observed in the data, again with a tight correspondence between quantitative model predictions and experimental data (reverse correlation analysis, shown in **Figure 4d**).

These results indicate that the FOF is either (a) itself directly involved in the process of accumulating evidence, and the inactivations made the accumulator

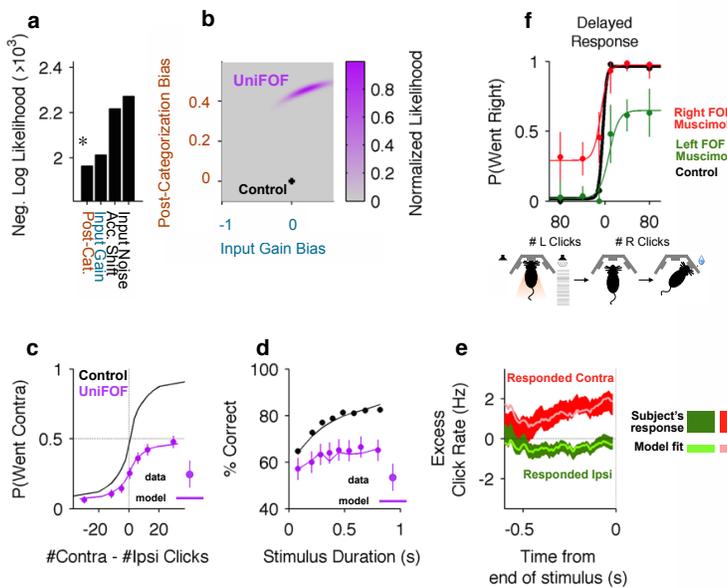

Figure 6. Detailed accumulator model shows that behavior after unilateral FOF inactivation is best fit as a post-categorization bias. (a) A comparison of the likelihoods (i.e. best model fits) for the four different bias mechanisms illustrated in Figure 5. The post-categorization bias model is better than the next best model (biased input gain) by 50 log-units. (b) The 2-dimensional normalized likelihood surface for the two best single-parameters: post-categorization bias and input gain bias. By definition, in the control data (black marker) post-cat. bias=0 and input gain bias=0. The peak of the magenta likelihood surface for the inactivation data is significantly different from control for post-categorization bias (from 0 to 0.4588) but not significantly different from control for input gain bias. (c) Psychometric curves for control and inactivation data. The black line is the model fit to the control data. The magenta circles with error bars are experimental data from unilateral FOF inactivation sessions, and indicate fraction of Contra choice trials (mean \pm binomial 95% conf. int.) across trial groups, with different groups having different # Contra - # Ipsi clicks. The magenta line is the predicted psychometric curve from the post-categorization bias model. (d) Performance as a function of stimulus duration for data from control sessions one day before (black), and for data from unilateral FOF sessions (magenta, mean \pm std. err.). The lines are the chronometric curves predicted by the accumulator model fit to each data group (for inactivation data, parameter values are post-categorization bias model). (e) Reverse correlation analyses showing the relative contributions of clicks throughout the stimulus in the rats' decision process. The thick dark red and green lines are the means \pm std. err. across trials for contralateral and ipsilateral trials. Thin light red and green lines are the reverse correlation traces predicted by the post-categorization bias model. (f) Psychometric curves for single-sided trials in control (black), right FOF infusion (red) and left FOF infusion (green) sessions.

leaky; or (b) the FOF is a requisite component in the output pathway of an accumulator with a long time constant, i.e., the FOF is part of the chain of regions that would transform evidence accumulated over times longer than 0.24 seconds into the choice-reporting motor act.

Unilateral FOF inactivations produce a post-categorization bias

We also used the behavioral model to analyze the strong ipsilateral bias induced by unilateral inactivations. However, the original model of Brunton et al. (Figure S1) contains only one parameter that can generate a left/right bias. We therefore extended the model with three additional parameters, each of which represented a possible imperfection that could generate a side bias. Simultaneously fitting all 12 parameters substantially increased the computational difficulty of the fitting process. We consequently took the strategy of first fitting the original 9-parameter model to the control data from one day before infusion sessions, and then, starting from those best-fitting parameter values, asking which of the bias-inducing single-parameter changes would best fit the data from the unilateral FOF inactivations (other parameters were held fixed at the control data best-fit values). In other words, we asked, “if we changed only one parameter, which one would it be to best fit the data?” Finding the maximum likelihood value was made practical by the fact that each of the four fits performed was a single-parameter fit.

The four single-parameter changes we considered corresponded to hypotheses regarding possible functions of the FOF, and are conceptually illustrated in Figure 5. (a) First, we considered the possibility that the FOF is part of the output pathway of the accumulator, perhaps part of computing or

representing the animal's discrete choice after having categorized the accumulator value (into “Go Right” vs. “Go Left” categories), potentially in the service of preparing a motor action (Erlich et al., 2011). Unilaterally perturbing the FOF might then bias this post-categorization representation. To implement this idea in the model, we added a parameter that biased outcomes after the R/L decision was made on each trial. Independently of the stimulus that led to the decision, we let a randomly-chosen fraction, β_R (pronounced “sho-right”), of right decisions and a randomly-chosen fraction β_L of left decisions be reversed (i.e., $R \rightarrow L$ and $L \rightarrow R$; see Figure 5a). These reversals scale the vertical endpoints of the psychometric curve towards the Went Right=50% level. The scaling is biased when $\beta_R \neq \beta_L$. (b) Next, we considered the possibility that since the FOF has been suggested as analogous to primate FEF, perturbing it might affect attentional processes, perhaps causing a lateralized sensory neglect that would bias the perceptual impact of auditory clicks from the two different sides. In other words, during unilateral inactivation, right and left clicks could have different magnitudes of their impact on the accumulating evidence (C_R and C_L , instead of the single common C of Eq. 2 in Figure S1). We described this as a “biased input gain” (see Figure 5b). (c) We next considered the possibility that the FOF plays a role in the accumulation process itself, and quantified biases in accumulation through an “accumulation shift” that shifts the value of the accumulator a at the end of the stimulus (see Figure 5c, equivalent to bias parameter in Figure S1). Changes in this parameter will cause horizontal shifts in the psychometric curve. (d) In the fourth and final model, we considered a second possible form of

