Running title: Genomic basis of G×E and local adaptation

Abstract

A substantial portion of intraspecific diversity is associated with local adaptation to environment, which is driven by genotype-by-environment interactions ($G \times E$) for fitness. Local adaptation is often studied via 1) multiple common garden experiments comparing performance of genotypes in different environments and 2) sequencing genotypes from multiple locations and characterizing geographic patterns in allele frequency. Both approaches aim to characterize the same pattern (local adaptation), yet the complementary information from each approach has not been coherently integrated into a modeling framework. Here, we develop a genome-wide association model of genotype interactions with continuous environmental gradients ($G \times E$). We employ an imputation approach to synthesize evidence from common garden and genome-environment associations, allowing us to identify loci exhibiting environmental clines where alleles are associated with higher fitness in home environments. We apply this model to simulations and published data on *Arabidopsis thaliana*. Simulations showed our approach increases power to detect loci causing local adaptation. In *Arabidopsis*, our approach revealed candidate genes for local adaptation based on known involvement in environmental stress response. Most identified SNPs exhibited home allele advantage and fitness tradeoffs along climate gradients, suggesting selective gradients maintain allelic clines. SNPs exhibiting $G \times E$ associations with fitness were enriched in genic regions, putative partial selective sweeps, and $G \times E$ associations with an adaptive phenotype (flowering time). We discuss extensions for situations where only adaptive phenotypes other than fitness are available. Many types of data may point toward the loci underlying $G \times E$ and local adaptation; coherent models of these diverse data provide a principled basis for synthesis.

Introduction

Populations commonly exhibit strong phenotypic differences, often due to local adaptation to environment (Leimu and Fischer 2008; Hereford 2009). Local adaptation is defined as a genotype-by-environment interaction ($G \times E$) for fitness that favors home genotypes (Kawecki and Ebert 2004). Local adaptation has long interested empirical and theoretical biologists (Clausen *et al.* 1940, 1948; Levene 1953; Slatkin 1973). However, little is known about the genomic basis of local adaptation, *e.g.* genetic architecture, major molecular mechanisms, and how much genomic divergence among populations is driven by local adaptation. Because local adaptation involves organismal responses to environmental gradients, understanding the mechanisms of local adaptation has important applications in agriculture and biodiversity conservation under climate change (Aitken and Whitlock 2013; van Oppen *et al.* 2015; Lasky *et al.* 2015). Additionally, genotype-by-environment interactions are important in human phenotypes like disease (Anastasi 1958; Hunter 2005; Gage *et al.* 2016). Understanding the genomic basis of $G \times E$ is an emerging area of biomedical research (Thomas 2010; Keller 2014) as are the genomics of local adaptation (reviewed by (Des Marais *et al.* 2013; Manel and Holderegger 2013; Tiffin and Ross-Ibarra 2014; Adrion *et al.* 2015; Bragg *et al.* 2015; Hoban *et al.* 2016)).

A central question in local adaptation genetics is whether selective gradients can maintain allelic clines at individual loci, or whether stochastic processes, like limited dispersal, are required to explain clines at individual loci causing local adaptation (Mitchell-Olds *et al.* 2007; Anderson *et al.* 2011b). If selective gradients cause rank changes in alleles with the highest relative fitness at an individual locus, selection may maintain a cline, a pattern known as genetic tradeoff or antagonistic pleiotropy (Ågren *et*

al. 2013). Detecting loci that exhibit antagonistic pleiotropy has been challenging, partly
 75 due to limited statistical power of approaches that conduct multiple tests of significance
 for opposing fitness effects in different environments (ANDERSON *et al.* 2013). Here,
 we develop a model that explicitly tests marker associations with G×E for relative fitness
 variation, allowing us to identify loci with patterns indicative of antagonistic pleiotropy.

Common garden experiments have been employed for over 200 years to
 80 characterize genetic variation in phenotypes (Langlet 1971). In particular, reciprocal
 common gardens at multiple positions along environmental gradients are a powerful tool
 to reveal local adaptation (Clausen *et al.* 1940, 1948). One approach to identifying the
 loci underlying local adaptation is to combine fitness data from multiple common garden
 experiments with genomic data (Lowry and Willis 2010; Fournier-Level *et al.* 2011a;
 85 Anderson *et al.* 2011a; Ågren *et al.* 2013). Recently, the ability to sequence large panels
 of diverse genotypes has allowed genome-wide association mapping of loci underlying
 traits in common gardens (Atwell *et al.* 2010). However, common gardens are logistically
 challenging, limiting biologists' ability to phenotype diverse panels in multiple
 environments across a species range. Additionally, it is unclear how the typically small
 90 spatiotemporal scales of common gardens relate to the scales of processes that generate
 local adaptation in the wild (Weigel and Nordborg 2015).

