

Evidence for a probabilistic, brain-distributed, recursive mechanism for decision-making

Javier A. Caballero^{1,2,3}, Mark D. Humphries^{1,4}, Kevin N. Gurney^{2,4}

Abstract

Decision formation recruits many brain regions, but the procedure they jointly execute is unknown. To characterize it, we introduce a recursive Bayesian algorithm that makes decisions based on spike trains. Using it to simulate the random-dot-motion task, based on area MT activity, we demonstrate it quantitatively replicates the choice behaviour of monkeys, whilst predicting losses of usable sensory information. Its architecture maps to the recurrent cortico-basal-ganglia-thalamo-cortical loops, whose components are all implicated in decision-making. We show that the dynamics of its mapped computations match those of neural activity in the sensory-motor cortex and striatum during decisions, and forecast those of basal ganglia output and thalamus. This also predicts which aspects of neural dynamics are and are not part of inference. Our single-equation algorithm is probabilistic, distributed, recursive and parallel. Its success at capturing anatomy, behaviour and electrophysiology suggests that the mechanism implemented by the brain has these same characteristics.

1 Introduction

Decisions rely on evidence that is collected for, accumulated about, and contrasted between available options. Neural activity consistent with accumulation over time has been reported in parietal and frontal sensory-motor cortex (Roitman and Shadlen, 2002; Huk and Shadlen, 2005; Churchland et al., 2008; Ding and Gold, 2012a; Hanks et al., 2015), and in the subcortical striatum (Ding and Gold, 2010, 2012b). What overall computation underlies these local snapshots, and how is it distributed across cortical and subcortical circuits, is unclear.

Multiple models of decision making reproduce aspects of recorded choice behaviour, associated neural activity or both (Furman and Wang, 2008; Wong et al., 2007; Albantakis and Deco, 2009; Mazurek et al., 2003; Ditterich, 2006; Lo and Wang, 2006; Grossberg and Pilly, 2008). While successful, they lack insight into the underlying decision procedure (but see Beck et al. (2008)). In contrast, other studies have shown how exact inference algorithms may be plausibly implemented by a range of neural circuits (Bogacz and Gurney, 2007; Larsen et al., 2010; Lepora and Gurney, 2012; Caballero et al., 2015); however, none of these has been demonstrated to reproduce experimental decision data.

Here we close that gap by showing that a recursive quasi-Bayesian algorithm —whose components naturally map to recurrent cortico-subcortical loops— can originate the choice behaviour observed in primates during the random dot motion task, as well as its known neural activity correlates, as a direct transformation of the information in sensory cortex. Introducing this algorithm enables us to predict which aspects of neural activity are necessary for inference in decision making, and which are not. Our analysis predicts that evidence accumulation occurs over the entire feedback loop and, in particular, that it is not exclusive to increasing firing rates, but that, counter-intuitively, it can even take the form of rate decrements. Our algorithm explains the decision-correlated experimental data more comprehensively than preceding models, thus introducing a formal, systematic framework to interpret this data. Collectively, our analyses and simulations indicate that mammalian decision-making is implemented as a probabilistic, recursive and parallel procedure distributed across the cortico-basal-ganglia-thalamo-cortical loops.

2 Results

We tested our models against behavioural and electrophysiological data recorded by Churchland et al. (2008), from monkeys performing 2- and 4-alternative reaction-time versions of the random dot motion task (Fig. 1b,c). In all forms of the task, the monkey observes the motion of dots and indicates the dominant direction of motion with a saccadic eye movement to a target in that direction. Task difficulty is controlled by the coherence of the motion: the percentage of dots moving in the target’s direction.

During the dot motion task, neurons in the middle-temporal visual area (MT) respond more vigorously to visual stimuli moving in their “preferred” direction than in the opposite “null” direction (Britten et al., 1992a). Both the mean (Fig. 1d) and variance (Fig. 1e) of their response are proportional to the coherence of the motion. MT responses are assumed to be the uncertain evidence upon which a choice is made in the random dots task (Roitman and Shadlen, 2002; Mazurek et al., 2003).

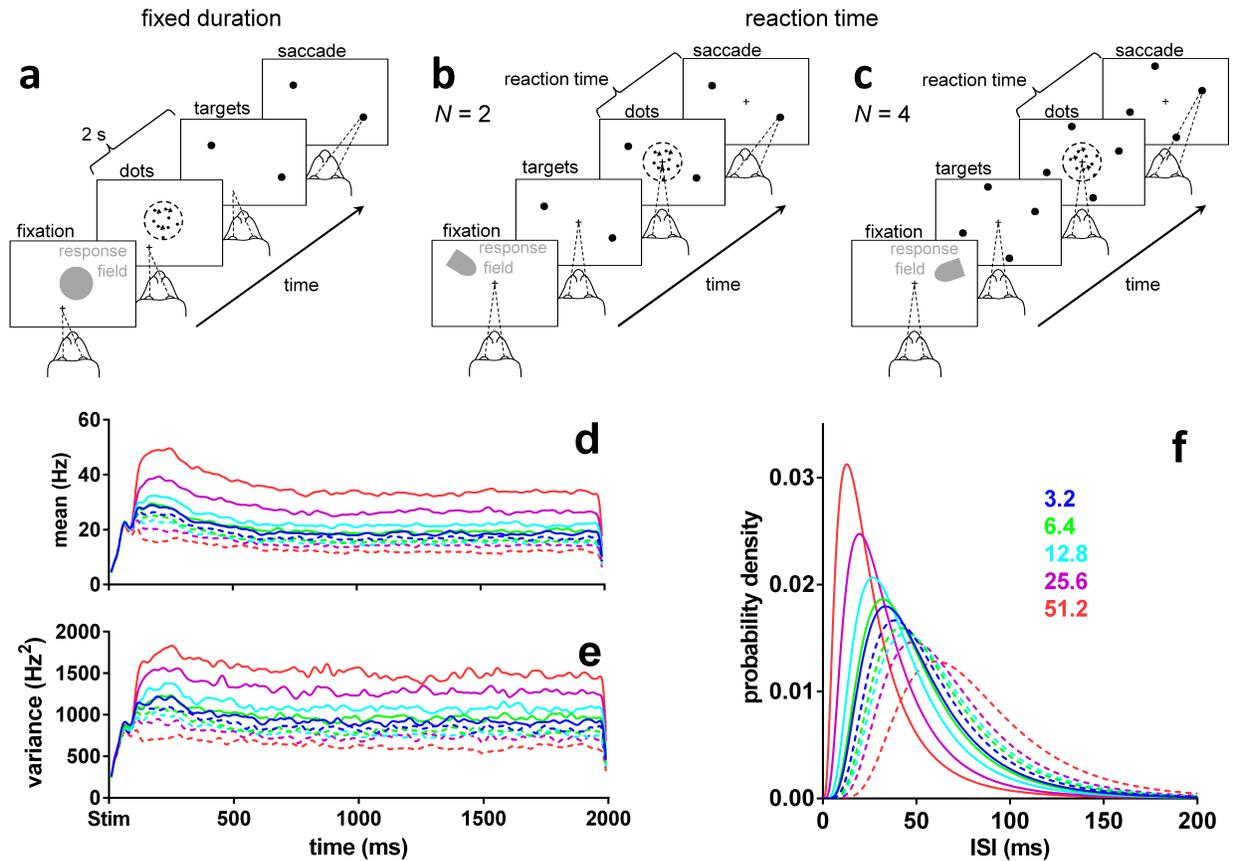

Figure 1: Random dot motion task and MT data. (a) Fixed duration task for MT recordings (Britten et al., 1992a). (b, c) Reaction time task for LIP recordings, $N = 2, 4$ alternatives (Churchland et al., 2008). (d, e) Smoothed population moving mean and variance of the firing rate in MT during the fixed duration dot motion task, aligned at onset of the dot stimulus (Stim), for a variety of coherence percentages (colour-coded as in the legend in panel f). Solid lines are statistics when dots were moving in the preferred direction of the MT neuron. Dashed lines are statistics when dots were moving in the opposite, null direction. Data from Britten et al. (1992a), re-analysed. (f) Lognormal density functions for the inter-spike intervals (ISI) specified by the statistics over the approximately stationary segment of (d, e) before smoothing (parameter set Ω in table S1). Preferred and null motion directions by line type as in (d, e).

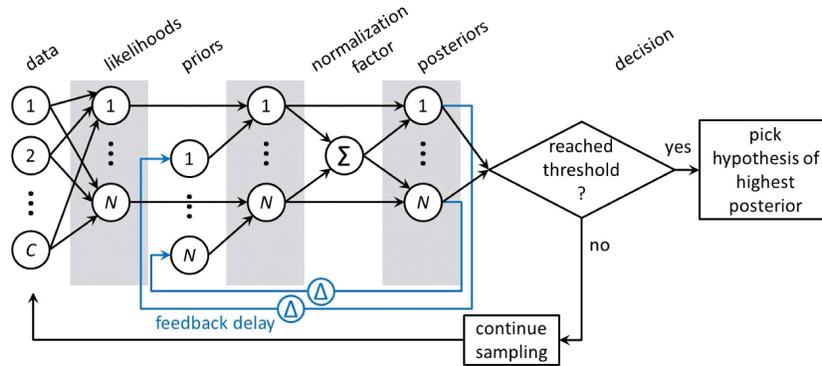

Figure 2: The MSPRT and rMSPRT in schematic form. Circles joined by arrows are the Bayes’ rule. All C evidence streams (data) are used to compute every one of the N likelihood functions. The product of the likelihood and prior probability of every hypothesis is normalized by the sum (Σ) of all products of likelihoods and priors, to produce the posterior probability of that hypothesis. All posteriors are then compared to a constant threshold. A decision is made every time with two possible outcomes: if a posterior reached the threshold, the hypothesis with the highest posterior is picked, otherwise, sampling from the evidence streams continues. The MSPRT as in Baum and Veeravalli (1994) and Bogacz and Gurney (2007) only requires what is shown in black. The general recursive MSPRT introduced here re-uses the posteriors Δ time steps in the past for present inference; hence the rMSPRT is shown in black and blue. If we are to work with the negative-logarithm of the Bayes’ rule and its computations —as we do in this article— all relations between computations are preserved, but products of computations become additions of their logarithms and the divisions for normalization become their negative logarithm. Eq. 13 shows this for the rMSPRT. The rMSPRT itself is formalized by Eq. 14.

2.1 Recursive MSPRT

Normative algorithms are useful benchmarks to test how well the brain approximates an optimal algorithmic computation. The family of the multi-hypothesis sequential probability ratio test (MSPRT) (Baum and Veeravalli, 1994) is an attractive normative framework for understanding decision-making. However, the MSPRT is a feedforward algorithm. It cannot account for the ubiquitous presence of feedback in neural circuits and, as we show ahead, for slow dynamics in neural activity that result from this recurrence during decisions. To solve this, we introduce a recursive generalization, the rMSPRT, which uses a generalized, feedback form of the Bayes’ rule we deduced from first principles (Eq. 9).

Here we schematically review the MSPRT and introduce the rMSPRT (Fig. 2), giving full mathematical definitions and deductions in the Supplemental Experimental Procedures. The (r)MSPRT decides which of N parallel, competing alternatives (or hypotheses) is the best choice, based on C sequentially sampled streams of evidence (or data). For modelling the dot-motion task, we have $N = 2$ or $N = 4$ hypotheses —the possible saccades to available targets (Fig. 1b,c)— and the C uncertain *evidence streams* are assumed to be simultaneous spike trains produced by visual-motion-sensitive MT neurons (Roitman and Shadlen, 2002; Mazurek et al., 2003; Caballero et al., 2015). Every time new evidence arrives, the (r)MSPRT refreshes ‘on-line’ the likelihood of each hypothesis: the plausibility of the combined evidence streams assuming that hypothesis is true. The likelihood is then multiplied by the probability of that hypothesis based on past experience (the prior). This product for every hypothesis is then normalized by the sum of the products from all N hypotheses; this normalisation is crucial for decision, as it provides the competition between hypotheses. The result is the probability of each hypothesis given current evidence (the posterior) —a *decision variable* per hypothesis. Finally, posteriors are compared to a threshold, and a decision is made to either choose the hypothesis whose posterior probability crosses the threshold, or to continue sampling the evidence streams. Crucially, the (r)MSPRT allows us to use the same algorithm irrespective of the number of alternatives, and thus aim at a unified explanation of the $N = 2$ and $N = 4$ dot-motion task variants.