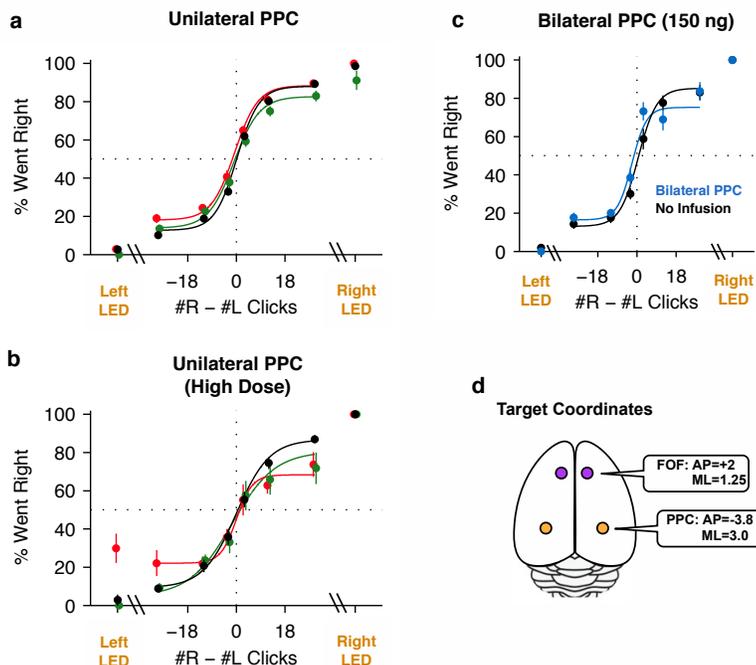

Figure 7. PPC Infusions. (a). As in Figure 3b, but for unilateral infusions of muscimol into the PPC, which result in a minimal impairment. In black are data from control sessions one day before an infusion (n=65 sessions, 14 rats). In red are data from right PPC infusions (n=31 sessions, 14 rats, 150 or 300 ng). In green are data from left PPC infusions (n=34 sessions, 14 rats, 150 or 300 ng). (b). As in (a), but using very high doses of muscimol. Only very small effects are seen. In black are data from control sessions one day before an infusion (n=11 sessions, 9 rats). In red are data from right PPC infusions (n=3 sessions, 3 rats, 600 or 2500 ng muscimol). In green are data from left PPC infusions (n=8 sessions, 8 rats, 600 or 2500 ng). (c) Bilateral infusion of muscimol into the PPC does not produce a markedly bigger impairment. In black are data from control sessions one day before an infusion (n=8 sessions, 4 rats). In blue are data from bilateral PPC infusions (n=8 sessions, 4 rats, 150 ng per side). (d) Schematic view of the brain, duplicated from Figure 3a to remind readers of the location of FOF and PPC on the cortical surface.

lateralized sensory neglect, in the form of “unbalanced input noise” (see Figure 5d). In this version of the model, right and left clicks could have different signal-to-noise ratios by having different values of the sensory noise parameter ($\sigma_{s,R}^2$ and $\sigma_{s,L}^2$, instead of the single common σ_s^2 of Figure S1). For each of models (a), (b), and (d), the original fit to the control data was constrained to be balanced. To fit the bias generated by unilateral FOF inactivation, that constraint was relaxed. For each model, we kept the corresponding ipsilateral parameter fixed, and let the contralateral parameter be free to best fit the data. The difference between the best-fitting contralateral parameter minus the ipsilateral parameter was then defined as the bias for that model.

Of these four models, the one that best fit the experimental data was (a), the post-categorization bias model in which the FOF is part of the output pathway of the accumulator (Figure 6a, S7B). The value of β contralateral to the inactivation (β_c) that best fit the data was 0.52, suggesting that on over 50% of trials rats reversed their contra-choices to ipsi-choices. The next best model (which was worse by ~50 log-units than the post-decision model, Figure 6a) was (b), the biased input gain model. This model failed to accurately fit the data on difficult trials (in which $|\#Contra - \#Ipsi\ Clicks|$ is small, Figure S7C). The best-fit model for (c), the accumulator shift model, was clearly a poor fit even when analyzed through psychometric curves, fitting particularly poorly for trials with a preponderance of contralateral clicks (Figures 6a and S7D). The worst fitting model was (d), the unbalanced input noise model (Figures 6a and Figure S7E).

To ask whether a combination of changes to two parameters could provide a significantly better description of the data than our single-parameter fits,

we estimated the 2-dimensional likelihood surface for the two best models. This surface (Figure 6b) clearly demonstrated that fitting the data requires a large shift away from the balanced control value in the post-categorization bias, but not in input gain. Thus, the dominant effect of unilateral FOF inactivation could be parsimoniously explained by a post-categorization bias, consistent with the known role of the FOF in movement planning (Erlich et al., 2011). As described above, the post-categorization model predicts that the psychometric curve after unilateral inactivations should be a vertical scaling of the control psychometric curve. This scaling was found in the data, with a tight correspondence between the quantitative model prediction and the experimental psychometric curve (Figure 6c). A similar tight correspondence between model predictions and data were also found for the chronometric curves (Figure 6d) and the reverse correlation (Figure 6e).

One of the characteristics of a post-categorization bias model is that since the biasing process occurs after the accumulated evidence has been categorized into “Go Right” or “Go Left”, the bias is independent of whether trials are easy (large value of $|\#R - \#L\ clicks|$) or difficult (small value of $|\#R - \#L\ clicks|$). To further probe this prediction, we randomly intermixed regular accumulation trials with a new set of unusually easy “single-sided” trials (Figure 6f). In these trials the speaker from only one side produced clicks at 100 clicks/sec (noticeably higher than the 40Hz rate on accumulation trials), lasting until the “Go” signal indicating the end of center port fixation. Consistent with the post-categorization bias predictions, the unilateral FOF inactivations produced a vertically-scaled ipsilateral bias in these single-sided trials that was similar to that seen during the

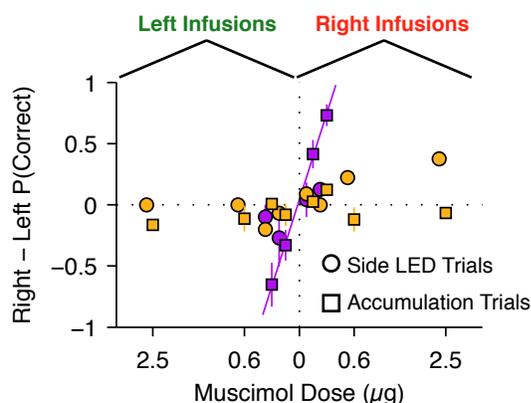

Figure 8. Summary of dose-bias relationship for all unilateral infusions into the FOF (magenta) and the PPC (yellow). Circles indicate bias on LED trials, squares indicate bias on accumulation trials. The magenta lines indicate a significant correlation between signed dose (+ for right infusions, - for left infusions) and performance bias ($p < 0.01$). The plotted x-location of the side LED trials are slightly offset for visualization.

accumulation trials (**Figure 6f**, compare to **Figure 6c** data): i.e., the bias was independent of how easy or how difficult the trials were.

Unilateral PPC Inactivations and comparison to unilateral FOF inactivations

Given that unilateral PPC lesions in rats lead to contralateral neglect (Crowne et al., 1986; Reep et al., 2004) and that PPC has been posited as central to rodent perceptual decision-making (Carandini and Churchland, 2013; Harvey et al., 2012), we predicted that unilateral PPC inactivations would cause a strong contralateral impairment (or, in other words, in the context of our binary forced-choice task, an ipsilateral bias, similar to that seen with the FOF inactivations). Surprisingly, our PPC inactivations resulted in a small effect that was $\sim 10\times$ smaller than the effect in the FOF. The average ipsilateral bias was $4.2 \pm 2.4\%$ (mean \pm s.e.) (**Figure 7a**; t-test $t(13)=1.76$, $p > 0.1$). Moreover, this small bias was largely due to data from the first infusion session in group 1 rats (**Figure S4A**) which led to a small but significant shift in rightward responding in right vs. left infusions in the group 1 rats ($p=0.024$, GLMM test). No consistent effects of unilateral PPC infusions were found in 10 subsequent infusion sessions with group 1 (a total of eleven group 1 unilateral PPC infusion sessions, **Figure S4A**), even when the muscimol dose was substantially increased, to 600 ng (**Figure S4A**).