An alternative approach to discovering genetic and ecological mechanisms of
 local adaptation is to study changes in allele frequency along environmental gradients
 (Hedrick *et al.* 1976; Tiffin and Ross-Ibarra 2014; Adrion *et al.* 2015; Bragg *et al.* 2015;
 95 Rellstab *et al.* 2015; Hoban *et al.* 2016). In this approach, known as a genome-
 environment association study, individuals are sequenced from multiple locations along

environmental gradients. Genetic markers and environmental gradients showing the strongest correlations are then considered as loci and selective gradients potentially involved in local adaptation (e.g. Hancock *et al.* 2008, 2011; ECKERT *et al.* 2010; Turner *et al.* 2010; Coop *et al.* 2010; Lasky *et al.* 2012; Jones *et al.* 2012; Fitzpatrick and Keller 2015). A challenge of both genome-phenotype and genome-environment association studies is that the genomic variation is observational and is not experimentally randomized (as opposed to linkage mapping with experimental crosses) (Devlin and Roeder 1999; Hancock *et al.* 2008; Kang *et al.* 2008; Nordborg and Weigel 2008). Thus many loci may show spurious associations with phenotypes or with environment (Price *et al.* 2010; Schoville *et al.* 2012; Bragg *et al.* 2015). Spurious associations are particularly problematic for environmental gradients that are spatially autocorrelated due to confounding with population structure (Schaffer and Johnson 1974). A technique for dealing with this confounding is to control for putative population structure when testing associations (Coop *et al.* 2010), *e.g.* by controlling for genome-wide (identity-in-state) similarity among accessions (Yoder *et al.* 2014; Lasky *et al.* 2014). Thus, this approach identifies loci that show strong associations with environment that deviate from genome-wide associations with environment

Understanding the genomic basis of adaptation may benefit from synthesizing lines of evidence, *i.e.* combining multiple types of genome scans to strengthen the evidence that a locus is under selection (Lasky *et al.* 2014; Evans *et al.* 2014). For example, researchers have identified overlap between outliers for selection statistics and markers associated with putatively adaptive phenotypes (Horton *et al.* 2012) or between SNPs associated with phenotypes and those associated with climate gradients (Berg and

120 Coop 2014). (Lasky *et al.* 2015) used a Bayesian approach to combine associations with
phenotype and environment, first calculating climate associations and then using each
marker's association to determine the prior probability it was associated with G×E for
adaptive phenotypes, yielding a posterior. Although combining multiple lines of evidence
is potentially useful, the quantitative basis of synthesis in past studies has often been *ad*
125 *hoc* and lacked reasoned principles. Here we develop a modeling framework to conduct
genome-wide association scans for G×E while coherently synthesizing multiple data
types. Existing approaches to genome-wide association studies (GWAS) with G×E
(sometimes referred to as genome-wide interaction studies, GWIS) have dealt with
categorical nominal environments (Murcay *et al.* 2009; Thomas 2010; Korte *et al.* 2012;
130 Gauderman *et al.* 2013; Marigorta and Gibson 2014), but have not been applied to G×E
along continuous environmental gradients. Despite the existence of studies where fitness
was measured in multiple common gardens for diverse genotyped accessions (Fournier-
Level *et al.* 2011a), studies where linkage mapping was conducted for fitness at multiple
sites (Ågren *et al.* 2013), and studies where authors conducted association mapping for
135 G×E effects on phenotypes (Li *et al.* 2014), we found no example of association studies
of G×E for fitness, *i.e.* the basis of local adaptation.

Because the underlying processes generating local adaptation are the same
regardless of whether genome-environment associations or common gardens are used for
inference, it is natural to synthesize these data. Furthermore, by combining datasets into a
140 single inferential framework we may increase power and accuracy for detecting causal
loci. Here, we simultaneously leverage data from multiple common gardens and genome-
environment associations. In the remainder, we describe our approach, present test cases

using simulations and published data on *Arabidopsis thaliana* (hereafter Arabidopsis),
and discuss promising avenues for extension.

145

Methods

Genome-wide association study of G×E effects on fitness

In common garden experiments environment is often treated as a factor. But when more
150 than two gardens are conducted, variation among them may be considered in a more
general fashion. For a given environmental gradient, each common garden may be
located along the gradient (*i.e.* single dimension) according to its conditions. Describing
common gardens as such may be informative about the specific ecological mechanisms
driving selective gradients, taking advantage of the ordered nature of gardens’
155 environments. We leverage multiple common garden experiments to identify markers
(single nucleotide polymorphisms, SNPs) that show the strongest associations with G×E
effects, *i.e.* loci where allelic state shows the strongest interaction with environment in its
association with fitness.