The MSPRT is a special case of the rMSPRT (in its general form in Eqs. 9 and 14) when priors do not change or, equivalently, for an infinite recursion delay; this is, $\Delta \rightarrow \infty$. Also, the previous recurrent extension of MSPRT (Larsen et al., 2010; Ditterich, 2010) is a special case of the rMSPRT when $\Delta = 1$. Hence, the rMSPRT generalizes both in allowing the re-use of posteriors from *any* given time in the past as priors for present inference. This uniquely allows us to map the rMSPRT onto neural circuits containing arbitrary feedback delays, in particular solving the

problem of decomposing the decision-making algorithm into distributed components across multiple brain regions. We show below how this allows us to map the rMSPRT onto the cortical-basal-ganglia-thalamo-cortical loops.

Inference using recursive and non-recursive forms of Bayes' rule gives the same results (*e.g.* see Sivia and Skilling (2006)), and so MSPRT and rMSPRT perform identically. Thus, like MSPRT (Baum and Veeravalli, 1994; Bogacz and Gurney, 2007), for $N = 2$ rMSPRT also collapses to the sequential probability ratio test of Wald (1947) and is thereby optimal in the sense that it requires the smallest expected number of observations to decide, at any given error rate (Wald and Wolfowitz, 1948). This is to say that the (r)MSPRT is quasi-Bayesian in general: the physical limit of performance or ideal (Bayesian) observer for two-alternative decisions ($N = 2$), and an asymptotic approximation to it for decisions between more than two ($N > 2$) (Baum and Veeravalli, 1994; Bogacz and Gurney, 2007).

2.2 Upper bounds of decision time predicted by the (r)MSPRT

We first use a particular instance of rMSPRT (Eqs. 13 and 14) to determine bounds on the decision time in the dot motion task. We can then ask how well monkeys approximate such bounds. This results from using a minimal amount of sensory information, by assuming as many evidence streams as alternatives; that is, $C = N$. Thus, it gives the upper bound on optimal expected decision times (exact for $N = 2$ alternatives, approximate for $N = 4$) per *condition* (given combination of coherence and N); assuming $C > N$ would predict shorter decision times (see Caballero et al. (2015)).

Following Caballero et al. (2015), we assume that during the random dot motion task (Fig. 1a-c), the evidence streams for every possible saccade come as simultaneous sequences of inter-spike intervals (ISI) produced in MT. On each time step, fresh evidence is drawn from the appropriate (null or preferred direction) ISI distributions extracted from MT data (Fig. 1f). By repeating the simulations for thousands of trials per condition, we can compare model and monkey performance.

Using these data-determined MT statistics, the (r)MSPRT predicts that the mean decision time on the dot motion task is a decreasing function of coherence (Fig. 3a). For comparison with monkey reaction times, the model's reaction times are the sum of its decision times and estimated non-decision time, encompassing sensory delays and motor execution. For macaques 200–300 ms of non-decision time is a plausible range (Resulaj et al., 2009; Drugowitsch et al., 2012). Within this range, monkeys tend not to reach the predicted upper bound of reaction time.

The (r)MSPRT framework suggests that decision times depend on the discrimination information in the evidence. Discrimination information here is measured as the divergence between the ISI distributions of MT neurons for dots moving in their preferred and null directions. Intuitively, the larger this divergence, the easier and hence faster the decision. We can estimate how much discrimination information monkeys used by asking how much the (r)MSPRT would require to obtain the same reaction times on correct trials as the monkeys, per condition. We thus find that monkeys tended to use less discrimination information than that in ISI distributions in their MT when making the decision (Fig. 3b). In contrast, the (r)MSPRT uses the full discrimination information available. This implies that the decision-making mechanism in monkeys lost large proportions of MT discrimination information (Fig. 3c). Since these (r)MSPRT decision times are upper bounds, this in turn means that this loss of discrimination information is the minimum.

2.3 (r)MSPRT with depleted information reproduces monkey performance

To verify if this information loss alone could account for the monkeys' deviation from the (r)MSPRT upper bounds, we depleted the discrimination information of its input distributions to exactly match the estimated monkey loss in Fig. 3c per condition. We did so only by modifying the mean and standard deviation of the null direction ISI distribution, to make it more similar to the preferred distribution (exemplified in Fig. 3d).

Using these information-depleted statistics, the mean reaction times predicted by the (r)MSPRT in correct trials closely match those of monkeys (Fig. 4a). Strikingly, although this information-depletion procedure is based only on data from correct trials, the (r)MSPRT now also matches closely the mean reaction times of monkeys from error trials (Fig. 4b). Moreover, for both correct and error trials the (r)MSPRT accurately captures the relative scaling of mean reaction time by the number of alternatives (Fig. 4a,b).

The reaction time distributions of the model closely resemble those of monkeys in that they are positively skewed and exhibit shorter right tails for higher coherence levels (Fig. 4c-f). These qualitative features are captured across both correct and error trials, and 2 and 4-alternative tasks. Together, these results support the hypothesis that the primate brain approximates an algorithm similar to the rMSPRT.

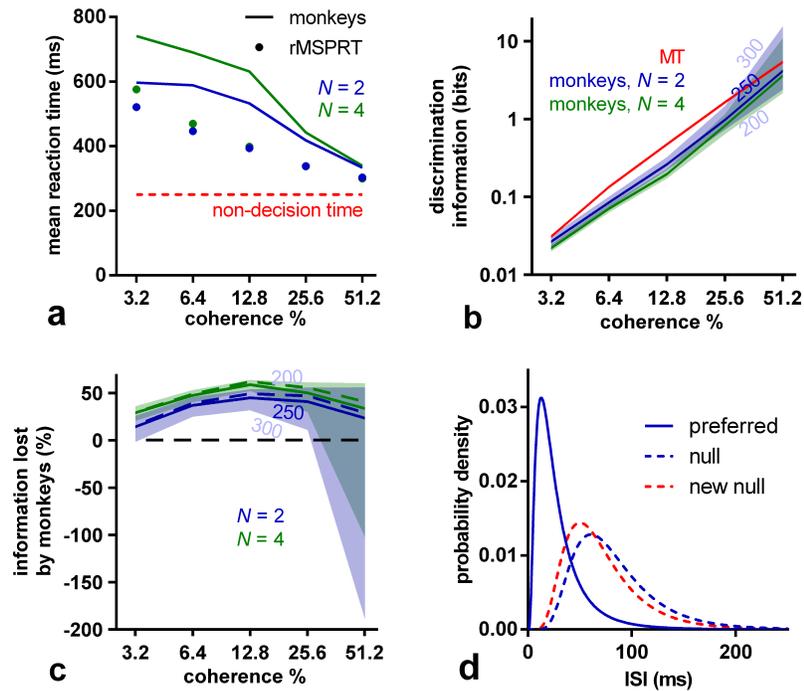

Figure 3: (r)MSPRT predicts information loss during decision making. (a) Comparison of mean reaction time of monkeys for 2 and 4 alternatives (lines) with that predicted by (r)MSPRT (markers), both for correct trials. Red line: assumed 250 ms of non-decision time. Simulation values are means over 100 Monte Carlo experiments each comprising 3200, 4800 total trials for $N = 2, 4$, correspondingly, under the parameter set Ω extracted from MT recordings. (b) Discrimination information per ISI in MT statistics (red) compared to the (r)MSPRT's predictions of the discrimination information available to the monkeys. Central lines are for a non-decision time of 250 ms; the edges of the correspondingly-coloured shaded regions are for non-decision times of 300 and 200 ms. (c) As per panel (b), but expressed as a percentage of information lost by monkeys with respect to the information available in MT for the three assumed non-decision times (solid lines and shadings). The information lost if the reaction time match is perfected (see Supplemental note S1.2.1) is shown as dashed lines (assuming 250 ms of non-decision time). (d) Example ISI density functions before (blue) and after (solid blue and dashed red) information depletion; $N = 2$, 51.2 % coherence and 250 ms of non-decision time. The null distribution was adjusted to become the 'new null' by changing its mean and standard deviation to make it more similar to the preferred distribution. After adjustment, the discrimination information between the preferred and 'new null' distributions matches that estimated from the monkeys performance (panel b).

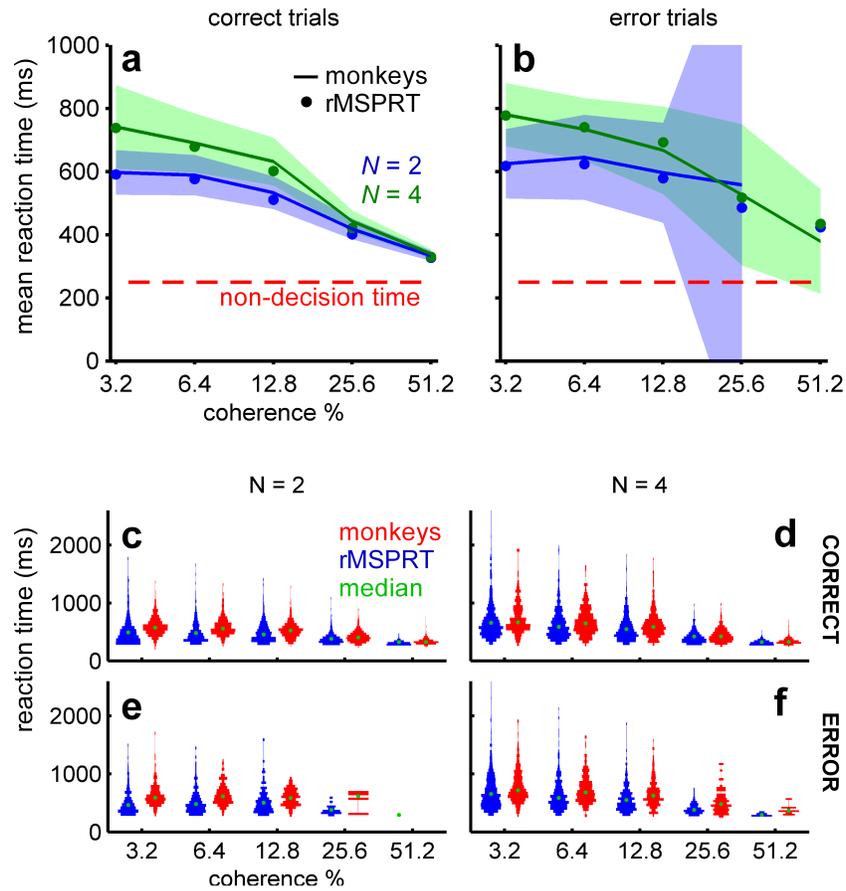

Figure 4: Monkey reaction times are consistent with (r)MSPRT using depleted discrimination information. (a, b) Mean reaction time of monkeys (lines) with 99 % Chebyshev confidence intervals (shading) and (r)MSPRT predictions for correct (a; Eq. 1) and error trials (b; Eq. 2) when using information-depleted statistics (MT parameter set Ω_d). (r)MSPRT results are means of 100 simulations with 3200, 4800 total trials each for $N = 2, 4$, respectively. Confidence intervals become larger in error trials because monkeys made fewer mistakes for higher coherence levels. (c-f) ‘Violin’ plots of reaction time distributions (vertically plotted histograms reflected about the y-axis) from monkeys (red; 766–785, 1170–1217 trials for $N = 2, 4$, respectively) and (r)MSPRT when using information-depleted statistics (blue; single example Monte Carlo simulation with 800, 1200 total trials for $N = 2, 4$).

2.4 rMSPRT maps onto cortico-subcortical circuitry

Beyond matching behaviour, we then asked whether the rMSPRT could account for the simultaneously recorded neural dynamics during decision making. To do so, we first must map its components to a neural circuit. Being able to handle arbitrary signal delays means the rMSPRT could in principle map to a range of feedback neural circuits. Because cortex (Roitman and Shadlen, 2002; Huk and Shadlen, 2005; Churchland et al., 2008; Ding and Gold, 2012a; Hanks et al., 2015), basal ganglia (Redgrave et al., 1999; Ding and Gold, 2010) and thalamus (Watanabe and Funahashi, 2004) have been implicated in decision-making, we sought a mapping that could account for their collective involvement.

In the visuo-motor system, MT projects to the lateral intra-parietal area (LIP) and frontal eye fields (FEF)—the ‘sensory-motor cortex’. The basal ganglia receives topographically organized afferent projections (Heimer et al., 1995) from virtually the whole cortex, including LIP and FEF (Petras, 1971; Saint-Cyr et al., 1990; Hamani et al., 2004). In turn, the basal ganglia provide indirect feedback to the cortex through thalamus (Alexander et al., 1986; Middleton and Strick, 2000). This arrangement motivated the feedback embodied in rMSPRT.