To test whether PPC inactivation could produce a quickly adapting effect (i.e., perhaps an effect from muscimol inactivation is observable only in the first session), we repeated our unilateral PPC inactivations

using a second group of rats. However, no significant effect was found in any of the PPC infusion sessions in group 2 rats even on the first day of infusion (GLMM test, $p=0.92$; **Figure S4B**). Notably, even extremely high doses (up to 2500 ng) of muscimol in PPC, were ineffective at biasing the rats on accumulation trials (**Figure 7b**). Thus, our data from group 2 suggest that the bias on the first day in group 1 occurred by chance. (See Supplemental Experimental Procedures for a more detailed description).

Our PPC coordinates for group 1 and 2 (At 3.8 mm posterior and ~ 3 mm lateral to Bregma) were based on the Paxinos and Watson rat atlas, the neural correlates of accumulation found at this location (T.D.H. et al.) and several published studies of rat PPC (Paxinos and Watson, 2004; Whitlock et al., 2012; Nitz, 2006). Nevertheless, some authors have suggested that PPC is slightly more posterior: 4-6 mm posterior to Bregma (Kolb and Walkey, 1987). We therefore repeated the PPC experiments with a third group of rats, this time implanting cannulae at 4.5 mm posterior to Bregma (**Figure S2C**). Once again, as in group 2, there was no ipsilateral bias due to muscimol (at 300 ng) in the PPC (GLMM test, $p=0.47$), nor was there a detectable effect on the first inactivation session.

Performance of side LED trials at regular muscimol doses (150 or 300 ng) was not significantly affected by PPC infusions (**Figure 7a**; t-test $t(7)=1.0$, $p > 0.35$), and the response times on these trials were also unaffected (repeated-measures ANOVA, $F(1,6)=2.48$, $p > 0.15$). At very large doses, a significant effect on side LED trials led to a small correlation between dose and bias for side LED trials ($r=0.43$, $p=0.032$; **Figure 8** yellow circles). Given the very large muscimol doses used, and the fact that visual cortical areas lie immediately posterior to PPC (Paxinos and Watson, 2004), this weak correlation on side LED trials may be a result of spread of muscimol to the adjacent visual cortex.

To summarize, inactivation of PPC did not reliably bias accumulation trials in three separately tested groups of rats. Based on the large doses used we were confident that the lack of effect was not due to a failure to inactivate PPC. There was no correlation between dose and bias magnitude in our PPC infusions on accumulation trials (**Figure 8**, yellow squares; $p > 0.09$), strongly contrasting with the significant correlation between dose of muscimol infused into the FOF and bias on accumulation trials (accumulation trials $r=0.86$, $p < 10^{-6}$; **Figure 8**, magenta squares). The correlation in the FOF data was specific to accumulation trials ($p > 0.5$ for side LED trials; **Figure 8**, magenta circles).

Bilateral PPC Inactivations

It is possible that during unilateral inactivations, the silenced PPC may be compensated for by the PPC of

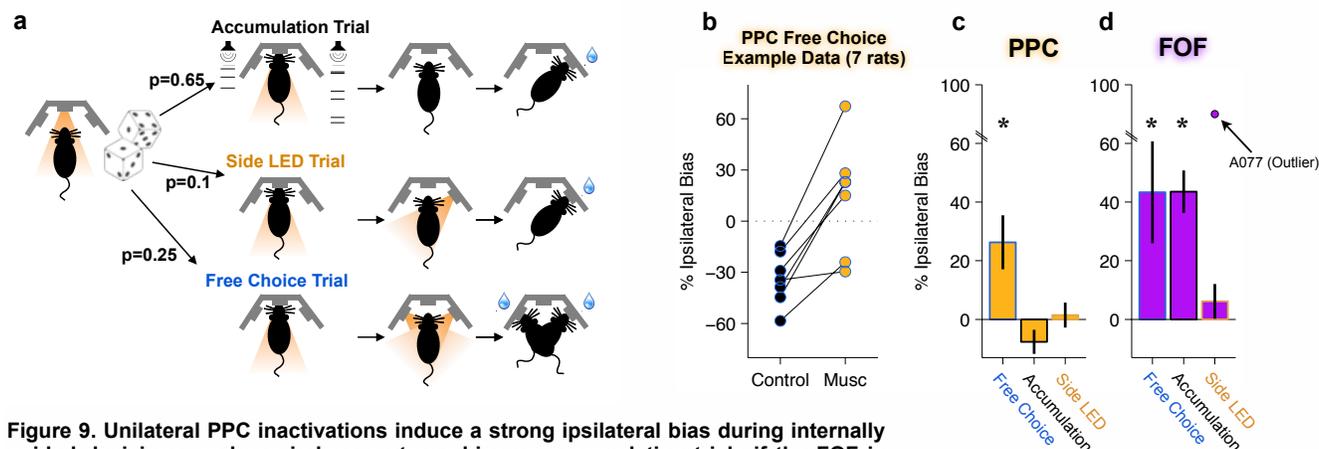

Figure 9. Unilateral PPC inactivations induce a strong ipsilateral bias during internally guided decisions, and can induce a strong bias on accumulation trials if the FOF is bilaterally inactivated. **a-d.** Effect of unilateral PPC or FOF inactivations on free choice trials intermixed with regular accumulation trials. **(a)** A cartoon of the three interleaved trial types: Accumulation, Side LED and Free Choice trials. Accumulation and side LED trials proceeded as described in Figure 1. On free choice trials (25% of all trials), after withdrawal from the center port both side LEDs were illuminated and rats were rewarded for going to either port. **(b)** After a few sessions, rats quickly developed an intrinsic bias on free choice trials (Control) even while showing no bias on instructed trials (Accumulation and side LED trials). When muscimol was infused into the PPC free choices were significantly biased toward the side of the infusion, compared to the control session on the previous day. This panel shows an example from a single infusion day where the side of the infusions was chosen to be opposite to their intrinsic control bias, together with data from the previous control day. **(c)** Unilateral PPC infusions generated a significant $26 \pm 9\%$ (mean \pm s.e. across rats, $n=7$) ipsilateral bias on free choice trials compared to control sessions (the day earlier). During infusion sessions there was a small $8 \pm 4\%$ (mean \pm s.e., $n=7$ rats) contralateral bias on accumulation trials, perhaps compensatory to the free choice ipsilateral bias. There was no effect on side LED trials **(d)**. Unilateral FOF infusions generated significant ipsilateral biases on free choice and accumulation trials, but not on side LED trials. One rat (A077) was extremely biased (90% ipsilateral choices) on Side LED trials during FOF inactivation, indicated as an outlier. $^*p < 0.01$. **(e)** Combined bilateral infusion of muscimol into the FOF with unilateral infusion of muscimol into the PPC results in a substantial ipsilateral bias on accumulation trials. In black are data from control sessions one day before an infusion ($n=32$ sessions, 4 rats). In red are data from bilateral FOF infusions with right PPC infusion ($n=8$ sessions, 4 rats, 75 ng per side in the FOF, 300 ng in right PPC). In green are data from bilateral FOF infusions with left PPC infusion ($n=8$ sessions, 4 rats, 75 ng per side in the FOF, 300 ng in left PPC)