Local adaptation requires a genotype by environment interaction for fitness at the
160 whole genome-level. To assess this interaction at an individual locus, we assume that the
relative fitness of individual i in a single location, w_i , satisfies the linear model

$$w_i = \alpha + \beta_E E_i + \beta_G G_{i,l} + \beta_{G \times E} G_{i,l} E_i + \varepsilon_i,$$

(eqn 1)

where $G_{i,l}$ is the genotype of individual i at locus l and E_i is the value of a single
165 environmental variable at the location where w_i was measured. The β_E parameter gives

the effect of environment on fitness and β_G gives the effect of genotype on fitness. Our primary interest lies in the $\beta_{G \times E}$ parameter, which gives the strength and direction of G×E effects, *i.e.* $\beta_{G \times E}$ determines how responses to environmental gradients are mediated by genotype. α gives the fitness intercept. We assume that the vector of errors, $\boldsymbol{\varepsilon}$, can be expressed as

$$\boldsymbol{\varepsilon} = \mathbf{E}\mathbf{v} + \mathbf{e}$$

where \mathbf{E} is a diagonal matrix of the environmental values, and

$$\mathbf{v} \sim N_n(0, \sigma_{G \times E}^2 \mathbf{K}) \quad \mathbf{e} \sim N_n(0, \sigma_e^2 \mathbf{I}).$$

(eqn 2)

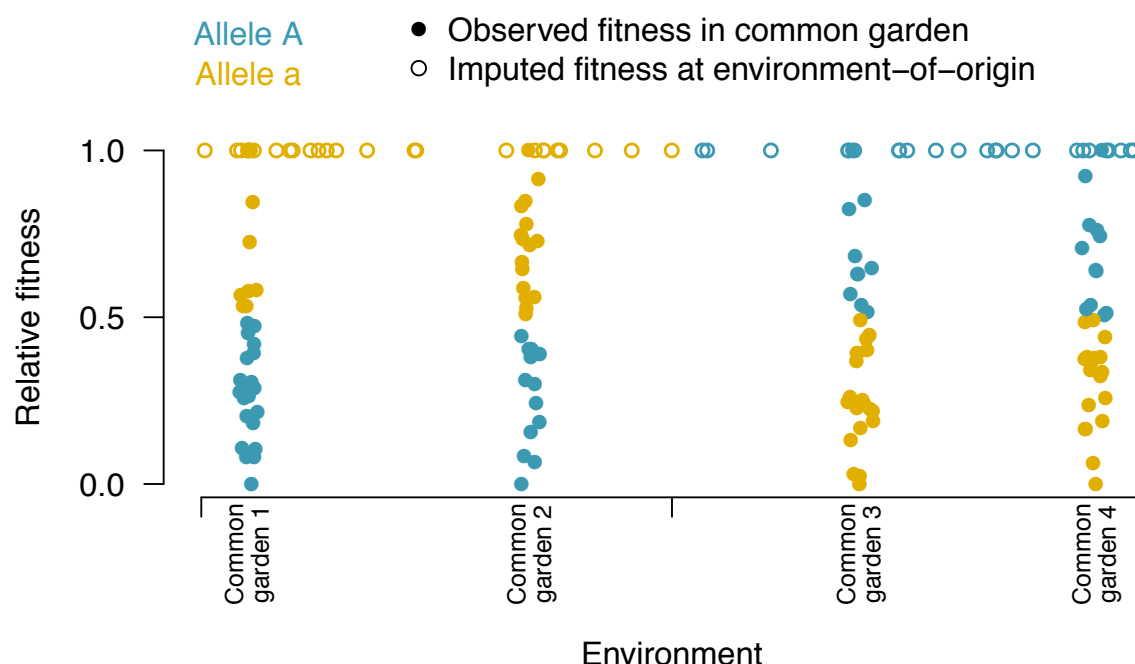

Here \mathbf{v} and \mathbf{e} are independent. The matrix \mathbf{K} is calculated as the genome-wide identity in state for each pair of accessions (Kang *et al.* 2008). Random effects \mathbf{v} are included because a substantial portion of G×E may be associated with population structure (Lasky *et al.* 2015); naively applying standard F-tests to assess the interaction effects can result in a dramatic increase in Type I error rates. To ameliorate this issue, the random effect \mathbf{v} represents the genetic background interactions with environment (G×E, magnitude of their variance determined by $\sigma_{G \times E}^2$), while \mathbf{e} represents the independent and identically distributed error in the model (variance determined by σ_e^2). However, it is important to note that incorporating random effects may also increase Type II error when causal loci covary with genomic background.

Coherent synthesis of common gardens and genome-environment associations via imputation

We now tackle the goal of synthesizing genome-environment associations and $G \times E$ observed in multiple common gardens, given that both patterns are expected to inform on the same process of local adaptation. The challenge in synthesizing these approaches is that genome-environment associations are purely observational and lack common garden phenotypic data. However, a typically unstated but implicit assumption in studies of genome-environment associations is that local adaptation occurs. That is, if a common garden were conducted at each location where genotypes are collected, the home genotype would tend to be most fit. Here, we make this assumption of genome-environment association studies explicit. A formal consequence of this assumption is an (imputed) observation of highest relative fitness for genotypes at home, which we combine with observed sequence and environment of origin data (Figure 1). Next, we scale relative fitness within each common garden so that the maximum observed fitness is given a relative fitness of unity, yielding a measure that can be directly observed or imputed in each type of study (common garden and genome-environment association). For imputation, we then assume that each genotype collected from wild populations is locally adapted at its home and thus has a relative fitness = 1 (Figure 1). After imputation, we can calculate marker associations with $G \times E$ for fitness, where each fitness observation arises from either (A) observations on a given genotype by common garden combination or (B) imputation on a given genotype collected from its natural home and subsequently sequenced.