Multiple parallel recurrent loops connecting cortex, basal ganglia and thalamus can be traced anatomically (Alexander et al., 1986; Middleton and Strick, 2000). Each loop in turn can be sub-divided into topographically organised parallel loops (Alexander and Crutcher, 1990; Middleton and Strick, 2000). Based on this, we conjecture the organization of these circuits into N functional loops, for decision formation, to simultaneously evaluate the possible hypotheses.

Our mapping of computations within the rMSPRT to the cortico-basal-ganglia-thalamo-cortical loop is shown in Fig. 5. Its key ideas are, first, that areas like LIP or FEF in the cortex evaluate the plausibility of all available alternatives in parallel, based on the evidence produced by MT, and join this to any initial bias. Second, that as these signals traverse the basal ganglia, they compete, resulting in a decision variable per alternative. Third, that the basal ganglia output nuclei uses these to assess whether to make a final choice and what alternative to pick. Fourth, that decision variables are returned to LIP or FEF via thalamus, to become a fresh bias carrying all conclusions on the decision so far. The rMSPRT thus predicts that evidence accumulation happens in the overall, large-scale loop, rather than in a single site. Lastly, our mapping of the rMSPRT provides an account for the spatially diffuse cortico-thalamic projection (McFarland and Haber, 2002); it predicts the projection conveys a hypothesis-independent signal that does not affect the inference carried out by the loop, but may produce the increasing offset required to facilitate the cortical re-use of inhibitory feedback decision information from the basal ganglia (see Supplemental note S1.2.2).

2.5 Electrophysiological comparison

With the mapping above, we can compare the proposed rMSPRT computations to recorded activity during decision-making in area LIP and striatum. We first consider the dynamics around decision initiation. During the dot motion task, the mean firing rate of LIP neurons deviates from baseline into a stereotypical dip soon after stimulus onset, possibly indicating the reset of a neural integrator (Roitman and Shadlen, 2002; Furman and Wang, 2008). LIP responses become choice- and coherence-modulated after the dip (Roitman and Shadlen, 2002). We therefore reasoned that LIP neurons engage in decision formation from the bottom of the dip and model their mean firing rate from then on. After this, mean firing rates “ramp-up” for ~ 40 ms, then “fork”: they continue ramping-up if dots moved towards the response (or movement) field of the neuron (inRF trials; Fig. 6a, solid lines) or drop their slope if the dots were moving away from its response field (outRF trials; dashed lines) (Roitman and Shadlen, 2002; Churchland et al., 2008). The magnitude of LIP firing rate is also proportional to the number of available alternatives (Fig. 6a,b) (Churchland et al., 2008).

The model LIP in rMSPRT (sensory-motor cortex) captures each of these properties: activity ramps from the start of the accumulation, forks between putative in- and out-RF responses, and scales with the number of alternatives (Fig. 6c). Under this model, inRF responses in LIP occur when the likelihood function represented by neurons was best matched by the uncertain MT evidence; correspondingly, outRF responses occur when the likelihood function was not well matched by the evidence.

The rMSPRT provides a mechanistic explanation for the ramp-and-fork pattern. Initial accumulation (steps 0–2) occurs before the feedback has arrived at the model sensory-motor cortex, resulting in a ramp. The forking (at step 3) is the point at which the posteriors from the output of the model basal ganglia first arrive at sensory-motor cortex to be re-used as priors. By contrast, non-recursive MSPRT (without feedback of posteriors) predicts well-separated neural signals throughout (Fig. 6e). Consequently, the rMSPRT suggests that the fork represents the time at which updated signals representing the competition between alternatives—here posterior probabilities—are made available to the sensory-motor cortex.

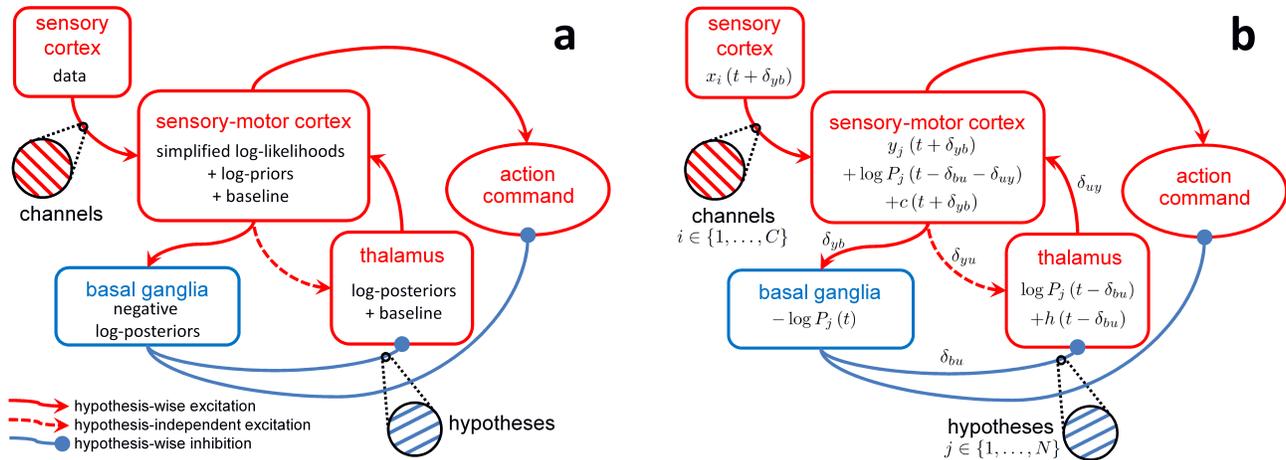

Figure 5: Mapping of rMSPRT computations to the cortico-basal-ganglia-thalamo-cortical loops. (a) Mapping of the negative logarithm of rMSPRT components from Fig. 2. Sensory cortex (*e.g.* MT) produces fresh evidence for the decision, delivered to sensory-motor cortex in C parallel channels (*e.g.* MT spike trains). Sensory-motor cortex (*e.g.* LIP or FEF) computes in parallel the simplified log-likelihoods of all hypotheses given this evidence and adds log-priors —or fed-back log-posteriors after the delay Δ has elapsed. It also adds a hypothesis-independent baseline comprising a simulated constant background activity (*e.g.* from LIP before stimulus onset) and a time-increasing term from the interaction with the thalamus. The basal ganglia bring the computations of all hypotheses together into new negative log-posteriors that are then tested against a threshold. Negative log-posteriors will tend to decrease for the best-supported hypothesis and increase otherwise. This is consistent with the idea that basal ganglia output selectively removes inhibition from a chosen motor program while increasing inhibition of competing programs (Basso and Wurtz, 2002; Humphries et al., 2006; Bogacz and Gurney, 2007; Redgrave et al., 1999). Further details of this computation are in Supplemental Fig. S1. Finally, the thalamus conveys the updated log-posterior from basal ganglia output to be used as a log-prior by sensory-motor cortex. Thalamus' baseline is given by its diffuse feedback from sensory-motor cortex. (b) Corresponding formal mapping of rMSPRT's computational components, showing how Eq. 13 decomposes. All computations are delayed with respect to the basal ganglia via the integer latencies δ_{pq} , from p to q ; where $p, q \in \{y, b, u\}$, y stands for the sensory-motor cortex, b for the basal ganglia and u for the thalamus. $\Delta = \delta_{yb} + \delta_{bu} + \delta_{uy}$ with the requirement $\Delta \geq 1$.

The rMSPRT further predicts that the scaling of activity in sensory-motor cortex by the number of alternatives is due to cortico-subcortical loops becoming organized as N parallel functional circuits, one per hypothesis. This would determine the baseline output of the basal ganglia. Until task related signals reach the model basal ganglia, their output codes the initial priors for the set of N hypotheses. Their output is then an increasing function of the number of alternatives (Fig. 6f). This increased inhibition of thalamus in turn reduces baseline cortical activity as a function of N . The direct proportionality of basal ganglia output firing rate to N recorded in the substantia nigra pars reticulata (SNr) of macaques during a fixed-duration choice task (Basso and Wurtz, 2002) lends support to this hypothesis.

The rMSPRT also captures key features of dynamics at decision termination. For inRF trials, the mean firing rate of LIP neurons peaks at or very close to the time of saccade onset (Fig. 6b). By contrast, for outRF trials mean rates appear to fall just before saccade onset. The rMSPRT can capture both these features (Fig. 6d) when we allow the model to continue updating after the decision rule (Eq. 14) is met. The decision rule is implemented at the output of the basal ganglia and the model sensory-motor cortex peaks just before the final posteriors have reached the cortex. The rMSPRT thus predicts that the activity in LIP lags the actual decision.

This prediction may explain an apparent paradox of LIP activity. The peri-saccadic population firing rate peak in LIP during inRF trials (Fig. 6b) is commonly assumed to indicate the crossing of a threshold and thus decision termination. Visuo-motor decisions must be terminated well before saccade to allow for the delay in the execution of the motor command, conventionally assumed in the range of 80–100 ms in macaques (Mazurek et al., 2003; Resulaj et al., 2009). It follows that LIP peaks too close to saccade onset (~ 15 ms before) for this peak to be causal. The rMSPRT suggests that the inRF LIP peak is not indicating decision termination, but is instead a delayed read-out of termination in an upstream location.

LIP firing rates are also modulated by dot-motion coherence (Fig. 7a,b,i,j). Following stimulus onset, the response of LIP neurons tends to fork more widely for higher coherence levels (Fig. 7a,i) (Roitman and Shadlen, 2002; Churchland et al., 2008). The increase in activity before a saccade during inRF trials is steeper for higher coherence levels, reflecting the shorter average reaction times (Fig. 7b,j) (Roitman and Shadlen, 2002; Churchland et al., 2008). The rMSPRT shows coherence modulation of both the forking pattern (Fig. 7c,k) and slope of activity increase (Fig. 7d,l). rMSPRT also predicts that the apparent convergence of LIP activity to a common level in inRF trials is not required for inference and so may arise due to additional neural constraints. We take up this point in the Discussion.

Similar modulation of population firing rates during the dot motion task has been observed in the striatum (Ding and Gold, 2010). Naturally, the striatum in rMSPRT, which relays cortical input (Supplemental Fig. S1), captures this modulation (Supplemental Fig. S2).

2.6 Electrophysiological predictions

Our proposed mapping of the rMSPRT’s components (Fig. 5) makes testable qualitative predictions for the mean responses in basal ganglia and thalamus during the dot motion task. For the basal ganglia output, likely from the oculomotor regions of the SNr, rMSPRT (like MSPRT) predicts a drop in the activity of output neurons in inRF trials and an increase in outRF ones. It also predicts that these changes are more pronounced for higher coherence levels (Fig. 7e,f,m,n). These predictions are consistent with recordings from macaque SNr neurons showing that they suppress their inhibitory activity during visually or memory guided saccade tasks, in putative support of saccades towards a preferred region of the visual field (Handel and Glimcher, 1999; Basso and Wurtz, 2002), and enhance it otherwise (Handel and Glimcher, 1999).

For visuo-motor thalamus, rMSPRT predicts that the time course of the mean firing rate will exhibit a ramp-and-fork pattern similar to that in LIP (Fig. 7g,h,o,p). The separation of in- and out-RF activity is consistent with the results of Watanabe and Funahashi (2004) who found that, during a memory-guided saccade task, neurons in the macaque medio-dorsal nucleus of the thalamus (interconnected with LIP and FEF), responded more vigorously when the target was flashed within their response field than when it was flashed in the opposite location.

2.7 Predictions for neural activity features not crucial for inference

Understanding how a neural system implements an algorithm is complicated by the need to identify which features are core to executing the algorithm, and which are imposed by the constraints of implementing computations using neural elements—for example, that neurons cannot have negative firing rates, so cannot straightforwardly represent negative numbers. The three free parameters in the rMSPRT allow us to propose which functional and anatomical properties of the cortico-basal-ganglia-thalamo-cortical loop are workarounds within these constraints, but do not affect inference.