the opposite hemisphere. In this case, bilateral inactivations of the PPC should produce a behavioral impairment markedly larger than any small impairment found after unilateral inactivations. To probe this prediction, we initially used a high dose (300 ng per side) for bilateral PPC infusions in group 1 rats, but only 2 of 6 rats completed trials, with inconsistent results. We subsequently used a weaker dose in group 2 rats (150 ng per side, still double the dose per side for the bilateral FOF inactivations described above) and all rats completed at least 150 trials per session. During the bilateral PPC inactivation sessions there was a very small but significant 3.6% decrease in performance on accumulation trials (**Figure 7b**, $p < 0.02$, GLMM test). This effect was not individually significant in any rat (0/4). Critically, the effect size we found was not bigger—in fact, it was slightly smaller—than the average unilateral PPC effect, and thus does not provide support for the hypothesis of hemispheric compensation. Performance on side LED trials was not significantly different between bilateral PPC infusion and control sessions (t -test, $p > 0.4$; **Figure 7b**).

Free-choice trials

Our results from PPC contrasted with previous studies that found a strong effect of PPC inactivations in a mouse memory-guided navigation task (Harvey et al., 2012) and a strong effect of permanent unilateral PPC lesions in inducing contralateral neglect in rats (Crowne et al., 1986; Reep et al., 2004). This motivated us to seek a positive control task. The primate literature suggested an internally-guided decision task whose trials could be readily intermixed with our evidence accumulation task. Wilke et al. (2012) interspersed regular memory-guided saccade trials (“instructed” trials), in which a single saccade target was presented on each trial, with internally-guided “free choice” trials, in which both an ipsilateral and a contralateral target were presented, and the monkey was rewarded regardless of its response choice. By design, subjects were free to respond as they pleased in free choice trials, and they typically displayed a bias towards one side or another in these trials. Wilke et al. found that muscimol inactivation of area LIP within PPC produced no effect on choices in the instructed memory-guided

saccade trials, but produced a profound ipsilateral bias during intermixed free choice trials. Inspired by Wilke et al.'s results, we modified the task for seven of our group 2 & group 3 cannulated rats (The six group 1 rats and one group 3 rat had been already sacrificed for histology). We randomly intermixed 25% free choice trials with 65% accumulation trials and 10% Side LED trials (**Figure 9a**). Free-choice trials were indicated by a lack of auditory click stimuli, and by illumination of both side LEDs after the animals had withdrawn from the center port. We refer to sessions with interleaved accumulation, side LED, and free-choice trials as “free-choice” sessions. After a few free-choice sessions with no infusions, rats performed the mix of trials reliably, and expressed a consistent bias on free choice trials but no detectable bias on accumulation trials.

In remarkable parallel to Wilke et al.'s results in primates, unilateral PPC inactivations (300ng of muscimol) during free-choice sessions produced a very strong and reliable ipsilateral bias on free choice trials (**Figure 9b and 9c**; t-test $t(26)=3.70$, $p=0.001$). The strong ipsilateral bias in free choice trials was observed even while, consistent with our previous PPC inactivations, there was no ipsilateral bias on the intermixed accumulation trials (t-test $t(26)=-0.99$, $p=0.329$) nor on the Side LED trials (t-test $t(8)=1.42$, $p=0.194$; **Figure 9c**). The free-choice bias was highly reproducible: 85% (23/27, sign-test, $p<0.001$) individual rat PPC inactivation sessions produced an increased fraction of ipsilateral free choices when compared to free choices on immediately preceding control days (see **Figure 9b** for an example of a control day and subsequent PPC infusion). The effect on free choice trials was thus similar in its robustness and reproducibility to the effect of unilateral FOF inactivation on accumulation trials. These free choice trial inactivation results provide a clear positive control for our PPC inactivations. Moreover, they are consistent with the parietal neglect literature in both rats (Crowne et al., 1986; Reep et al., 2004) and primates (Mesulam, 1999).

Inactivation of FOF, like the PPC, also induced an ipsilateral bias on free choice trials (t-test, $t(24)=3.86$, $p=0.001$). Consistent with our previous experiments, FOF inactivations in free-choice sessions continued to produce an ipsilateral bias on accumulation trials (t-test $t(24)=4.85$, $p<0.001$) but not on side LED trials (t-test $t(18)=1.65$, $p=0.117$; **Figure 9d**).

Simultaneous FOF and PPC inactivation

Are there any conditions under which silencing the PPC could affect choices in auditory click accumulation trials? To probe whether inactivation of the FOF could reveal an effect of PPC inactivation, we bilaterally inactivated the FOF while simultaneously infusing a 300ng of muscimol unilaterally into the PPC. This combination of infusions produced a significant 15.1% bias ipsilateral

to the side of the PPC infusion (**Figure 9e**, $p<0.0012$, GLMM test). These data constitute a second positive control for our unilateral PPC inactivations. The data furthermore suggest that during accumulation trials the PPC may have a real but weak influence on choice that is normally overridden by a stronger signal from the FOF.

DISCUSSION

In two-alternative forced choice tasks driven by accumulation of sensory evidence, such as the random dots task used with primates (Newsome et al., 1989) or the Poisson Clicks task used here with rats (Brunton et al., 2013), subjects gradually accumulate evidence over time; make a decision by categorizing the graded value of the accumulated evidence into a binary choice; use their decision to prepare a movement; and finally execute their decision-reporting motor act (these different components could potentially overlap). In primates, 5 recurrently interconnected brain regions have been associated with the overall process (superior colliculus, striatum, PPC, FEF, and dlPFC; Horwitz and Newsome, 1999, Ratcliff et al., 2007, Ding and Gold, 2010, Shadlen and Newsome, 2001; Roitman and Shadlen, 2002, Ding and Gold, 2012, Kim and Shadlen, 1999, Heitz and Schall, 2012, Mante et al., 2013), but despite some theoretical suggestions (Lo and Wang, 2006), the specific contributions of each brain region to the different aspects of the overall process, and the circuit logic of the network, remain unclear. Here we focused on the role of two rat cortical areas, posterior parietal cortex (PPC) and frontal orienting fields (FOF), that are considered critical for rodent decision-making (Erlich et al., 2011; Harvey et al., 2012; Carandini and Churchland, 2013; Sul et al., 2011), and that display neural correlates of gradually accumulating evidence (T.D.H. et al.). As in primates, the specific roles of each of these rat areas within the overall evidence accumulation and decision process remain undetermined.