Figure 1. Illustration of our imputation technique and stereotypical pattern captured by our approach. Here we show hypothetical data from four common gardens along an environmental gradient (solid circles in four vertical streaks, with small amount of noise added to environmental values for visualization) that have fitness scaled to a maximum of 1. We also show accessions (or ecotypes) collected in home environments and sequenced (open circles in horizontal line across top) having imputed relative fitness of 1 in their home environment (environment-of-origin). The locus in question shows strong $G \times E$ for fitness and

215 antagonistic pleiotropy, such that allele A (blue) is more fit (observed, solid circles) and more common (imputed, open circles) at the upper end (right side) of the environmental gradient while allele a (yellow) is more fit and more common at the lower end (left side) of the gradient.

220 *Comparing approaches and fitting models*

We compared three approaches to genome-wide G×E association study. In Approach 1, we ignored potential confounding of population structure, *i.e.* we used least squares to fit the model in eqn 1 where ϵ is normal, independent, and identically distributed (*i.e.* excluding random effects ν), and include imputed fitness data. In Approach 2, we fit the full mixed-effects model (including random effects ν), but only including observed fitness data from common gardens (*i.e.* excluding imputed fitness data). In Approach 3, we fit the full mixed-effects model while including imputed fitness data.

To improve computation time for the mixed-model approaches (2 & 3), we used the method of (Kang *et al.* 2010) and first fit the random effects with covariance determined by kinship, and then fixed these effects while testing the effects of each SNP

230

on the phenotype. We included the environmental covariate effect in this initial step, following the recommendation of (Kang *et al.* 2010) for fitting additional (i.e. non-SNP) covariates. In other words, we first fit the model:

$$w_i = \alpha + \beta_E E_i + \varepsilon_i,$$

235 (eqn 3)

with $\alpha + \beta_E E_i$ being removed from eqn 1 and instead fit here, and ε_i defined as in eqn 2, to obtain parameter estimates $\hat{\alpha}, \hat{\beta}_E, \hat{\sigma}_e^2, \hat{\sigma}_{G \times E}^2$. We then take the variance parameter estimates and use them to estimate the remaining slope coefficients in eqn 1 using generalized least squares. We fit the discussed mixed-model using Minimum Norm
240 Quadratic Unbiased Estimation, MINQUE (Rao 1971; Brown 1976; Reimherr and Nicolae 2015). This approach is equivalent to REML, but rephrased in a way that more fully exploits the linearity of the model, resulting in a flexible framework that can be quickly computed.

245 *Simulation*

We used simulation to demonstrate that our imputation technique can improve our power to identify loci causing G×E for fitness. We previously simulated local adaptation in a square two-dimensional 92160 x 92160 grid-cell landscape along a continuous environmental gradient (Forester *et al.* 2016), using the program CDPOP v1.2 (Landguth
250 and Cushman 2010). We simulated 5,000 diploid individuals with 100 bi-allelic loci, one of which was under selection (99 neutral loci). All loci had a 0.0005 mutation rate per generation, free recombination, and no physical linkage. We ran 10 Monte Carlo

replicates of the simulation for 1,250 generations, using the first 250 generations as a burn-in, with no selection imposed, to establish a spatial genetic pattern.

255 In the simulation, selection changed linearly along an environmental gradient, with *AA* and *aa* genotypes favored at different ends of the gradient (North and South, Fig. S1). The selection strength of $s=0.10$ was mediated through density-independent mortality determined by an individual's genotype at the selected locus, where *AA* experienced 0% mortality in the North and s mortality in the South, while *aa* genotypes 260 experienced the opposite selection gradient. *Aa* genotypes experienced uniform selection of $s/2$ across the gradient. Mating pairs of hermaphroditic individuals and dispersal locations of offspring were chosen using a random draw from the inverse-square probability function of distance, truncated at a distance equal to 10% of a landscape edge (*i.e.* truncated at 9216 pixels). Individuals near landscape edges were unable to disperse 265 or mate with individuals beyond the edge (*i.e.* boundaries were not periodic).

The number of offspring produced from mating (fitness) was determined from a Poisson distribution ($\lambda = 4$), which produced an excess of individuals each generation, maintaining a constant population size of 5,000 individuals at every generation. Carrying capacity of the landscape surface was 5,000 individuals, and excess individuals were 270 discarded once all 5,000 locations became occupied.

We sampled 500 individuals randomly from the 5,000 available. We then established four common gardens at equal intervals along the gradient, encompassing the extremes of the selection surface (Fig. S1). We subsampled 100 individuals from the full 500, and then averaged fitness for 10 clones of each individual (each with the identical 275 adaptive genotype of their parent clone) in each common garden using the above

parameters for selection and fitness. After imputing fitness for the 400 individuals not included in common gardens, we had a total of 900 observations of fitness \times location (i.e. 500 imputed observations + 400 real observations).