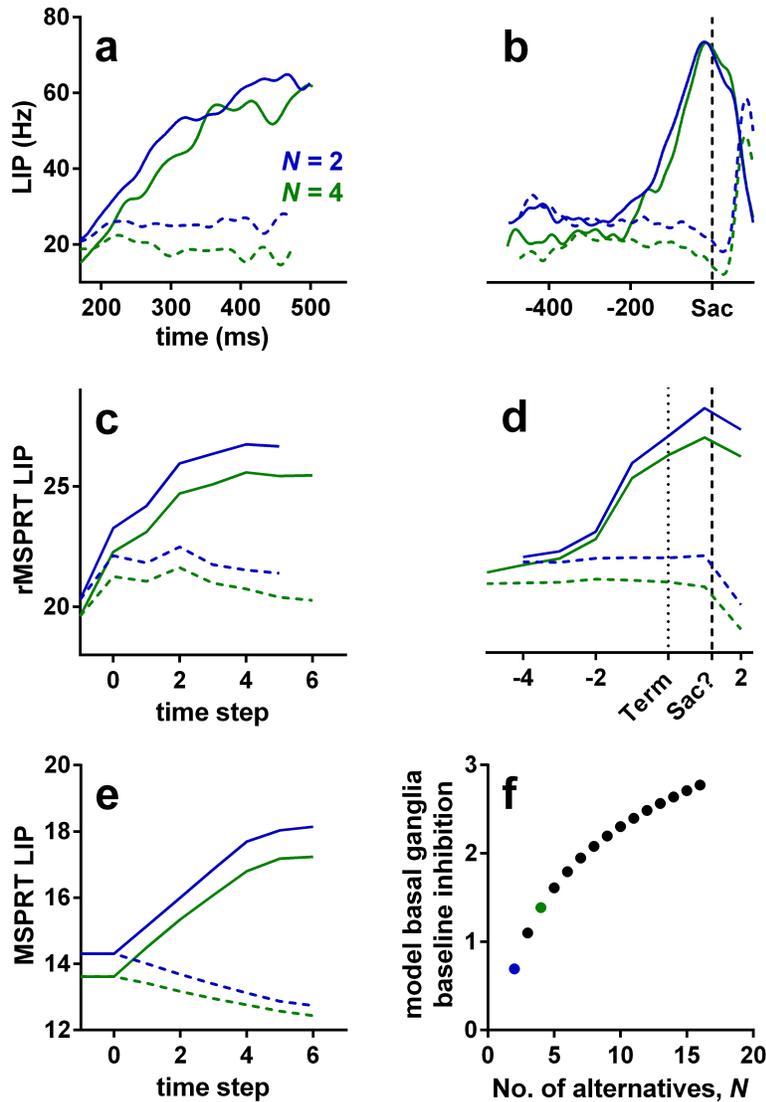

Figure 6: Example LIP firing rate patterns and predictions of rMSPRT and MSPRT at 25.6 % coherence. (a, b) Mean population firing rate of LIP neurons during correct trials on the reaction-time version of the dot motion task. By convention, inRF trials are those when recorded neurons had the motion-cued target inside their response field (solid lines); outRF trials are those when recorded neurons had the motion-cued target outside their response field (dashed lines). (a) Aligned at stimulus onset, starting at the stereotypical dip, illustrating the “ramp-and-fork” pattern between average inRF and outRF responses. (b) Aligned at saccade onset (vertical dashed line). (c, d) Mean time course of the model sensory-motor cortex in rMSPRT aligned at decision initiation (c; $t = 1$) and termination (d; Term; dotted line), for correct trials. Initiation and termination are with respect to the time of basal ganglia output. Note the suggested saccade time “Sac?”, close to the peak of inRF computations. Simulations are a single Monte Carlo experiment with 800, 1200 total trials for $N = 2, 4$, respectively, using parameter set Ω_d . We include an additional step at -1 determined only by initial priors and baseline, where no inference is carried out ($y_i(t + \delta_{yb}) = 0$ for all i). Conventions as in (a). (e) Same as in (c), but for the standard, non-recursive MSPRT (defined as Eq. 14 using only the first case of Eqs. 12 and 13). (f) Baseline output of the model basal ganglia increases as a function of the number of alternatives, thus increasing the initial inhibition of thalamus and cortex. For uniform priors, the rMSPRT predicts this function is: $-\log P(H_i) = -\log(1/N)$. Coloured dots indicate $N = 2$ (blue) and $N = 4$ (green).

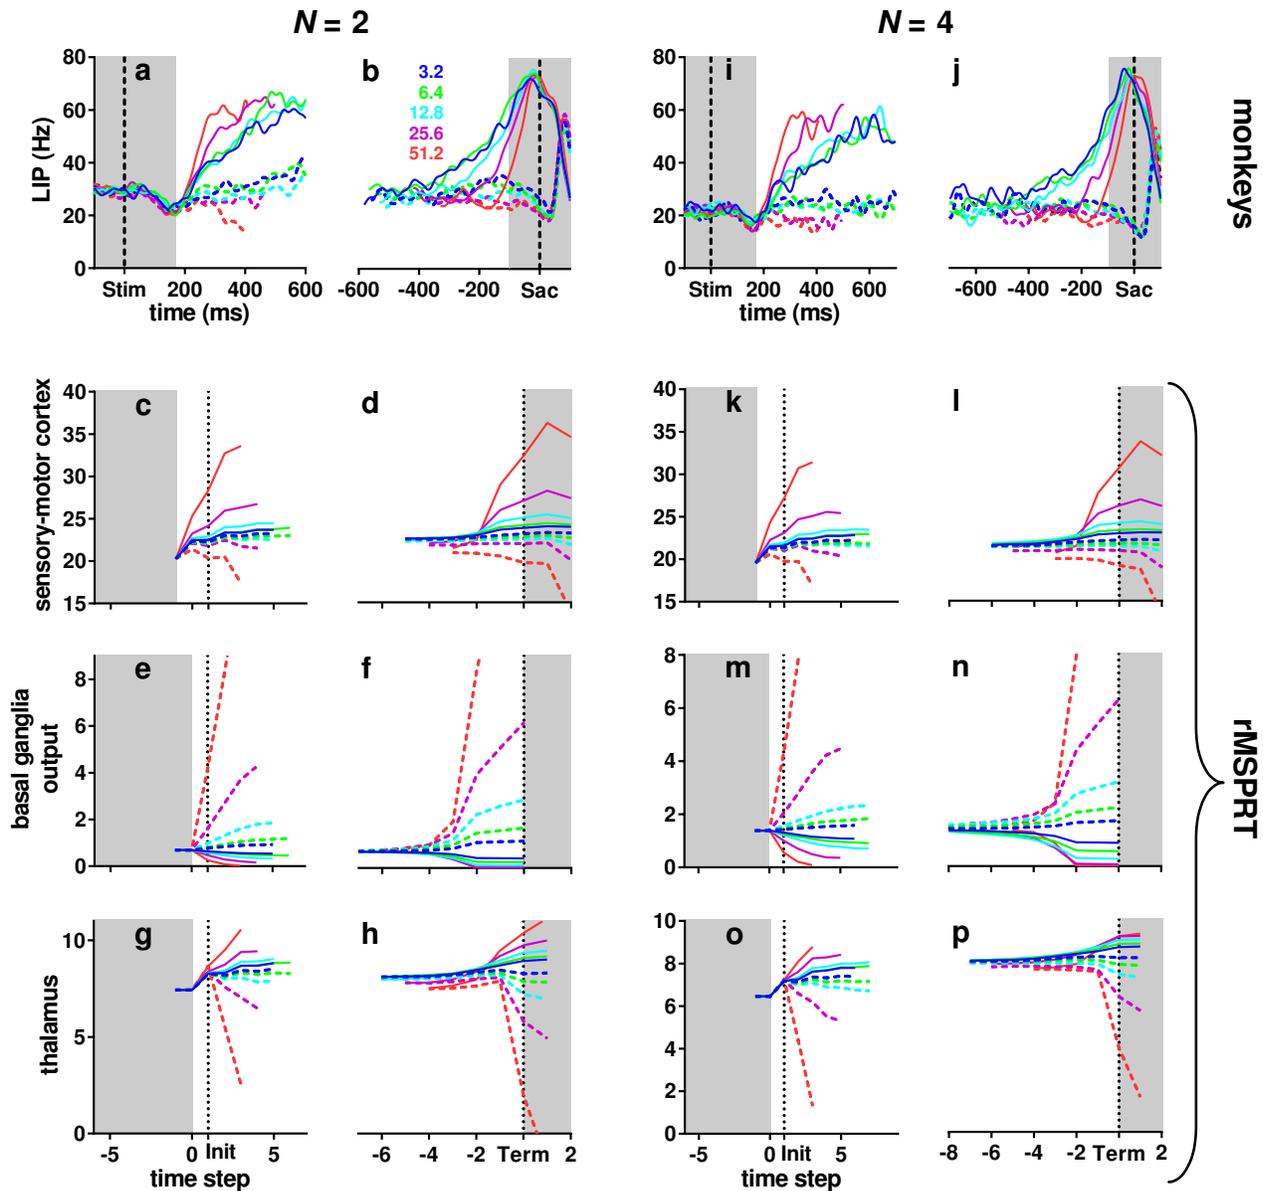

Figure 7: Modulation of activity by coherence throughout the cortico-basal-ganglia-thalamo-cortical loop. (a-h) $N = 2$. (i-p) $N = 4$. Top row: mean firing rate in LIP over time, aligned to stimulus onset (Stim; a, i) or saccade onset (Sac; b, j) (vertical dashed lines). (c-h, k-p) mean rMSPRT computations as mapped in Fig. 5, aligned at decision initiation or termination (Init/Term; dotted lines); single Monte Carlo experiment with 800, 1200 total trials for $N = 2, 4$, respectively. (c, d, k, l) predicted time course of the model sensory-motor cortex (*e.g.* LIP). (e, f, m, n) predicted simultaneous course of mean firing rate in SNr. (g, h, o, p) predicted course in thalamic relay nuclei. Solid: inRF. Dashed: outRF. Coherence % as in legend. Unshaded regions indicate approximate periods where a mechanism of decision formation should aim to reproduce the recordings.

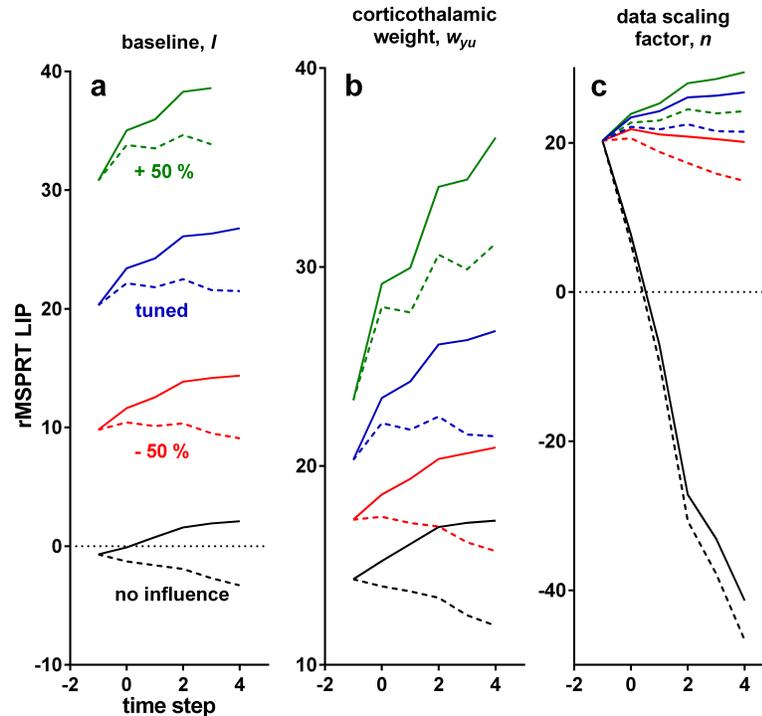

Figure 8: Effect of variations of free parameters on the time course of the model LIP in rMSPRT. Each solid and dashed set of lines is the mean of correct trials in a single Monte Carlo experiment, with 800 total trials, 25.6 % coherence and $N = 2$. Computations aligned at decision initiation. Solid: inRF. Dashed: outRF. Blue: with parameters as tuned for this study. Green: increasing parameter value by 50 %, keeping other parameters as tuned. Red: decreasing it by 50 %, keeping others as tuned. Black: removing the effect of the tested parameter ($l = 0$, $w_{yu} = 0$, $n = 1$), keeping others as tuned. (a) Varying the baseline, l . (b) Varying the cortico-thalamic weight, w_{yu} . (c) Varying the data scaling factor n .