Using a within-subject design, we implanted cannulae in both of these areas, and carried out pharmacological inactivations, quantifying the impairments by fitting to the data a detailed model of the decision-making process for the Poisson Clicks task (Brunton et al., 2013). Different parameters of the model quantified different possible variations from control behavior. We also compared inactivation effects on the Poisson Clicks task (“accumulation trials”) to three types of control trials: free-choice (in which the animal was free to choose either of two visual stimuli to obtain a reward); single-sided (in which decisions were guided by a simple auditory stimulus that did not require gradual evidence accumulation, and rats had to withhold their response for several hundred milliseconds after receiving enough information to make their decision); and side LED trials (in which decisions were guided by a

simple visual stimulus that did not require gradual evidence accumulation, and rats were free to report their decision as soon as they made it).

ROLE OF FOF

Our results demonstrate that the FOF is an essential part of the circuit for decisions driven by accumulating evidence (**Figure 3**). Unilateral FOF inactivations had a strong effect on both accumulation trials, signaled by auditory clicks, and on free choice trials, signaled by a bilateral visual stimulus (**Figure 9**), indicating that the effects are not specific to a single sensory modality. Critically, the model-based analysis suggested a specific location for the FOF within the functional process chain required by our accumulation of evidence task. The specific suggestion is that the FOF is not part of the accumulator but is instead part of the premotor output pathway that leads from the graded evidence accumulator to the decision-reporting motor act. This suggestion is derived from (a) the sharp reduction in the accumulation time constant induced by bilateral FOF inactivations (from slightly unstable $\tau \sim +0.8$, to very leaky $\tau \sim -0.24$ s), which demonstrates that the FOF is either involved in the accumulation process itself, or is part of the output pathway of the accumulator (**Figure 4**); (b) the effects induced by unilateral inactivation of the FOF, which are captured in quantitative detail, for both accumulation trials and single-side trials, as having induced a post-categorization bias that is subsequent to the accumulation process (**Figure 6**); and (c) the lack of an effect of FOF inactivations on side LED trials, which rules out a simple motor role for the FOF (**Figure 3**). A parsimonious explanation of this set of results is thus that the FOF is a requisite premotor component of the output pathway of an evidence accumulator with a long time constant (> 0.24 s). This suggestion is different from, but consistent with, the FOF's known role in short-term memory, as well as the FOF's greater importance in memory-guided (i.e., long time constant) versus sensory-guided (short time constant) orienting decisions (Erlich et al., 2011). In decisions driven by gradual accumulation of evidence, the gradual accumulation process occurs prior to the binary decision. An intriguing possibility suggested by our results that the decision process itself—i.e., the categorization of the gradually accumulated evidence into a binary choice—might be performed in the FOF, perhaps in conjunction with the superior colliculus (Lo and Wang, 2006).

It is possible that unilateral FOF inactivations would induce a hemispheric imbalance so strong that a real but nuanced role for the FOF in gradual accumulation might have been obscured by a strong post-categorization bias. We nevertheless currently favor the interpretation of the FOF's role as subsequent to, not part of, the graded accumulator. We

favor this interpretation first, because of its parsimony; and second, because parallel electrophysiological work from our laboratory found that the representation of the accumulated evidence in the FOF could be approximately described as the answer to the categorical question “if the GO signal came now, which side port should I choose?” (T.D.H. et al.), and in addition, because in further parallel work from our laboratory, transient unilateral optogenetic silencing of the FOF was unable to cause an effect on behavior if it occurred during the evidence accumulation period, sufficiently prior to the GO signal (T.D.H. et al.). Those results, in combination with the pharmacological data, three control trial types, and model-based analyses reported here, all consistently support the interpretation of the FOF as a requisite component of the output pathway of an evidence accumulator with a long time constant (> 0.24 s). This view is consistent with the fact that side LED trials, which involve decisions that do not require gradual evidence accumulation or storing a motor plan in short-term memory, are not impacted by FOF inactivations. Such decisions, including perhaps decisions that require evidence accumulation over only short times (< 0.24 s), may depend on pathways that bypass the FOF, perhaps involving direct connections from auditory cortex to the striatum (Znamenskiy and Zador, 2013).

ROLE OF PPC

Given the view that the PPC plays a key causal role in rodent perceptual decisions (Harvey et al. 2012, Carandini and Churchland 2013) and that neural activity in PPC displays correlates of accumulating evidence (T.D.H. et al.), we were surprised to find that unilateral inactivation of the PPC did not cause a side bias on accumulation, side LED, or single-sided trials. Compensation from the unperturbed hemisphere did not explain the lack of an effect, because bilateral inactivation of the PPC caused a minimal decrease in performance (3.6%) that was not significantly different from unilateral inactivations. Thus, the PPC plays at most a minimal role in choice behavior during decisions guided by evidence accumulation.

Unilateral PPC inactivations did cause a strong ipsilateral bias under two conditions: in internally-guided decisions (free choice trials, signaled by a visual stimulus, **Figure 9a-c**), and when the FOF was simultaneously bilaterally inactivated in accumulation trials (auditory stimulus, **Figure 9e**). These results suggest that in the intact brain, weak but real side choice signals from the PPC may be overridden by stronger signals from the FOF. They also suggest that the PPC's role is not specific to a particular sensory modality.

The PPC is relatively extended in the medial-lateral direction (~ 4 mm) but it is thin (~ 0.75 mm) in

the anterior-posterior direction (Paxinos and Watson, 2004). Spread of muscimol into areas immediately anterior or posterior to the PPC is therefore inevitable, and, in the two cases where positive effects were observed, raises concerns about region specificity. Immediately anterior to the PPC is the somatosensory cortex (for the trunk). Particularly in light of the intact motor capacities, as indicated by the intact side LED trials, the somatosensory cortex is not expected to have caused any of the observed effects. Immediately posterior to the PPC are a set of individually small visual areas, collectively referred to as secondary visual cortex (V2; Montero, 1993; Wang and Burkhalter, 2007). These visual areas are unlikely to be involved in auditory click accumulation trials, and are therefore not expected to have caused the effects we saw after simultaneous unilateral PPC and bilateral FOF inactivations (**Figure 9e**). However, the bias we observed on free-choice trials may have been partly due to an effect in one or more of these small secondary visual areas. Nevertheless, ipsilateral biases in untrained orienting responses (potentially analogous to the free-choice task) due to PPC lesions have been observed in the rat even when those choices were to tactile or auditory stimuli (Burcham et al., 1997; Corwin et al., 1996; Burcham et al., 1998). We also note that our free choice results closely parallel the results from primate PPC free choice experiments (Wilke et al., 2012), which do not suffer from this spillover concern.