We then compared our three approaches to genome-wide G \times E association study.

280 In Approach 1, we ignored potential confounding of population structure but included imputed fitness data. In Approach 2, we fit the full mixed-effects model, but only including observed fitness data from common gardens (*i.e.* excluding imputed fitness). In Approach 3, we fit the full mixed-effects model while including imputed fitness data.

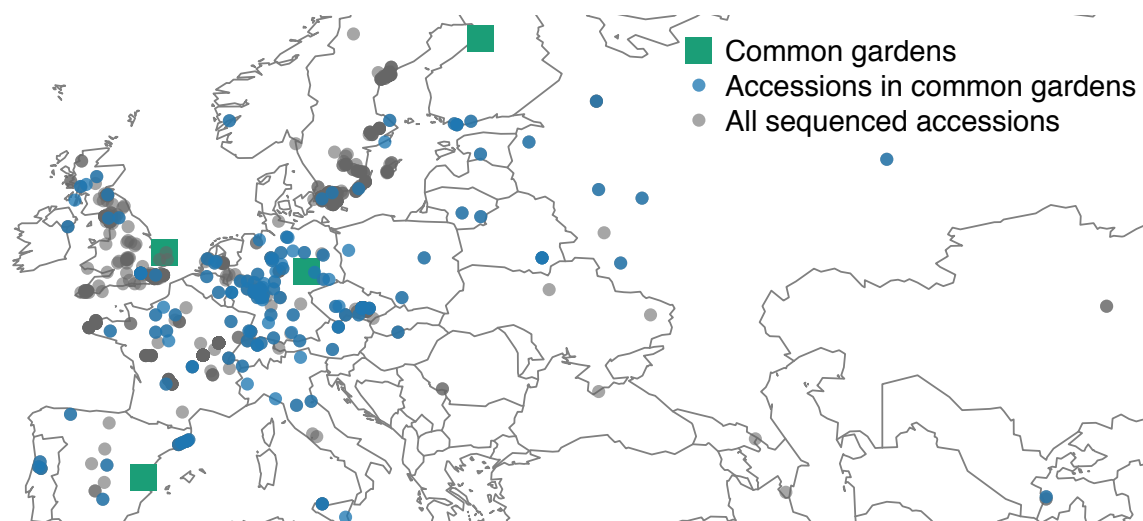

285 *Case study: local adaptation to climate in Arabidopsis thaliana*

We next applied these approaches to published data from studies of *Arabidopsis thaliana* in its native Eurasian range. Fournier-Level *et al.* (2011) conducted replicated common gardens at four sites across Europe: Spain, England, Germany, and Finland (Figure 2).

With these common garden data, (Fournier-Level *et al.* 2011a; b; Wilczek *et al.* 2014)

290 showed evidence that genotypes are locally adapted to their home temperature and moisture regimes and that alleles associated with high fitness in a given garden tended to be found nearer to that garden than alternate alleles, suggesting these loci were involved in local adaptation. At each site the authors transplanted 157 accessions (59 in the case of Finland) on a date in the fall matched to germination of local winter-annual natural
295 populations (Fournier-Level *et al.* 2011a). The authors calculated survival (out of individuals surviving transplant) and average fecundity (where individuals that died before reproducing had fecundity zero) giving an estimate of absolute fitness (excluding the seed to seedling transition) (Fournier-Level *et al.* 2011a).

Figure 2. Data used in case study on Arabidopsis. The location of common gardens, natural accessions in common gardens, and all other sequenced natural accessions are shown.

These accessions were part of a panel of 1,307 accessions from around the globe that were genotyped at ~250k SNPs using a custom Affymetrix SNP tiling array (AtSNPtile1), with 214,051 SNPs remaining after quality control (Figure 2) (Horton *et al.* 2012). This array was generated by resequencing 19 diverse ecotypes from across the range of Arabidopsis (Kim *et al.* 2007). Of the 1,307 genotyped accessions, we used 1,001 accessions that were georeferenced and likely not contaminant lines (Anastasio *et al.* 2011), in addition to being from the native range in Eurasia (Hoffmann 2002; Lasky *et al.* 2012a), and excluding potentially inaccurate high altitude outliers (i.e. > 2000 m). After imputing fitness for accessions in their home environments we had a total of 1,531 observations of fitness \times location (i.e. 1001 imputed observations + 530 real observations). We removed from association tests SNPs having minor allele frequency (MAF) below 0.01, though we also considered a more conservative threshold of MAF = 0.1.

We used climate data compiled previously (Lasky *et al.* 2012a) from published global climate datasets (Hijmans *et al.* 2005; Zomer *et al.* 2008). Here we focus on four climate variables that differ among common gardens, are not strongly correlated, and may be involved in local adaptation: minimum temperature of the coldest month, average monthly minimum temperature in the growing season, coefficient of variation of monthly growing season precipitation, and aridity index.