One free parameter enforces the baseline activity that LIP neurons maintain before and during the initial stimulus presentation (Fig. 7a,i). Varying this parameter, l , scales the overall activity of LIP, but does not change the inference performed (Fig. 8a). Consequently, this suggests that the baseline activity of LIP depends on N but does not otherwise affect the inference algorithm implemented by the brain.

The second free parameter, w_{yt} , sets the strength of the spatially diffuse projection from cortex to thalamus. Varying this weight changes the forking between inRF and outRF computations but does not affect inference (Fig. 8b). The third free parameter, n , sets the overall, hypothesis-independent temporal scale at which sampled input ISIs are processed; changing n varies the slope of sensory-motor computations, even allowing all-decreasing predicted mean firing rates (Fig. 8c). By definition, the log-likelihood of a sequence tends to be negative and decrease monotonically as the sequence lengthens. Introducing n is required to get positive simplified log-likelihoods, capable of matching the neural activity dynamics, without affecting inference. Hence, n may capture a workaround of the decision-making circuitry to represent these whilst avoiding signal ‘underflow’, by means of scaling the input data.

Traditionally, evidence accumulation is exclusively associated with increasing firing rates during decision, and previous studies have questioned whether the often-observed decision-correlated yet non-increasing firing rates (*e.g.* in outRF conditions in Fig. 7a,i and Roitman and Shadlen (2002); Churchland et al. (2008); Huk and Shadlen (2005); Hernández et al. (2002); Hanks et al. (2015); Kira et al. (2015)) are consistent with accumulation (Park et al., 2014). The diversity of patterns predicted by rMSPRT in sensory-motor cortex (Fig. 8) solves this by demonstrating that both increasing and non-increasing activity patterns can house evidence accumulation.

3 Discussion

We sought to characterize the mechanism that underlies decisions by using the knowable function of a normative algorithm—the rMSPRT—as a systematic framework. With the currently available range of experimental studies giving us local snapshots of cortical and sub-cortical activity during decision-making tasks, the rMSPRT shows us how, where, and when these snapshots fit into a complete inference procedure. While it is not plausible that the brain implements exactly a specific algorithm, our results suggest that the essential structure of its underlying decision mechanism includes the following. First, that the mechanism is probabilistic in nature—the brain utilizes the uncertainty in neural signals, rather than suffering from it. Second, that the mechanism works entirely ‘on-line’, continuously updating representations of hypotheses that can be queried at any time to make a decision. Third, that this processing is distributed, recursive and parallel, producing a decision variable for each available hypothesis. And fourth, that this recursion allows the mechanism to adapt to the observed statistics of the environment, as it can re-use updated probabilities about hypotheses as priors for upcoming decisions.

We have pushed the analogy between a single-equation statistical test and the neural decision-making algorithm a long way before it broke down. We find it remarkable that, starting from data-constrained spike-trains, a monolithic statistical test in the form of the rMSPRT can simultaneously account for much of the anatomy, behaviour and electrophysiology of decision-making.

3.1 Why implement a recursive algorithm in the brain?

Prior work proposed that the cortex and basal ganglia alone could implement the non-recurrent MSPRT (Bogacz and Gurney, 2007; Lepora and Gurney, 2012). However, the looped cortico-basal-ganglia-thalamo-cortical architecture implies a recursive computation. This raises the question of why such a complex, distributed feedback architecture exists.

First, recursion makes trial-to-trial adaptation of decisions possible. Priors determined by previous stimulation (fed-back posteriors), can bias upcoming similar decisions towards the expected best choice, even before any new evidence is collected. This can shorten reaction times in future familiar settings without compromising accuracy.

Second, recursion provides a robust memory. A posterior fed-back as a prior is a sufficient statistic of all past evidence observations. That is, it has taken ‘on-board’ all sensory information since the decision onset. In rMSPRT, accumulation happens over the whole cortico-subcortical loop, so the sensory-motor cortex only need keep track of observations in a moving time window of maximum width Δ —the delay around the loop—rather than keeping track of the entire sequence of observations. For a physical substrate subject to dynamics and leakage, like a neuron in LIP or FEF, this has obvious advantages: it would reduce the demand for keeping a perfect record (*e.g.* likelihood) of all evidence, from the usual hundreds of milliseconds in decision times to the ~ 30 ms of latency around the cortico-basal-ganglia-thalamo-cortical loop (adding up estimates from Nambu et al. (1988); Hikosaka et al. (1993); Gerfen and Wilson (1996)).

3.2 Lost information and perfect integration

The rMSPRT predicts that monkeys do not make full use of the discrimination information available in MT (Fig. 3b). Here rMSPRT needs only $C = N$ MT spike-trains to outperform monkeys: as this is the upper bound of rMSPRT mean decision time, this implies the monkey’s predicted loss (Fig. 3c) is a minimum.

This gap arises because rMSPRT is a generative model of the task, which assumes initial knowledge of coherence, which in turn determines appropriate likelihoods for the task at hand. Any deviation from this ideal will tend to degrade performance (Beck et al., 2012), whether it comes from one or more of the inherent leakiness of neurons, correlations, or the coherence to likelihood mapping (Caballero et al., 2015). LIP neurons change their coding during learning of the dot motion task and MT neurons do not (Law and Gold, 2008), implying that learning the task requires mapping of MT to LIP populations by synaptic plasticity (Law and Gold, 2009). Consequently, even if the MT representation is perfect, the learnt mapping only need satisfy the task requirements, not optimally perform.

Excellent matches to performance in both correct and error trials were obtained solely by accounting for lost information in the evidence streams. No noise was added within the rMSPRT itself. Prior experimental work reported perfect, noiseless integration by both rat and human subjects performing an auditory task, attributing all effects of noise on task performance to the variability in the sensory input (Brunton et al., 2013). Our results extend this observation to primate performance on the dot motion task, and further support the idea that the neural decision-making mechanism can perform perfect integration of uncertain evidence.

3.3 Neural response patterns during decision formation

Neurons in LIP, FEF (Ding and Gold, 2012a) and striatum (Ding and Gold, 2010) exhibit a ramp-and-fork pattern during the dot motion task. Analogous choice-modulated patterns have been recorded in the medial premotor cortex of the macaque during a vibro-tactile discrimination task (Hernández et al., 2002) and in the posterior parietal cortex and frontal orienting fields of the rat during an auditory discrimination task (Hanks et al., 2015). The rMSPRT indicates that such slow dynamics emerge from decision circuits with a delayed, inhibitory drive within a looped architecture. Together, this suggests that decision formation in mammals may approximate a common recursive computation.

A random dot stimulus pulse delivered earlier in a trial has a bigger impact on LIP firing rate than a later one (Huk and Shadlen, 2005). This highlights the importance of capturing the initial, early-evidence ramping-up before the forking. However, multiple models omit it, focusing only on the forking (*e.g.* Mazurek et al. (2003); Ditterich (2006); Beck et al. (2008)). Other, heuristic models account for LIP activity from the onset of the choice targets, through dots stimulation and up until saccade onset (*e.g.* Wong et al. (2007); Grossberg and Pilly (2008); Furman and Wang (2008); Albantakis and Deco (2009)). Nevertheless, their predicted firing rates rely on two fitted heuristic signals that shape both the dip and the ramp-and-fork pattern. In contrast, the ramp-and-fork dynamics emerge naturally from the delayed inhibitory feedback in rMSPRT during decision formation (see Supplemental note S1.2.3 for more details on the relation of the rMSPRT to prior models of decision-making).

rMSPRT replicates the ramp-and-fork pattern for individual coherence levels and given N (Fig. 6). However, comparing its predictions across N (Fig. 6d) or over coherence levels (Fig. 7d,l) reveals that the model sensory-motor cortex does not converge to a common value around decision termination in inRF trials, as the LIP does (Fig. 6b, Fig. 7b,j and Churchland et al. (2008)). Here we have reached the limits where the direct comparison of the single-equation statistical test to neural signals breaks down. Our mapping of rMSPRT onto the cortico-basal-ganglia-thalamo-cortical circuitry suggests the core underlying computation contributed per site during decision formation (Fig. 5); that is, what is required for inference, such as the negative log-posterior probability at the basal ganglia. Even if these suggestions are accurate, we would still expect other factors to influence the dynamics of recorded neural signals. These regions after all engage in multiple other computations, some of which are likely orthogonal to decision formation.

One possibility is that the convergence of LIP activity to a common value just prior to saccade onset may result from monotonic transformations of these core computations. For instance, the successful fitting of previous computational models to neural data has been critically dependent on the addition of heuristic signals (Wong et al., 2007; Grossberg and Pilly, 2008; Furman and Wang, 2008; Albantakis and Deco, 2009). The incorporation of similar heuristic signals may also convert the present qualitative resemblance of the recordings, by rMSPRT, to a quantitative reproduction. This is, however, beyond the scope of this study, whose aim is to test how closely a normative mechanism can explain behaviour and electrophysiology during decisions.

3.4 Emergent predictions

Inputs to the rMSPRT were determined solely from MT responses during the dot-motion task, and it has only three free parameters, none of which affect inference. It is thus surprising that it renders emergent predictions that are consistent with experimental data. First, our information-depletion procedure used exclusively statistics from correct trials. Yet, after depletion, rMSPRT matches monkey behaviour in correct and error trials (Fig. 4), suggesting a mechanistic connection between them in the monkey that is naturally captured by rMSPRT. Second, the values of the three free parameters were chosen solely so that the model LIP activity resembled the ramp-and-fork pattern observed in our LIP data-set (Fig. 6a,c). As demonstrated in Fig. 8, the ramp-and-fork pattern is a particular case of two-stage patterns that are an intrinsic property of the rMSPRT, guaranteed by the feedback of the posterior after the delay Δ has elapsed (Eq. 9). Nonetheless, the model also matches LIP dynamics when aligned at decision termination (panels b and d). Third, the predictions of the time course of the firing rate in SNr and thalamic nuclei naturally emerge from the functional mapping of the algorithm onto the cortico-basal-ganglia-thalamo-cortical circuitry. These are already congruent with existing electrophysiological data; however, their full verification awaits recordings from these sites during the dot motion task. These and other emergent predictions are an encouraging indicator of the explanatory power of a systematic framework for understanding decision formation, embodied by the rMSPRT.

4 Experimental Procedures

4.1 Experimental paradigms

Behavioural and neural data was collected in two previous studies (Britten et al., 1992a; Churchland et al., 2008), during two versions of the random dots task (Fig. 1a-c). Detailed experimental protocols can be found in such studies. Below we briefly summarize them.

4.1.1 Fixed duration

Three rhesus macaques (*Macaca mulatta*) were trained to initially fixate their gaze on a visual fixation point (cross in Fig. 1a). A random dot kinematogram appeared covering the response field of the MT neuron being recorded (grey patch); task difficulty was controlled per trial by the proportion of dots (coherence %) that moved in one of two directions: that to which the MT neuron was tuned to —its preferred motion direction— or its opposite —null motion direction. After 2 s the fixation point and kinematogram vanished and two targets appeared in the possible motion directions. Monkeys received a liquid reward if they then saccaded to the target towards which the dots in the stimulus were predominantly moving (Britten et al., 1992a).

4.1.2 Reaction time

Two macaques learned to fixate their gaze on a central fixation point (Fig. 1b,c). Two (Fig. 1b) or four (Fig. 1c) eccentric targets appeared, signalling the number of alternatives in the trial, N ; one such target fell within the response (movement) field of the recorded LIP neuron (grey patch). This is the region of the visual field towards which the neuron would best support a saccade. Later a random dot kinematogram appeared where a controlled proportion of dots moved towards one of the targets. The monkeys received a liquid reward for saccading to the indicated target when ready (Churchland et al., 2008).

4.2 Data analysis

For comparability across databases, we only analysed data from trials with coherence levels of 3.2, 6.4, 12.8, 25.6, and 51.2 %, unless otherwise stated. We used data from all neurons recorded in such trials. This is, between 189 and 213 visual-motion-sensitive MT neurons (see table S1; data from Britten et al. (1992a,b)) and 19 LIP neurons whose activity was previously determined to be choice- and coherence-modulated (data from Churchland et al. (2008)). The behavioural data analysed was that associated to LIP recordings. For MT, we analysed the neural activity between the onset and the vanishing of the stimulus. For LIP we focused on the period between 100 ms before stimulus onset and 100 ms after saccade onset.