A minimal effect following PPC inactivation in our rat auditory click accumulation task is reminiscent of Guo et al.'s finding of no effect after PPC inactivation in a mouse somatosensory-cued, memory-guided task (Guo et al., 2014). But it contrasts with Harvey et al.'s finding of a severe performance impairment after PPC inactivation in a mouse visually-cued, memory-guided navigation task (Harvey et al., 2012). Following our own preliminary reports (Erlich et al., 2012), a preliminary report from Raposo et al. has suggested an impairment after rat PPC inactivations in a visual, but not in an auditory, version of a closely related task (Raposo et al., 2013). This contrasts with a preliminary report from Yates et al. that suggested no effect from primate PPC inactivation in a visual accumulation of evidence task (Yates et al., 2014). One possibility is that rodent PPC is unlike primate PPC in being required for accumulation of evidence for a specific modality, vision. An alternative possibility, which would make all these results (Harvey et al., Erlich et al., Guo et al., Raposo et al., Yates et al.), including mouse, rat, and primate, fully consistent with each other, is that the impairments in visual tasks observed by Harvey et al. and Raposo et al. were due to inactivation spillover into one the immediately adjacent secondary visual areas, as described above, rather than inactivation of the PPC itself. Distinguishing the two possibilities

will require a far better characterization of the reliability of the border between PPC and secondary visual areas than what is currently available.

COMPARISON TO PRIMATES

To date, the accumulation of evidence literature is mostly composed of electrophysiological experiments with primates. Based on a number of criteria, the rat PPC and FOF have been suggested as analogous to the primate PPC and FEF, respectively (Erlich et al., 2011; Kolb and Walkey, 1987; Reep and Corwin, 2009), and accumulation of evidence signals very similar to those in primates have been found in these two rat areas (T.D.H. et al.) It is therefore tempting to speculate that our results in rat might also hold in primate, and to consider potential interpretations that would be consistent across mammalian model systems.

There have been no published inactivation experiments in primate PPC or FEF during accumulation of evidence tasks. There have, however, been inactivation experiments in related tasks, which in general are in agreement with our findings: prefrontal perturbations strongly bias behavior while posterior parietal perturbations do not. In memory-guided saccade tasks, LIP inactivations have no effect on the choice of saccading either towards or away from the correct hemifield (Chafee and Goldman-Rakic, 2000; Wardak et al., 2002; Liu et al., 2010; Wilke et al., 2012), while FEF and prefrontal inactivations reliably generate profound ipsilateral choice biases (Dias and Segraves, 1999; Sommer and Tehovnik, 1997; Chafee and Goldman-Rakic, 2000). Similarly, in a covert visual search task, LIP inactivation has no effect on error rates (Wardak et al., 2002), while inactivation of the FEF generates significant increase in error rates for contralateral targets (Wardak et al., 2006). Again similarly, in a memory-guided task with distractors, Suzuki et al. (2013) found no errors after LIP inactivations while finding significant contralateral errors after prefrontal cortex inactivations.

We are aware of only a few studies where LIP inactivation produces choice biases (Balan and Gottlieb, 2009; Wilke et al., 2012; Wardak et al., 2002). One of these studies (Wilke et al., 2012) inspired our intermixing free choice trials with accumulation trials. Consistent with a good analogy between rat PPC and primate PPC, our results in rats closely paralleled Wilke et al.'s results in primates, with our accumulation of evidence trials playing the role of their memory-guided saccade trials (**Figure 8**). Also consistent with our rat data and with a good analogy between rat and primate PPC, a preliminary report has suggested that unilateral primate PPC inactivations have no effect on accumulation of evidence trials, while causing an ipsilateral bias on free choice trials (Yates et al. 2014).

There has been one perturbation study in the primate FEF during an accumulation of evidence task (Gold and Shadlen, 2000). This microstimulation study concluded that “developing oculomotor commands may reflect the formation of the monkey’s direction judgement” (i.e., its decision). Our results in rat FOF are consistent with those of Gold and Shadlen, but go considerably further in specifically suggesting the FOF as a requisite premotor component of the output pathway of a long time constant (> 0.24 s) evidence accumulator.

There has been one perturbation study in the primate PPC during an accumulation of evidence task (Hanks et al., 2006). This microstimulation study used a reaction time version of the Random Dots task, and found a pattern of results following LIP microstimulation that could be quantitatively explained in an accumulation-to-bound model if the microstimulation added a small constant offset to the value of the accumulator (Hanks et al., 2006). Unlike the task used by Hanks et al., our task (and that of Yates et al., 2014) was not a reaction time task, which could explain the difference in results. An alternative possibility, noted in their discussion (Hanks et al., 2006), and which would reconcile our results with theirs, is that microstimulation may activate axon terminals or fibers of passage (Histed et al., 2009; 2013; but see Tehovnik and Slocum, 2013). The behavioral effects produced by microstimulation of LIP may thus have been due to activation of neurons with somata not in LIP, but in regions of the brain that project to LIP. Since muscimol does not affect axons or fibers of passage, this possibility would be consistent with our data.

If the PPC plays a causal role in internally-guided decisions, but does not play a causal role in choice behavior during accumulation of evidence tasks, what role is then played by the firing rate correlates of evidence accumulation signals observed in PPC, in both rats and primates? Accumulation signals are also correlated with confidence (Kiani and Shadlen, 2009; Komura et al., 2013). One possibility is that, instead of being used to drive choice behavior, the accumulation signals observed in the PPC are used for computing choice confidence (Kiani and Shadlen, 2009). Confidence could be part of a process for optimizing behavior over many trials, or, in a reaction time version of the task, confidence could be part of determining when the subject chooses to commit to a decision.

CONCLUSION

In the rat, our data now suggests a specific functional role for the FOF in decisions driven by accumulation of evidence: the FOF appears to be a requisite component of the output pathway of an evidence accumulator with a long time constant (> 0.24 s). Decisions with shorter processing times may

involve circuits that bypass the FOF. It is possible that categorizing the graded accumulator’s value into a discrete choice —the final decision itself— could occur in the FOF. In contrast, the PPC seems to play a surprisingly negligible role in choice behavior during decisions guided by accumulation of evidence, even while it plays an important role in internally-guided decisions. Neither region appears likely to play a major causal role in the gradual evidence accumulation process *per se*.

METHODS

Subjects

Animal use procedures were approved by the Princeton University Institutional Animal Care and Use Committee and carried out in accordance with National Institutes of Health standards. All subjects were male Long-Evans rats (Taconic, NY). Rats were placed on a restricted water schedule to motivate them to work for water reward. Rats were kept on a reversed 12h light-dark cycle and were trained in their dark cycle.

Behavior

We trained fourteen male Long-Evans rats on the Poisson Clicks accumulation task (**Figure 1**). Training took place in a behavior box with three nose ports (left, center and right), and with two speakers, placed above the right and left nose ports. Each accumulation trial began with a visible light-emitting diode (LED) turning on in the center port. This cued the trained rat to place its nose in the center port, and keep it there until the LED was turned off. We refer to this period as the “nose in center” or “fixation” period. The duration of fixation was 2 seconds for all accumulation trials. During the fixation period a variable duration auditory stimulus (0.1-1 sec, experimenter controlled) would play, consisting of two randomly timed trains of clicks, playing simultaneously, one from the left and one from the right speaker. At the end of the auditory stimulus, the LED in the center port would extinguish, which was the signal to the rat to make their response by poking into one of the side ports. The timing of the clicks from each speaker was generated by two independent Poisson processes. The total generative click rate (left + right rate) was held constant at 40 clicks/second, and trial difficulty was controlled by adjusting the relative left vs. right rates, as well as the duration of the stimulus. Trials where rats exited the center port during the fixation period were considered violation trials, aborted, and a new trial was started. These trials are not included in any analyses.