Genome-wide $G \times E$ associations

We separately tested for each SNP's interaction with each of the four environmental variables, *i.e.* for each of the three approaches we fit a model for each combination of SNP and environmental variable. To characterize the types of patterns identified by our approach, we studied variation in the SNPs in the 0.01 lower tail of p-values for the hypothesis that $\beta_{G \times E} = 0$ (the coefficient for SNP \times environment effects on fitness) for each climate gradient. We asked whether these SNPs showed patterns consistent with home genotype advantage via changes in the allele with greatest relative fitness along the environmental gradient (*i.e.* local adaptation via antagonistic pleiotropy). For these SNPs we calculated whether the direction of allelic differentiation along environmental gradients was consistent with the sign of $\beta_{G \times E}$. For example, if one allele was more common in accessions from warmer locations, we assessed whether that same allele showed an increase in relative fitness in warmer common gardens. Next, we assessed whether our model predicted that different alleles were most fit in the two common gardens at either extreme of a climate gradient, *i.e.* whether the SNP was associated with rank changes in fitness that are consistent with antagonistic pleiotropy. For example, if

one allele was estimated to be most fit in the coldest common garden, we asked whether a
 340 different allele was estimated to be most fit in the warmest common garden. Furthermore,
 we also quantified similarity (*i.e.* rank correlation in SNP scores and proportion of SNPs
 common to the strongest 0.01 tail of associations) between results from our G×E
 approach versus those from other recent studies of association with home climate in
 Arabidopsis (Hancock *et al.* 2011; Lasky *et al.* 2012a, 2014).

Enrichment of strong SNP×environment associations across the genome

We studied whether loci we identified as likely being involved in local adaptation
 exhibited supportive patterns in ancillary datasets. First, to assess whether our association
 approach is capable of identifying the signal of local adaptation rather than spurious
 350 background associations, we tested for enrichment of SNPs in genic versus intergenic
 regions. These tests are based on the hypothesis that loci involved in adaptation are on
 average more likely to be found near genes and linked to genic variation, in comparison
 with loci evolving neutrally (Hancock *et al.* 2011; Lasky *et al.* 2012a). For a test statistic,
 we calculated the portion of SNPs in the 0.01 lower p-value tail that were genic versus
 355 intergenic.

Second, we hypothesized that locally-adaptive alleles may have been subject to
 partial (*i.e.* local) selective sweeps, especially given that much of Arabidopsis' Eurasian
 range was recently colonized following the last glacial maximum. We tested for an
 enrichment of significant ($\alpha = 0.05$) pairwise haplotype sharing (PHS, (Toomajian *et*
 360 *al.* 2006)) in the SNPs (using PHS calculated by Horton *et al.* 2012) showing the greatest
 evidence of G×E for fitness. We also tested evidence that these SNPs are enriched for

significant ($\alpha = 0.05$) integrated extended haplotype homozygosity (standardized, iHS (Voight *et al.* 2006)), an additional metric of partial sweeps. We used ancestral SNP allele determinations from (Horton *et al.* 2012) (based on alignment with the *Arabidopsis* 365 *lyrata* genome) and the R package ‘rehh’ to calculate iHS (Gautier *et al.* 2012).

Third, we also studied whether loci we identified were associated with plasticity in flowering time, a trait that plays a major role in local adaptation to climate in plants (Hall and Willis 2006; Franks *et al.* 2007; Keller *et al.* 2012; Lowry *et al.* 2014).

Recently (Li *et al.* 2014) tested the flowering time response of 417 natural accessions to 370 simulated warming (up to $\sim 4^{\circ}\text{C}$), and then identified SNP associations with changes in flowering time across treatments, *i.e.* G \times E for flowering time. We tested whether SNPs we identified as having SNP \times environment interactions for fitness (0.01 lower p-value tail) were enriched in nominally significant associations ($\alpha = 0.05$) with G \times E for flowering time.

375 To generate a null expectation for each enrichment while maintaining a signal of linkage disequilibrium in the null model, we circularly permuted SNP categories (*e.g.* as genic vs intergenic, having significant iHS or not) along the genome and recalculated the test statistics 10,000 times (Hancock *et al.* 2011; Lasky *et al.* 2012a).

All data were previously published, including fitness (Data Dryad package 380 Fournier-Level *et al.* 2011b), environment (Data Dryad package Lasky *et al.* 2012b), and SNPs (Horton *et al.* 2012, available at http://bergelson.uchicago.edu/wp-content/uploads/2015/04/call_method_75.tar.gz).