To estimate moving statistics of neural activity we first computed the spike count over a 20 ms window sliding every 1 ms, per trial. The moving mean firing rate per neuron per condition was then the mean spike count over the valid bins of all trials divided by the width of this window; the standard deviation was estimated analogously. LIP recordings were either aligned at the onset of the stimulus or of the saccade; after or before these (respectively), data was only valid for a period equal to the reaction time per trial. The population moving mean firing rate is the mean of single-neuron moving means over valid bins; analogously, the population moving variance of the firing rate is the mean of single neuron moving variances. For clarity, population statistics were then smoothed by convolving them with a Gaussian kernel with a 10 ms standard deviation. The resulting smoothed population moving statistics for MT are in Fig. 1d,e. In Figs. 6a,b and 7a,b,i,j smoothed mean LIP firing rates are plotted only up to the median reaction time plus 80 ms, per condition.

Analogous procedures were used to compute the moving mean of rMSPRT computations, per time step. These are shown up to the median of termination observations plus 3 time steps in Figs. 6c-e and 7c-h,k-p.

4.3 Spikes and continuous time out of discrete time

We have defined rMSPRT to operate over a discrete time line; however, the brain operates over continuous time. Caballero et al. (2015) introduced a continuous-time generalization of MSPRT that uses spike-trains as inputs for decision. Thence, the length of ISIs was random and their sum up until decision is, by definition, a continuously distributed time. With all other assumptions equal, Caballero et al. (2015) demonstrated that, as an average, the traditional discrete-time MSPRT requires the same number of observations to decision, as the ISIs required by the more general spike-based MSPRT. This means that the number of observations to decision, T , in (r)MSPRT has

an interpretation as continuously-distributed time. So, the expected decision sample size for correct choices, $\langle T \rangle_c$, required by the simpler discrete-time (r)MSPRT, can be interpreted as the mean decision time

$$\tau_c = (\langle T \rangle_c + 0.5) \mu_* n \quad (1)$$

predicted by the more general continuous-time, spike-based MSPRT, where $\mu_* n$ is the mean ISI produced by a MT neuron whose preferred motion direction was matched by the stimulus and was thus firing the fastest on average. When the mean firing rate to a preferred characteristic of the stimulus is larger than that to a non-preferred one ($\mu_* < \mu_0$) —as in MT (Britten et al., 1992a), middle-lateral and anterolateral auditory cortex (Tsunada et al., 2016)— the hypothesis selected in error trials is that misinformed by channels with mean $\mu_0 n$ which intuitively happened to fire faster than those whose mean was actually $\mu_* n$. Hence, the mean decision time predicted by rMSPRT in error trials would be:

$$\tau_e = (\langle T \rangle_e + 0.5) \mu_0 n, \quad (2)$$

where $\langle T \rangle_e$ is the mean decision sample size for error trials. An instance of rMSPRT capable of making choices upon sequences of spike-trains is straightforward from the formal framework above and that introduced by Caballero et al. (2015); nevertheless, for simplicity here we choose to work with the discrete-time rMSPRT. After all, thanks to Eqs. 1 and 2 we can still interpret its behaviour-relevant predictions in terms of continuous time. We use these to compute the decision times that originate the reaction times in Figs. 3 and 4.

4.4 Estimation of lost information

We outline here how we use the monkeys' reaction times on correct trials and the properties of the rMSPRT, to estimate the amount of discrimination information lost by the animals. This is, the gap between all the information available in the responses of MT neurons, as fully used by the rMSPRT in Fig. 3a, and the fraction of such information actually used by monkeys.

The expected number of observations to reach a correct decision for (r)MSPRT, $\langle T \rangle_c$, depends on two quantities. First, the mean total discrimination information required for the decision, $I(\epsilon, N)$, that depends only on the error rate ϵ , and N . Second, the 'distance' between distributions of ISIs from MT neurons facing preferred and null directions of motion (Caballero et al., 2015). This distance is the Kullback-Leibler divergence from f_* to f_0

$$D = \int_x f_*(x) \log_2 \left(\frac{f_*(x)}{f_0(x)} \right) dx$$

which measures the discrimination information available between the distributions. Using these two quantities, the decision time in the (r)MSPRT is (Caballero et al., 2015):

$$\langle T \rangle_c \geq \frac{I(\epsilon, N)}{D}, \quad (3)$$

The product of our Monte Carlo estimate of $\langle T \rangle_c$ in the rMSPRT (which originated Fig. 3a) and D from the MT ISI distributions (Fig. 1f), gives an estimate of the limit $I(\epsilon, N)$ in expression 3, denoted by $\hat{I}(\epsilon, N)$.

The 'mean decision sample size' of monkeys —hence the superscript ^m— within this framework corresponds to $\langle \hat{T} \rangle_c^m = (\hat{\tau}_c^m / \mu_* n) - 0.5$ (from Eq. 1). Here, $\hat{\tau}_c^m$ is the estimate of the mean decision time of monkeys for correct choices, per condition; that is, the reaction time from Fig. 3a minus some constant non-decision time. With $\langle \hat{T} \rangle_c^m$ and $\hat{I}(\epsilon, N)$, we can estimate the corresponding discrimination information available to the monkeys in this framework as $\hat{D}^m = \hat{I}(\epsilon, N) / \langle \hat{T} \rangle_c^m$ (from expression 3).

Fig. 3b compares D (red line) to \hat{D}^m (blue/green lines and shadings) for monkeys, using non-decision times in a plausible range of 200–300 ms. Fig. 3c shows the discrimination information lost by monkeys as the percentage of D , $\left[1 - (\hat{D}^m / D) \right] \times 100$ %.

4.5 Information depletion procedure

Expression 3 implies that the reaction times predicted by rMSPRT should match those of monkeys if we make the algorithm lose as much information as the monkeys did. We did this by producing a new parameter set that brings f_0 closer to f_* per condition, assuming 250 ms of non-decision time; critically, simulations like those in Fig. 4 will give about the same rMSPRT reaction times regardless of the non-decision time chosen, as long as it is the same assumed in the estimation of lost information and this information-depletion procedure.

An example of the results of information depletion in one condition is in Fig. 3d. We start with the original parameter set extracted from MT recordings, Ω (‘preferred’ and ‘null’ densities in Fig. 3d), and keep μ_* and σ_* fixed. Then, we iteratively reduce/increase the differences $|\mu_0 - \mu_*|$ and $|\sigma_0 - \sigma_*|$ by the same proportion, until we get new parameters μ_0 and σ_0 that, together with μ_* and σ_* , specify preferred (‘preferred’ in Fig. 3d) and null (‘new null’) density functions that bear the same discrimination information estimated for monkeys, \hat{D}^m ; hence, they exactly match the information loss in the solid lines in Fig. 3c. Intuitively, since the ‘new null’ distribution in Fig. 3d is more similar to the ‘preferred’ one than the ‘null’, the Kullback-Leibler divergence between the first two is smaller than that between the latter two. The resulting parameter set is dubbed Ω_d and reported in table S1.

4.6 Simulation procedures

For rMSPRT decisions to be comparable to those of monkeys, they must exhibit the same error rate, $\epsilon \in [0, 1]$. Error rates are taken to be an exponential function of coherence (%), s , fitted by non-linear least squares ($R^2 > 0.99$) to the behavioural psychometric curves from the analysed LIP database, including 0 and 72.4 % coherence for this purpose. This resulted in:

$$\epsilon = \begin{cases} 0.50 \exp(-0.11s), & \text{for } N = 2 \\ 0.75 \exp(-0.08s), & \text{for } N = 4 \end{cases} \quad (4)$$

Since monkeys are trained to be unbiased regarding choosing either target, initial priors for rMSPRT are set flat ($P(H_i) = 1/N$ for all i) in every simulation. During each Monte Carlo experiment, rMSPRT made decisions with error rates from Eq. 4. The value of the threshold, θ , was iteratively found to satisfy ϵ per condition (Caballero et al., 2015); an example of the θ s found is shown in Fig. S3a in the Supplement. Decisions were made over data, $x_j(t)/n$, randomly sampled from lognormal distributions specified for all channels by means and standard deviations μ_0 and σ_0 , respectively. The exception was a single channel where the sampled distribution was specified by μ_* and σ_* . This models the fact that MT neurons respond more vigorously to visual motion in their preferred direction compared to motion in a null direction, *e.g.* against the preferred. Effectively, this simulates macaque MT neural activity during the random dot motion task. The same parameters were used to specify likelihood functions per experiment. All statistics were from either the Ω or Ω_d parameter sets as noted per case. Note that the statistics actually used in the simulations are those from MT in table S1, divided by the scaling factor n .

Author Contributions JAC deduced the rMSPRT, and performed all simulations and data analyses; all authors discussed the results and wrote the article.

Acknowledgements We thank Anne Churchland, Roozbeh Kiani and Michael Shadlen for sharing their experimental data and the Humphries lab (Abhinav Singh, Mathew Evans and Silvia Maggi), Rafal Bogacz and Long Ding for discussions. This work was supported by a National Council of Science and Technology (CONACyT) Fellowship (JAC) and a Medical Research Council Senior non-Clinical Fellowship (MDH).

S1 Supplemental Information

S1.1 Supplemental Experimental Procedures

S1.1.1 Definition of rMSPRT

Let $\mathbf{x}(t) = (x_1(t), \dots, x_C(t))$ be a vector random variable composed of observations, $x_j(t)$, made in C channels at time $t \in \{1, 2, \dots\}$. Let also $\mathbf{x}(r:t) = (\mathbf{x}(r)/n, \dots, \mathbf{x}(t)/n)$ be the sequence of i.i.d. vectors $\mathbf{x}(t)/n$ from r to t ($r < t$). Here $n \in \{\mathbb{R} > 0\}$ is a constant data scaling factor. If $n > 1$, it scales down incoming data, $x_j(t)$. Note that this is only effective from the likelihood on and does not affect the format or time interpretation of the data. This is key to reveal that the dynamics in rMSPRT computations match those of cortical recordings (Fig. 8c). Crucially, since n is hypothesis-independent, it does not affect inference.

Assume there are $N \in \{2, 3, \dots\}$ alternatives or hypotheses about the uncertain *evidence*, $\mathbf{x}(1:t)$ —say possible courses of action or perceptual interpretations of sensory data. The task of a decision maker is to determine which hypothesis H_i ($i \in \{1, \dots, N\}$) is best supported by this evidence as soon as possible, for a given level of accuracy. To do this, it requires to estimate the posterior probability of each hypothesis given the data, $P(H_i|\mathbf{x}(1:t))$, as formalized by Bayes’ rule. The mechanism we seek must be recursive to match the nature of the brain circuitry. This implies that it can use the outcome of previous choices to inform a present one, thus becoming adaptive and engaged in ongoing learning. Formally, $P(H_i|\mathbf{x}(1:t))$ will be initially computed upon starting priors $P(H_i)$ and likelihoods $P(\mathbf{x}(1:t)|H_i)$; however, after some time $\Delta \in \{1, 2, \dots\}$, it will re-use past posteriors, $P(H_i|\mathbf{x}(1:t-\Delta))$, Δ time steps ago, as priors, along with the likelihood function $P(\mathbf{x}(t-\Delta+1:t)|H_i)$ of the segment of $\mathbf{x}(1:t)$ not yet accounted by $P(H_i|\mathbf{x}(1:t-\Delta))$. A mathematical induction proof of this form of Bayes’ rule follows.