To test whether ipsilateral biases after FOF inactivations were due to the spatially competitive nature of accumulation trials (i.e. There was always at least one click from each speaker), we interleaved

“single-sided” trials with accumulation trials (and side LED trials in some sessions). A single-sided trial was much like an accumulation trial, but all the clicks came from one speaker and were played at a Poisson rate of 100 Hz. Since the 100Hz stimuli were easily distinguished from 40Hz stimuli and these trials did not require accumulation (all clicks on one side), rats probably made their decision quickly. However, they were still required to wait until the go cue. These trials comprised ~ 8% of a trials in a session.

In order to control for motor effects of inactivations, in group 2 & 3 rats, we included, randomly interleaved with other trial-types, “side LED” trials. On side LED trials no sounds were played during fixation, which lasted 1 second. Immediately after the end of fixation, one of the two side ports was illuminated, indicating availability of reward at the lit port (**Figure 1**). The right and left side LED trials, together, comprised less than 10% of the total trials.

In order to find a task that was sensitive to inactivation of the PPC, we randomly interleaved “free-choice” trials with the other trial-types. Free-choice trials were similar to side LED trials except at the end of fixation both side LEDs were illuminated and rats were rewarded regardless of whether they poked in the right or left nose port. These sessions took place after all of the experiments presented in **Figures 3-7 & 8E**.

Control sessions (non-infusion sessions) with poor performance (<70% correct overall or fewer than 8 correct trials on each side without fixation violations) were excluded from analyses. These sessions were rare and were usually caused by problems with the hardware (e.g. a clogged water-reward valve or a dirty IR-photodetector). We collected ~125,000 control trials over ~416 sessions from each rat from sessions without intracranial infusions or pre-session anesthesia.

Surgery

Surgical methods were identical to those described previously (Erlich et al., 2011). Briefly, rats were anesthetized with isoflurane and placed in a stereotax. The scalp was deflected and the skull was cleaned of tissue and blood. The stereotax was used to mark the locations of craniotomies for the FOF and PPC on the skull. Craniotomies and durotomies were performed and then the skull was coated with a thin coat of C&B Metabond (Parkell Inc., NY). Guide cannula (PlasticsOne, VA) were lowered to brain surface with dummy cannula extending 0.5 mm below brain surface. Dental acrylic (Duralay, Reliance Dental Mfg. Co, IL) was then used to secure the cannula to the skull. Rats were given 5 days to recover on free water before resuming training.

Cannula

Group 1 rats (n=6) were implanted bilaterally in FOF (+2 AP, ± 1.25 ML mm from Bregma) with 22 AWG guide cannula (C232G-2.5, PlasticsOne, VA) and the medial (3.8 mm posterior, 2.2 mm lateral to Bregma) and lateral (3.8 mm posterior, 3.4 mm lateral to Bregma) PPC with 26 AWG guide cannula (6 cannula per rat total). Group 2 rats (n=4) were implanted in FOF and in PPC (3.8 mm posterior, ± 2.8 mm lateral to Bregma; a total of 4 cannulae per animal) with bilateral 22 AWG guide cannula. Group 3 rats (n=4) were implanted with bilateral 22 AWG guide cannula in FOF and in PPC (4.5 mm posterior, ± 3.0 mm lateral to Bregma; 4 cannulae per animal).

The tip of the guide sat at brain surface and the dummy extended 0.5 mm into cortex. The injector for the 22 AWG guide cannula was a 28 AWG cannula that extended 1.5 mm below brain surface. The injector for the 26 AWG guide cannula was a 33 AWG cannula that extended 1.5 mm below brain surface.

Infusions

In general, infusions were performed once a week with control training days taking place on all other days of the week in order to minimize adaptation to the effects of the muscimol and to have good stable performance in the sessions immediately before infusion sessions. On an infusion day, the rat was placed into an induction chamber with 2% isoflurane, and then transferred to a nose cone with 2% isoflurane for the infusion procedure. Caps and dummy cannula were removed and cleaned. Injectors were placed into the relevant guide cannula and extended 1.5 mm past the end of the guide, into cortex. We used a hamilton syringe connected via tubing to the injector to infuse 0.3 μ L of muscimol (of various concentrations - see Results and **Figure S4**) into cortex. After injection, we left the injector in the brain for 4 minutes to allow diffusion before removal. After 4 minutes, cleaned dummies were placed into the guide cannula and capped and the rat was removed from isoflurane. After 30 minutes of recovery from isoflurane the rat was placed into a behavior box as usual. See **Figure S4** for the complete list of all infusion doses, regions, and order for each rat. Previous experiments in rat cortex, performing autoradiographic estimates (Martin, 1991), as well as simultaneous muscimol inactivation and recordings (Krupa et al., 1999), suggest that at the doses of muscimol we used, the expected area of inactivation would have an approximately ~1 mm radius for the smallest doses and >3mm radius for the largest doses.

Since the only difference between left and right infusions (and FOF and PPC infusions) are the location of the infusion any differences in behavior

can only be attributed to the infusion and not to handling. For bilateral infusions, we were interested in non-lateralized impairments compared to baseline performance. To rule out the possibility that the handling of rats for the infusion procedure could affect performance we did isoflurane-only sessions where rats were handled as they would be for an infusion (taken to the infusion room, placed into an induction chamber with 2% isoflurane, etc.) but given no infusion. These isoflurane-only sessions were used as a baseline to compare with the bilateral infusion sessions.

With pharmacological infusions, one concern is spread of inactivation to other structures. We based the volume and concentration of our infusions on previous literature to achieve inactivation volumes of 1mm radius for our small doses and 3mm radius for our largest doses (Krupa:1999te; Martin, 1991). This spread is within the anterior-posterior bounds of FOF, but could have spread medially to cingulate cortex (CG1) or laterally to M1 (Paxinos and Watson, 2004). In a previous study, we directly tested the effects of M1 inactivation and found them to be weaker than FOF inactivations and also they did not distinguish between sensory-guided and single-sided trials (Erlich et al., 2011). As such, it is unlikely that the effects we are attributing to FOF are due to M1 inactivation. We targeted our inactivations to 2mm anterior and 1.25mm lateral to Bregma. According to the Rat Atlas (Paxinos and Watson, 2004) CG1 may be within the spread of the drug. However, according to a recent cell-based mapping technique the medial boundary of FOF has been underestimated (Brecht et al., 2004), suggesting that most of spread of drug would be within FOF. Moreover, the CG1 is thought to play a role in cost-benefit decisions (Hillman and Bilkey, 2012; Holec et al., 2014), cognitive flexibility (Ragozzino and Rozman, 2007), or emotional reactivity (Bissière et al., 2008), not in movement planning. Therefore, the effects observed are more likely due to changes in FOF rather than an adjacent cortical region.