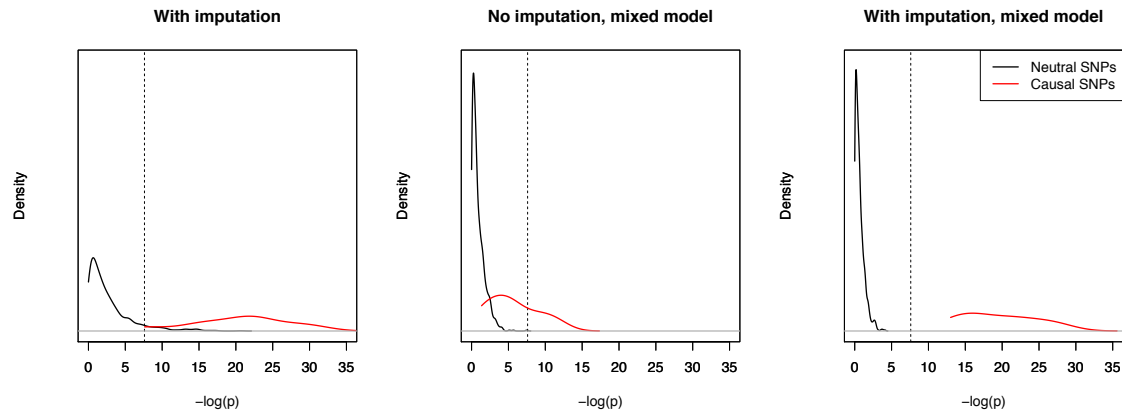

Results

We compared three approaches to genome-wide $G \times E$ association study. Approach 1 used observed and imputed fitness data, but no correction for population structure. Approach 2 fitted the full mixed-effects model, but only including observed fitness data from common gardens (*i.e.* excluding imputed fitness). Approach 3 fitted the full mixed-effects model while including both observed and imputed fitness data.

Simulations

We found that imputation of relative fitness for genotypes in their home environments increased the power of mixed-model associations to identify SNPs driving $G \times E$ for fitness (Figure 3). In each of the 10 simulations, the single causal SNP was detected as having the strongest (out of 100 SNPs) $G \times E$ for fitness when using imputed observations and a mixed model (Approach 3, Fig. 3 right). By contrast, when only using common gardens (Approach 2), the causal SNP did not have the strongest association in three simulations, when it was instead scattered among the top 10 SNPs (Fig. 3 middle). When including imputation but not random effects to control for population structure (Approach 1), the single causal SNP was detected as strongest in nine of ten simulations, though many neutral SNPs had very low p-values (false positive detections, Fig. 3 left).

Figure 3. Comparison of inferred SNP associations with $G \times E$ for fitness across 10 simulations, using imputation but no random effects (left) mixed models that used only observations from four common gardens (100 genotypes in each, middle) or mixed models combining imputed observations of relative fitness in home environments (500 genotypes) with common garden observations (right panel). Each simulation had 1 causal SNP and 99 neutral SNPs; density plots show aggregate distributions for all SNP by simulation combinations (*i.e.* total of 10 causal and 990 neutral SNPs). For reference, dashed line indicates a strict Bonferonni cutoff for $\alpha = 0.05$, $-\log(0.05/100) = 7.6$. Density curves are truncated at lower minimum values.

Case study on *Arabidopsis*

We found that simple linear model tests (Approach 1) of SNP \times environment interactions were highly enriched in very low p-values (Figure 4) relative to the theoretical

expectation. After incorporating the kinship \times environment random effects (but excluding imputed fitness observations, Approach 2), we found that SNP \times environment associations with fitness were closer to the theoretical expectation but still highly enriched in low p-values for three climate variables. After incorporating imputed fitness observations into

the mixed model (Approach 3, right column, Figure 4), we found p-value distributions hewed closer to the theoretical expectation and were slightly conservative (*i.e.* under-enriched in low p-values) for two climate variables. These three approaches tended to identified different SNPs as having the strongest SNP \times environment associations with fitness (Table S5).

435

440

445

Figure 4. Quantile-quantile plots of p-value distributions for three approaches to calculating genome-wide SNP×environment associations with fitness. X-axes show expected $-\log_{10}(p)$ and y-axes show observed $-\log_{10}(p)$.

450

Based on the results of our simulations and the p-value distributions noted above, we focus the remainder of analyses on results from mixed models with imputed fitness included (Approach 3). We found that climate variables differed in the importance of kinship-climate interaction associations with fitness (*i.e.* proportion of variance in fitness explained by random effects ν), suggesting that population structure in *Arabidopsis* is more strongly correlated with some climatic axes of local adaptation (G×E for fitness) compared to other climate gradients. For growing season minimum temperatures, kinship×environment interactions explained most of the variation in fitness ($R^2=0.78$, Table 1, row 3). By contrast, kinship×environment interactions for fitness were weaker along a gradient in winter minimum temperature ($R^2=0.07$).

Approach 3 tended to identify SNPs where SNP×environment interactions favored alleles in climates where they were relatively more common, that is, the sign of allelic differences in home climates were mirrored by the sign of fitted mixed model SNP×environment associations with relative fitness (Table 1, row 1, and see outlier examples in Figure 5). In addition to characterizing SNP×environment associations, we tended to identify SNPs where we estimated a rank change in relative fitness for alternate alleles along the environmental gradient between the two extreme common gardens (*i.e.* where the fitted model expectation was that the allele with higher fitness at one extreme common garden differed from the allele with higher fitness at the other extreme, Table 1, row 2). It appeared that the proportion of SNPs expected to show rank changes in relative fitness among the common gardens was related to how much of each climate variable's range was covered by gardens (Table 1, row 4). Thus the common gardens may have

been limited in their ability to capture rank changing of alleles at some loci involved in

475 local adaptation to aridity and growing season cold.