If say $\Delta = 2$, in the first time step, $t = 1$:

$$P(H_i|\mathbf{x}(1)/n) = \frac{P(\mathbf{x}(1)/n|H_i) P(H_i)}{P(\mathbf{x}(1)/n)} \quad (5)$$

By $t = 2$:

$$P(H_i|\mathbf{x}(2)/n, \mathbf{x}(1)/n) = \frac{P(\mathbf{x}(2)/n, \mathbf{x}(1)/n|H_i) P(H_i)}{P(\mathbf{x}(2)/n, \mathbf{x}(1)/n)}$$

Note that we are still using the initial fixed priors $P(H_i)$. Now, for $t = 3$:

$$P(H_i|\mathbf{x}(3)/n, \mathbf{x}(2)/n, \mathbf{x}(1)/n) = \frac{P(\mathbf{x}(3)/n, \mathbf{x}(2)/n, \mathbf{x}(1)/n|H_i) P(H_i)}{P(\mathbf{x}(3)/n, \mathbf{x}(2)/n, \mathbf{x}(1)/n)} \quad (6)$$

According to the product rule, we can segment the probability of the sequence $\mathbf{x}(1:t)$ as:

$$P(\mathbf{x}(1:t)) = P(\mathbf{x}(t-\Delta+1:t), \mathbf{x}(1:t-\Delta)) = P(\mathbf{x}(t-\Delta+1:t)|\mathbf{x}(1:t-\Delta)) P(\mathbf{x}(1:t-\Delta)) \quad (7)$$

And, since $\mathbf{x}(t)$ are i.i.d., the likelihood of the two segments is:

$$P(\mathbf{x}(1:t)|H_i) = P(\mathbf{x}(t-\Delta+1:t)|H_i) P(\mathbf{x}(1:t-\Delta)|H_i) \quad (8)$$

If we substitute the likelihood in Eq. 6 by Eq. 8, its normalization constant by Eq. 7 and re-group, we get:

$$P(H_i|\mathbf{x}(3)/n, \mathbf{x}(2)/n, \mathbf{x}(1)/n) = \left(\frac{P(\mathbf{x}(3)/n, \mathbf{x}(2)/n|H_i)}{P(\mathbf{x}(3)/n, \mathbf{x}(2)/n|\mathbf{x}(1)/n)} \right) \left(\frac{P(\mathbf{x}(1)/n|H_i) P(H_i)}{P(\mathbf{x}(1)/n)} \right)$$

It is evident that the rightmost factor is $P(H_i|\mathbf{x}(1)/n)$ as in Eq. 5. Hence, in this example, by $t = 3$ we start using past posteriors as priors for present inference as:

$$P(H_i|\mathbf{x}(3)/n, \mathbf{x}(2)/n, \mathbf{x}(1)/n) = \frac{P(\mathbf{x}(3)/n, \mathbf{x}(2)/n|H_i) P(H_i|\mathbf{x}(1)/n)}{P(\mathbf{x}(3)/n, \mathbf{x}(2)/n|\mathbf{x}(1)/n)}$$

So, in general:

$$P(H_i|\mathbf{x}(1:t)) = \begin{cases} \frac{P(\mathbf{x}(1:t)|H_i) P(H_i)}{P(\mathbf{x}(1:t))} & \text{for } t \leq \Delta \\ \frac{P(\mathbf{x}(t-\Delta+1:t)|H_i) P(H_i|\mathbf{x}(1:t-\Delta))}{P(\mathbf{x}(t-\Delta+1:t)|\mathbf{x}(1:t-\Delta))} & \text{for } t > \Delta \end{cases} \quad (9)$$

where the normalization constants are

$$\begin{aligned} P(\mathbf{x}(1:t)) &= \sum_{j=1}^N P(\mathbf{x}(1:t)|H_j) P(H_j) \\ P(\mathbf{x}(t-\Delta+1:t)|\mathbf{x}(1:t-\Delta)) &= \sum_{j=1}^N P(\mathbf{x}(t-\Delta+1:t)|H_j) P(H_j|\mathbf{x}(1:t-\Delta)) \end{aligned}$$

We stress that by $t > \Delta$, Eq. 9 starts making use of a past posterior as prior.

It is apparent that the critical computations in Eq. 9 are the likelihood functions. The forms that we consider ahead are based on the simplest shown by Caballero et al. (2015), where the number of evidence streams equals the number of hypotheses ($C = N$); however, as discussed by them, more complex ($C > N$), biologically-plausible ones can be formulated if necessary. Although not required, to simplify the notation when $C = N$, data in the channel conveying the most salient evidence for hypothesis H_i will bear its same index i , as $x_i(j)$ (see Caballero et al. (2015)). When $t \leq \Delta$ we have:

$$P(\mathbf{x}(1:t)|H_i) = a(t) \prod_{j=1}^t \frac{f_*(x_i(j)/n)}{f_0(x_i(j)/n)} \quad (10)$$

this is, the likelihood that $x_i(j)/n$ was drawn from a distribution, f_* , rather than from f_0 , that is assumed to have originated $x_k(j)/n$ ($k \neq i$) for the rest of the channels. In Eq. 10, $a(t) = \prod_{m=1}^t \prod_{k=1}^N f_0(x_k(m)/n)$ is a hypothesis-independent factor that does not affect Eq. 9 and thus needs not to be considered further.

When $t > \Delta$ only the observations in the time window $[t-\Delta+1, t]$ are used for the likelihood function because data before this window is already considered within the fed-back posterior, $P(H_i|\mathbf{x}(1:t-\Delta))$. Then, the likelihood function is:

$$P(\mathbf{x}(t-\Delta+1:t)|H_i) = d(t) \prod_{j=t-\Delta+1}^t \frac{f_*(x_i(j)/n)}{f_0(x_i(j)/n)} \quad (11)$$

where again $d(t) = \prod_{m=t-\Delta+1}^t \prod_{k=1}^N f_0(x_k(m)/n)$ need not to be considered further.

Now, for our likelihood functions to work upon a statistical structure like that produced by neurons in MT we need to be more specific. Caballero et al. (2015) showed that ISIs in MT during the random dot motion task are best described as lognormally distributed and we assume that decisions are made upon the information conveyed by them. Thus, from now on we assume that f_* and f_0 are lognormal and that they are specified by means μ_* and μ_0 and standard deviations σ_* and σ_0 , respectively. We can then conflate the logarithms of Eqs. 10 and 11 as the log-likelihood function, $y_i(t)$, substituting the lognormal-based form of it reported by Caballero et al. (2015):

$$y_i(t) = \begin{cases} g_0\Delta + g_1 \sum_{j=1}^t [\log(x_i(j)/n)]^2 + g_2 \sum_{j=1}^t \log(x_i(j)/n) & \text{for } t \leq \Delta \\ g_0\Delta + g_1 \sum_{j=t-\Delta+1}^t [\log(x_i(j)/n)]^2 + g_2 \sum_{j=t-\Delta+1}^t \log(x_i(j)/n) & \text{for } t > \Delta \end{cases} \quad (12)$$

with

$$\begin{aligned} g_0 &= \frac{\kappa_0^2}{2\Theta_0^2} - \frac{\kappa_*^2}{2\Theta_*^2} + \log\left(\frac{\Theta_0}{\Theta_*}\right) \\ g_1 &= \frac{1}{2\Theta_0^2} - \frac{1}{2\Theta_*^2} \\ g_2 &= \frac{\kappa_*}{\Theta_*^2} - \frac{\kappa_0}{\Theta_0^2} \end{aligned}$$

where $\kappa = \log(\mu^2/\sqrt{\sigma^2 + \mu^2})$ and $\Theta^2 = \log(\sigma^2/\mu^2 + 1)$ with appropriate subindices $*, 0$. The computations in Eq. 12 have been shown by Caballero et al. (2015) to be neurally plausible.

The terms $g_0\Delta$ in Eq. 12 are hypothesis-independent, can be absorbed into $a(t)$ and $d(t)$, correspondingly, and thus will not be considered further. As a result of this, the $y_i(t)$ used from now on is a ‘‘simplified’’ version of the log-likelihood.

We now take the logarithm of Eq. 9, define $-\log P_i(t) \equiv -\log P(H_i|\mathbf{x}(1:t))$ and substitute the simplified log-likelihood from Eq. 12 in the result, giving:

$$-\log P_i(t) = \begin{cases} -y_i(t) - \log P(H_i) - c(t) + \log \sum_{j=1}^N \exp(y_j(t) + \log P(H_j) + c(t)) & \text{for } t \leq \Delta \\ -y_i(t) - \log P_i(t-\Delta) - c(t) + \log \sum_{j=1}^N \exp(y_j(t) + \log P_j(t-\Delta) + c(t)) & \text{for } t > \Delta \end{cases} \quad (13)$$

The term $c(t)$ models a hypothesis independent baseline: importantly, as this term is uniform across all hypotheses, it has no effect on inference. It is defined in detail below.

The RMSPRT itself (shown schematically in Fig. 2) takes the form:

$$D(t) = \begin{cases} \text{Choose hypothesis } i: & \text{if } -\log P_i(t) = \min_{j \in \{1, \dots, N\}} -\log P_j(t) \leq \theta, \text{ at } t = T \\ \text{Continue sampling:} & \text{if } \min_{j \in \{1, \dots, N\}} -\log P_j(t) > \theta, \end{cases} \quad (14)$$

where $D(t)$ is the decision at time t , $\theta \in (0, -\log(1/N)]$ is a constant threshold, and T is the decision termination time.

S1.1.2 Cortical and thalamic baselines

The cortical baseline $c(t)$ in Eq. 13, delayed as mapped in Fig. 5 is

$$c(t + \delta_{yb}) = h(t - \delta_{bu} - \delta_{uy}) + l$$

It houses a constant baseline l and the thalamo-cortical contribution $h(t - \delta_{bu} - \delta_{uy})$, which in turn is the delayed cortical input to the thalamus

$$h(t - \delta_{bu}) = w_{yu} \frac{\sum_{i=1}^N (y_i(t + \delta_{yb} - \delta_{yu}) + \log P_i(t - \delta_{bu} - \delta_{uy} - \delta_{yu}) + c(t + \delta_{yb} - \delta_{yu}))}{N}$$

Here we have chosen $h(t - \delta_{bu})$ to be a scaled average of cortical contributions; nevertheless, any other hypothesis-independent function of them can be picked instead if necessary, rendering similar results.

Coherence %	No. neurons	Ω, Ω_d		Ω		$\Omega_d, N = 2$		$\Omega_d, N = 4$	
		μ_*n	σ_*n	μ_0n	σ_0n	μ_0n	σ_0n	μ_0n	σ_0n
3.2	206	54.1	33.1	59.4	34.5	59.0	34.4	58.5	34.3
6.4	211	52.0	32.2	62.9	35.3	60.6	34.7	59.8	34.4
12.5	213	46.1	30.5	65.5	36.1	60.3	34.6	58.3	34.0
25.5	208	37.7	28.0	70.2	37.2	62.0	34.9	59.9	34.3
51.2	189	29.9	26.0	83.5	40.6	75.5	38.5	71.8	37.4

Table S1: Population ISI statistics (ms) in MT per coherence (first column). Second column: number of neurons for which data was available per coherence. μ : mean. σ : standard deviation. n : scaling factor. The parameter set (Ω or Ω_d) to which each value corresponds is noted above them. Note that, due to the information depletion required to produce Ω_d , μ_0n and σ_0n take different values for $N = 2, 4$.

The definitions above introduce two free parameters $l \in \mathbb{R}^+$ and $w_{yu} \in [0, 1)$ that have the purpose of shaping and revealing the dynamics of the computations within rMSPRT during decision formation. The range of w_{yu} ensures that the value of computations in the cortico-thalamo-cortical, positive-feedback loop is not amplified to the point of disrupting inference in the overall loop. Crucially, since both parameters are hypothesis-independent, none affects inference.

S1.1.3 Model parameters

To parameterize the input stochastic processes and likelihood functions of rMSPRT, we estimated the means μ_*n and μ_0n and standard deviations σ_*n and σ_0n as those over the activity between 900 and 1900 ms after stimulus onset in the MT population, per condition (shown smoothed in Fig. 1d,e). The subscript $*$ indicates the condition when dots were predominantly moving in the direction preferred by the neuron. The subscript 0 indicates when they were moving against it. We dub the resulting parameter set Ω and report it in table S1. Fig. 1f shows the lognormal ISI distributions specified by Ω ; solid ones are f_* , in our notation, and dashed ones are f_0 , per coherence.

We use $l = 15$, $w_{yu} = 0.4$, $n = 40$ and $\delta_{yb}, \delta_{yu}, \delta_{bu}, \delta_{uy} = 1$ (hence $\Delta = 3$) for all of our simulations. The value of latencies was set to 1 for simplicity. The values of the first three free parameters come from a manual tuning exercise with the aim of revealing a pattern in the model LIP akin to the ramp-and-fork one in LIP recordings; note that such a two-segment pattern is already guaranteed by the two parts of Eq. 9.

S1.2 Supplemental items

S1.2.1 Information loss for a perfected match of monkey reaction times

The slight deviation of the mean reaction times of rMSPRT *vs* those of monkeys in Fig. 4a stems from the expression 3 being an inequality. Due to this, $\hat{I}(\epsilon, N)$ is a likely over-estimate of $I(\epsilon, N)$. Dividing $\hat{I}(\epsilon, N)$ by $\langle \hat{T} \rangle_c^m$ hence gives an over-estimate of the monkey discrimination information, \hat{D}^m . If then rMSPRT uses statistics consistent with this over-estimated \hat{D}^m , it renders under-estimated reaction times. This minor discrepancy can be corrected by further multiplying \hat{D}^m , per condition, by the corresponding ratio of the decision time of the model over that of the monkey, from Fig. 4a. Repeating the experiments with the implied parameter set would trivially render rMSPRT reaction times that more perfectly match those of monkeys (not shown). This will likely carry with it a better match in error trials which is, again, unconstrained in the procedure. Nonetheless, this exercise gives us the full information loss associated to such perfected match, shown in Fig. 3c as dashed lines for a 250 ms non-decision time (compare to solid lines); this constitutes a further refined measure of the minimum information lost by the animals according to this framework.