Analysis & Statistics

All analysis and statistics were computed either in Matlab (version 7 or better, The Mathworks, MA) or R (version 2.15.2, R Foundation for Statistical Computing, Vienna, Austria).

The accumulator model uses 9-parameters (described in **Figure S1**) to transform the stimulus on each trial (input to the model as the left and right click times) into a probability distribution about the choice of the rat. For example, if for a given set of parameter, the model predicts that trial 1 will result in 75% chance of the rat going right, and the rat in fact went right, that trial would be assigned a likelihood of 0.75. In the case that the rat went left, the trial would be assigned a likelihood of 0.25. We fit the model assuming that the trials are independent.

Therefore, for a model with parameters θ for all decisions D , the likelihood is given by:

$$P(D|\theta) = \prod_i P(d_i|t_{i,R}, t_{i,L}, \theta)$$

the product of the likelihoods of the decisions on trial i , d_i , given the times of the right clicks $t_{i,R}$, times of the left clicks $t_{i,L}$, and the set of 9 parameters, θ . A detailed description of the procedure for fitting the accumulator model can be found in the Modeling Methods section of the supplement of Brunton et al. (2013). For panels A, C, & D in **Figure 2** we first concatenated all trials across sessions and rats from sessions one day before an infusion session. The values of the parameters that maximized $P(D|\theta)$ for these concatenated data are described as “Meta-Rat” in **Table S1**. Since the model is fit to the individual trials, we describe the psychometric (2A), chronometric (2C) and reverse correlations (2D) of the model as predictions to make it clear that we are not performing a curve-fitting procedure for each panel. We also fit each rat individually and show the best-fit parameters for each rat in Table S1.

In **figures 3, 4E, 6, 8E & S3A** the psychometric curves were generated by concatenating trial data across sessions for each rat and fitting (using Matlab’s `nlinfit`) a 4-parameter sigmoid as follows. For these fits, x is the click difference on each trial (# Right Clicks - # Left Clicks), y is “P(Went Right)”, and the four parameters to be fit are: x_0 , the inflection point of the sigmoid; b , the slope of the sigmoid; y_0 , the minimum “P(Went Right)”; and $a+y_0$ is the maximum “P(Went Right)”.

$$y = y_0 + \frac{a}{1 + e^{\frac{-(x-x_0)}{b}}}$$

To generate chronometric curves (**Figure S3C, 2C**), we concatenated trials for each rat across sessions and binned trials into easy, medium and hard quantiles with equal number of trials based on the relative left-right click rate. For each of these three difficulty levels we binned trials by stimulus duration.

The detailed methods of generating the psychophysical reverse correlations (**Figures 2D, 4D, 5D, & S3D**) can be found in Brunton et al. (2013). For this analysis separation of right (red lines) and left (green lines) trials at each time in the trial indicates that there was a difference in local click rate at that time for trials in which the rat responded to the right versus to the left. If rats only used the early clicks for their decision (a primacy strategy), the lines would begin separated and come together. Likewise, if they only used the clicks at the end of the stimulus (a recency strategy) the lines would start together and separate towards the end of the trial. To generate the reverse correlation predicted by the accumulator models, each trial was assigned as the left and

right trial, according to the model's prediction for that trial. E.g. if the model predicted that a trial had a 67% change of a rightward choice, this trial would contribute 0.67 to the right trials and 0.33 to the left trials psychophysical kernel.

To estimate bias resulting from unilateral inactivations we subtracted the contralateral % correct from the ipsilateral % correct for each infusion session. To compute the overall bias we averaged the bias across sessions for each rat and then tested using a t-test whether the bias across rats was significantly different from 0. However, this statistical test is conservative, since it collapses across all trials of differing difficulty levels and different sessions. As well, this overall bias measure was inappropriate for testing the effects within each group, since the n per group was low.

As a more sensitive measure of inactivation effects we used a Generalized Linear Mixed-Model (GLMM) as implemented in the function "lmer" in package "lme4" (Bates and Sarkar, 2007; Bates et al., 2007). For unilateral infusions we specified a mixed-effects model where the rats' choice on each trial was a logistic function of # Right - # Left Clicks (Δ Clicks), infusion side and their interaction as fixed effects. The rat and an interaction of rat, infusion side, and Δ Clicks were modeled as within-subject random effects. The statistic reported in the text for unilateral infusions was the p value for the infusion side fixed effect. For bilateral infusions we specified a similar model comparing bilateral infusions to isoflurane-only sessions. For these models the relevant statistic was the significance of the interaction between infusion and Δ Clicks, i.e. a change in the slope of the logistic. Details of the data and code used to generate and compare the models is described in the supplementary information.

To test whether there were effects of unilateral infusions on response times (RT) on side LED trials, measured as time from go cue to side port response, we took the mean RT for each rat for left and right choices on left and right infusion days. We separated leftward and rightward responses because there can be large differences from rat to rat in the left vs. right response times. We then did a repeated-measures ANOVA (Rat X [Left vs. Right] X [Ipsi vs Contra]) to test whether there was an effect of muscimol on RTs. Since ANOVA must be balanced, only 4 rats (out of a possible 8 group 2 & 3 rats) performed enough side LED trials from FOF infusions for this analysis. For the PPC infusions 7 of 8 rats performed enough trials to be included.

For the analyses of biases during free-choice sessions we compared the bias (ipsilateral - contralateral % correct) on the infusion day with the control session one day before and performed t-tests across sessions for each region (PPC or FOF) and

trial-type (free-choice, accumulation or side LED). Some free-choice sessions had no side LED trials which is why there are fewer sessions in the t-tests for that trial-type. Side LED trials were also not analyzed for sessions if the bias in the side LED trials during the preceding control day was greater than 20%.

To better understand what aspect of the task was impaired by unilateral FOF inactivation we took advantage of the knowledge of the times of all the clicks and the rats' choices using our previous modeling work (Figure S1, Brunton et al., 2013) to fit four constrained Accumulator Models to the unilateral FOF infusion data. First, we created a "meta-rat" for both control and infusion data (the same data that was plotted in **Figure 2**). For the control meta-rat we combined the accumulation trials from all days that were one day before any infusion. This resulted in 47580 trials which we used to fit the full 9-parameter Accumulator Model (**Figure 2, S1**). For the infusion meta-rat we combined all 3836 trials from unilateral FOF sessions. Second, to avoid computing the gradient for a 12-parameter model than considering all potential sources of bias together, we fit constrained Accumulator Models that had one parameter free and the other parameters fixed to the best-fit parameters from the control meta-rat Accumulator Model. The details of the free parameter of each model are described in the results section.

To fit the bilateral FOF infusion data we concatenated all trials across all rats and fit 1809 trials with the 9-parameter accumulator model. We validated the error in these fits (which are given by the gradient around best-fit parameters) by sampling the likelihood surfaces 2-parameters at a time.