S1.2.2 Function of a diffuse cortico-thalamic projection

rMSPRT proposes a role for the spatially diffuse cortico-thalamic projection (McFarland and Haber, 2002). The thalamic baseline, contributed by cortex, $h(t - \delta_{bu})$, is predicted to constitute the offset within which updated inference results (posteriors made priors) from basal ganglia are conveyed back to cortex. This is another unique prediction of rMSPRT, not accounted for by previous probabilistic algorithms. Fig. S3b shows $h(t - \delta_{bu})$ along with the corresponding output of the model thalamus in inRF and outRF settings. Without the increasing range facilitated by a diffuse cortico-thalamic contribution (red in model) the biological thalamic output (blue in model) would be at risk of saturating at 0, especially in outRF trials where the basal ganglia inhibition is strongest,

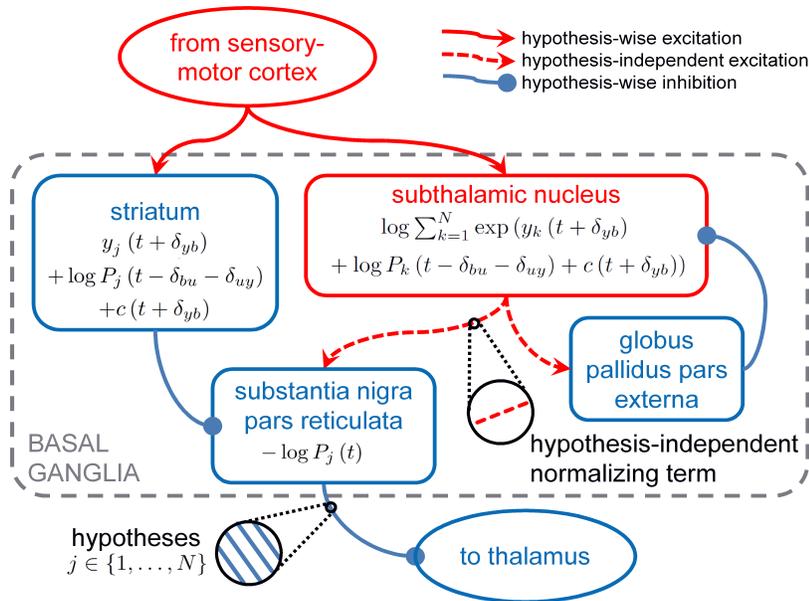

Figure S1: Mapping of rMSPRT computations to the basal ganglia. Parallel computations for N hypotheses —indexed by j — mapped onto the basal ganglia nuclei, within the grey dashed box (see Bogacz and Gurney (2007); Larsen et al. (2010); Bogacz and Larsen (2011)). Same conventions and notation as in Fig. 5. All computations are delayed with respect to the substantia nigra pars reticulata. $\log \sum_{k=1}^N \exp(y_k(t + \delta_{yb})) + \log P_k(t - \delta_{bu} - \delta_{uy}) + c(t + \delta_{yb})$: normalization term (from Eq. 13), putting together the cortical computations for all hypotheses into a hypothesis-independent contribution. Note that the model striatum represents a copy of the cortical signal (as in Fig. 5) but its influence on the substantia nigra pars reticulata is the negative of such cortical input.

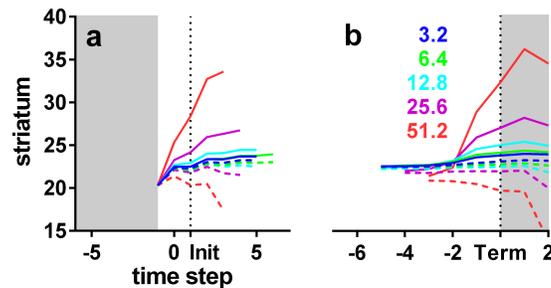

Figure S2: Qualitative prediction for the time course of striatum in rMSPRT. Same conventions as Fig. 7. (a) Aligned at decision initiation (Init; $t = 1$; dotted line). (b) Aligned at decision termination (Term; dotted line). Single Monte Carlo experiment with $N = 2$ and 800 total trials.

wasting then the segregation of hypotheses carried by it, represented by the fed-back posteriors in the model. If the biological thalamus were thus saturated, rMSPRT also predicts that the cortex would be limited to produce likelihood-proportional responses only on the basis of the immediately incoming data, instead of making use of the whole sequence.

Lastly, note that the increasing $h(t - \delta_{bu})$ becomes $h(t - \delta_{bu} - \delta_{uy})$ at the model sensory-motor cortex. This is the time changing component of the cortical baseline, $c(t + \delta_{yb})$ (Fig. 5). Thus, we argue that $h(t - \delta_{bu} - \delta_{uy})$ may form part of the increasing choice-independent drive, dubbed “urgency signal”, revealed by Drugowitsch et al. (2012) when averaging population responses of LIP neurons during the dot motion task across choices, for separate coherence levels.

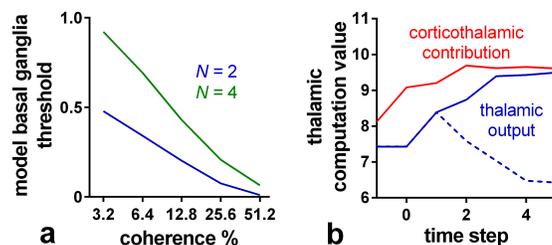

Figure S3: Threshold in basal ganglia and influence of cortico-thalamic contribution. (a) Position of the threshold, θ , set at the model basal ganglia in simulations like those of Figs. 4, 6 and 7, per condition. (b) Example mean cortico-thalamic contribution, $h(t - \delta_{bu})$ (red), compared to the mean thalamic output in inRF settings (solid blue) and outRF ones (dashed blue) for 25 % coherence and $N = 2$. Both (a) and (b) come from single Monte Carlo experiments with 800, 1200 trials for $N = 2, 4$, respectively.

S1.2.3 Relation of rMSPRT to existing decision models

The predictions of rMSPRT on the anatomical mapping of computations, neural dynamics, behaviour and the structure of the decision procedure in the brain, as explained here, are more comprehensive than those of prior models of decision-making. Here we explain the relationship of rMSPRT to the major classes of decision models to date.

As said before, our rMSPRT generalizes the MSPRT (Baum and Veeravalli, 1994; Bogacz and Gurney, 2007) in allowing the re-use of posteriors at any given distance in the past as priors for present inference, via recursion. The MSPRT collapses (Baum and Veeravalli, 1994) to the sequential probability ratio test (SPRT) of Wald (1947) for $N = 2$ alternatives. The non-recursive Bayes' rule in the first case of Eq. 9 is the MSPRT's test statistic (used by Eq. 14). Making a ratio of two such posteriors ($i = 1, 2$) gives a ratio of likelihoods times priors. If priors are flat, this gives a likelihood ratio, the original test statistic of SPRT; appropriate fixed thresholds and an equation analogous to Eq. 14, complete the specification of SPRT. For $N = 2$, MSPRT is thus the physical, optimal limit of performance. The rMSPRT performs identically to MSPRT and so enjoys this same privilege. However, if made to collapse in the same manner, the rMSPRT would produce a more flexible, recursive version of the SPRT allowing for a corresponding re-use of posteriors as priors.

The popular drift diffusion model (DDM; *e.g.* Ratcliff (1978); Mazurek et al. (2003); Palmer et al. (2005); Ding and Gold (2010, 2012a, 2013); Brunton et al. (2013); Tsunada et al. (2016)) is a non-recursive version of the SPRT (strictly for $N = 2$). It is thus optimal and is related to rMSPRT in the aforementioned manner. The popularity of the DDM stems from it incorporating continuous time and stochasticity in its input —a time-continuous Gaussian process. Adding time-continuity added plausibility to the hypothesis that the brain somehow implements the SPRT for decision (*e.g.* see Kira et al. (2015)), a problem also faced by the traditional discrete-time MSPRT. However, the existence of a Gaussian process in the brain to supply evidence for decisions, is unproven; since the the decision times predicted by DDM critically hinge on this process and its statistics (typically disconnected from the statistics of sensory neural activity), the interpretation of the DDM's behavioural predictions is obscured. To solve all this, Caballero et al. (2015) introduced a continuous-time generalization of the MSPRT whose inputs consist of stochastic spike-trains —the natural format of data in the brain. Caballero et al. also demonstrated that, as an average, this spiking MSPRT requires the same number of observations (inter-spike intervals) to decision as an equivalent instance of the discrete-time, traditional MSPRT. This established a solid, formal link between the discrete neural information used for decisions and the continuously distributed reaction times observed during behaviour. It also enabled us to interpret the discrete number of observations to decision in the simpler, discrete-time (r)MSPRT, as continuous decision times. This link from spike-trains to behaviour is the first advantage of rMSPRT over DDM. A second, related advantage is the rMSPRT's capability to relate choice behaviour to the statistics of the sensory data (spike trains) that determines it, as showcased here. A third is that the rMSPRT predicts multiple decision variables, one per hypothesis; all decision variables drop (or grow in a linear space) towards a single threshold (although a threshold per decision variable can be set, see Baum and Veeravalli (1994); Caballero et al. (2015)) when their associated hypothesis is well supported by input data. This contrasts with the single decision variable drifting towards one of two thresholds in the DDM and SPRT which has proven difficult to interpret neurobiologically. A fourth advantage is that (r)MSPRT is multi-alternative by design ($N > 2$), allowing us to analyse all realistic decision settings with the same mechanism.

Usher and McClelland (2001) introduced a dynamical model where a decision variable per alternative affects those of all other alternatives via mutual inhibition. This model incorporates time-continuity, stochasticity and competition (like SPRT, DDM and (r)MSPRT) but also leakage, and allows for $N > 2$. It has been shown that when leakage equals inhibition, the signal-to-noise ratio is set sufficiently low and $N = 2$, the Usher and McClelland (UM) model can approximate the DDM (SPRT) and achieve optimality (Bogacz et al., 2006; Bogacz and Gurney, 2007). Further, Ditterich (2010) has demonstrated that feedback and feedforward mutual-inhibition configurations perform equally, easing the constraints to map the UM model to brain circuits. From the UM model on we step away from hard statistical-inference algorithms (SPRT, DDM, (r)MSPRT) that aim at capturing biological decision formation at an algorithmic level of description, towards a set of models aimed at the same at an implementational level. In so doing, we trade exact inference and the straightforward use of probability theory to learn about decision formation for the gain of incorporating known neural properties (*e.g.* leakiness) and understanding how a biological neural network may implement decision (Beck et al. (2008) take important steps in this direction) and perhaps even approximate one of the hard, probabilistic algorithms, as shown here.

The last model we compare is the so-called Wang (2002) model and its extensions (*e.g.* Lo and Wang (2006); Wong et al. (2007); Furman and Wang (2008); Albantakis and Deco (2009)). Briefly, this is a biologically realistic implementation of the UM model via populations of spiking neurons (Bogacz et al., 2006); thus, the Wang model shares the UM model's relationship to (r)MSPRT. The Wang model is a further, essential step towards understanding neural implementation. It is only at this level of description that the constraints of networks of spiking neurons towards the execution of decision algorithms, fully manifest.

The road from algorithmic to neural implementation inevitably leads us to efficiency matters. Bogacz and Gurney (2007) demonstrated that, given the same conditions the UM (hence Wang's) model and the MSPRT (hence rMSPRT) can perform equally (optimally) for $N = 2$ but that MSPRT (thus rMSPRT) is much more efficient for $N > 2$; this is, it requires less observations, hence shorter decision times, to make choices at the same error rate. Our research poses that the sluggish mean reaction times of monkeys can be accounted-for by a quasi-Bayesian observer (rMSPRT) 'starved' of sensory discrimination information. Altogether, this calls for further research on how to close the performance gap between implementation-close models such as UM's and Wang's and hard inference algorithms like rMSPRT. After all, implementing a decision procedure that is faster in general ($N > 2$) is highly desirable, making it a trait that evolution would be expected to have optimized in animals.