Table 1. Characterization of patterns identified by Approach 3 (mixed model including imputations) for SNPs in 0.01 lower tail of p-values for SNP×environment interactions for fitness (first two rows of table) and for kinship×environment interactions for fitness (third row). SNPs with home allele advantage are defined as those where the sign of allelic differences in home climates were mirrored by the sign of fitted mixed model SNP×environment associations with relative fitness. Rank changing SNPs are those where we estimated a rank change in relative fitness for alternate alleles along the environmental gradient between the two extreme common gardens. The final row gives the proportion of total observed climate gradient (among ecotypes) captured by the two most extreme common gardens.

<i>Statistic</i>	<i>Aridity</i>	<i>CV grow. seas. prec.</i>	<i>Min. temp.</i>	<i>Min. temp. grow. seas.</i>
Proportion SNP×E with home allele advantage	0.46	0.89	0.92	>0.99
Proportion SNP×E rank changing	0.31	0.92	>0.99	0.73
Kinship×E R ² for fitness	0.08	0.58	0.07	0.43
Proportion climate gradient covered by gardens	0.13	0.65	0.78	0.31

485

We found non-random, but very weak overlap between the SNPs we identified and those outliers in previous analyses (Hancock *et al.* 2011; Lasky *et al.* 2012a, 2014).

When considering mixed model (Lasky *et al.* 2014) or partial Mantel (Hancock *et al.* 2011) SNP associations with the same climate variables (*i.e.* genome-environment

490 associations with no common garden data), we found significant overlap among the previously identified SNPs in the 0.01 lower tail of p-values versus those in the 0.01 tail identified here (permutation test, all $p < 0.05$, Table S6). However, rank correlations among SNP scores from previous approaches versus our current approach were very weak (all $\rho < 0.2$, Table S6).

495

SNP×environment associations with fitness are enriched in regions suggestive of local adaptation

To assess whether our approach identified certain types of SNPs, we tested for enrichment of genic and intergenic regions for SNP×environment effects on fitness (again focusing on Approach 3: mixed model including imputations). We found that SNP×environment interactions for fitness were significantly enriched in genic regions (Table 2; for reference, SNPs identified via Approach 1, without random effects, were not significantly enriched in genic regions). Additionally, we found that SNP×environment interactions for fitness were enriched for high pairwise haplotype sharing (PHS) and high integrated extended haplotype homozygosity (iHS, Table 2). Finally, SNPs associated with G×E for flowering time response to growing temperature (identified in Li *et al.* 2014) tended to also have strong SNP×growing season minimum temperature interactions for fitness ($p < 0.0002$) but not for other climate variables. (Table 2)

Enrichments reported above did not change qualitatively (with respect to statistical significance) when we only considered SNPs with $MAF > 0.1$.

Table 2. Permutation tests of enrichment p-values for various signals suggestive of local adaptation to climate. For each statistic, we tested for enrichment of signal in the SNPs in the 0.01 lower tail of p-values for SNP×environment associations with relative fitness. “Genic” tests enrichment of genic versus non-genic SNPs, “PHS” and “iHS” test for enrichment with significant ($\alpha = 0.05$) pairwise haplotype sharing and standardized integrated extended haplotype homozygosity, respectively. The final row shows enrichment with SNPs having significant ($\alpha = 0.05$) associations with change in flowering time (G×E) in response to warming during growth.

<i>Statistic</i>	<i>Aridity enrichment</i>	<i>CV grow. seas. prec. enrichment</i>	<i>Min. temp. enrichment</i>	<i>Min. temp. grow. seas. enrichment</i>
Genic	0.0036	<0.0002	0.0054	0.0006

iHS	0.2840	0.0006	0.0020	0.0008
Flowering time under warming, G×E	0.8582	0.0680	0.5844	<0.0002

520

SNP×environment associations with fitness identify genes potentially involved in local adaptation

Our approach identified a number of strong candidates for local adaptation at the top of lists of SNPs with the strongest SNP×environment associations with relative fitness

525 (Tables S1-S4). For example, the top SNP associated with aridity interaction effects on fitness (chr. 4, position 11005059) fell within LESION SIMULATING DISEASE 1 (LSD1), which affects a number of traits in Arabidopsis, including survival and fecundity under drought (Wituszyńska *et al.* 2013; Szechyńska-Hebda *et al.* 2016) (Figure 5), while the third SNP (chr. 2, position 7592008) fell within ATMLO8, MILDEW RESISTANCE

530 LOCUS O 8, homologous with barley MLO which controls resistance to the fungal pathogen powdery mildew (Büschges *et al.* 1997). The top SNP associated with winter cold interaction effects on fitness (chr. 5, position 7496047) falls within coding region of WRKY38, involved in the salicylic acid pathway and pathogen defense (Kim *et al.* 2008), and was the same locus identified as most strongly associated with multivariate

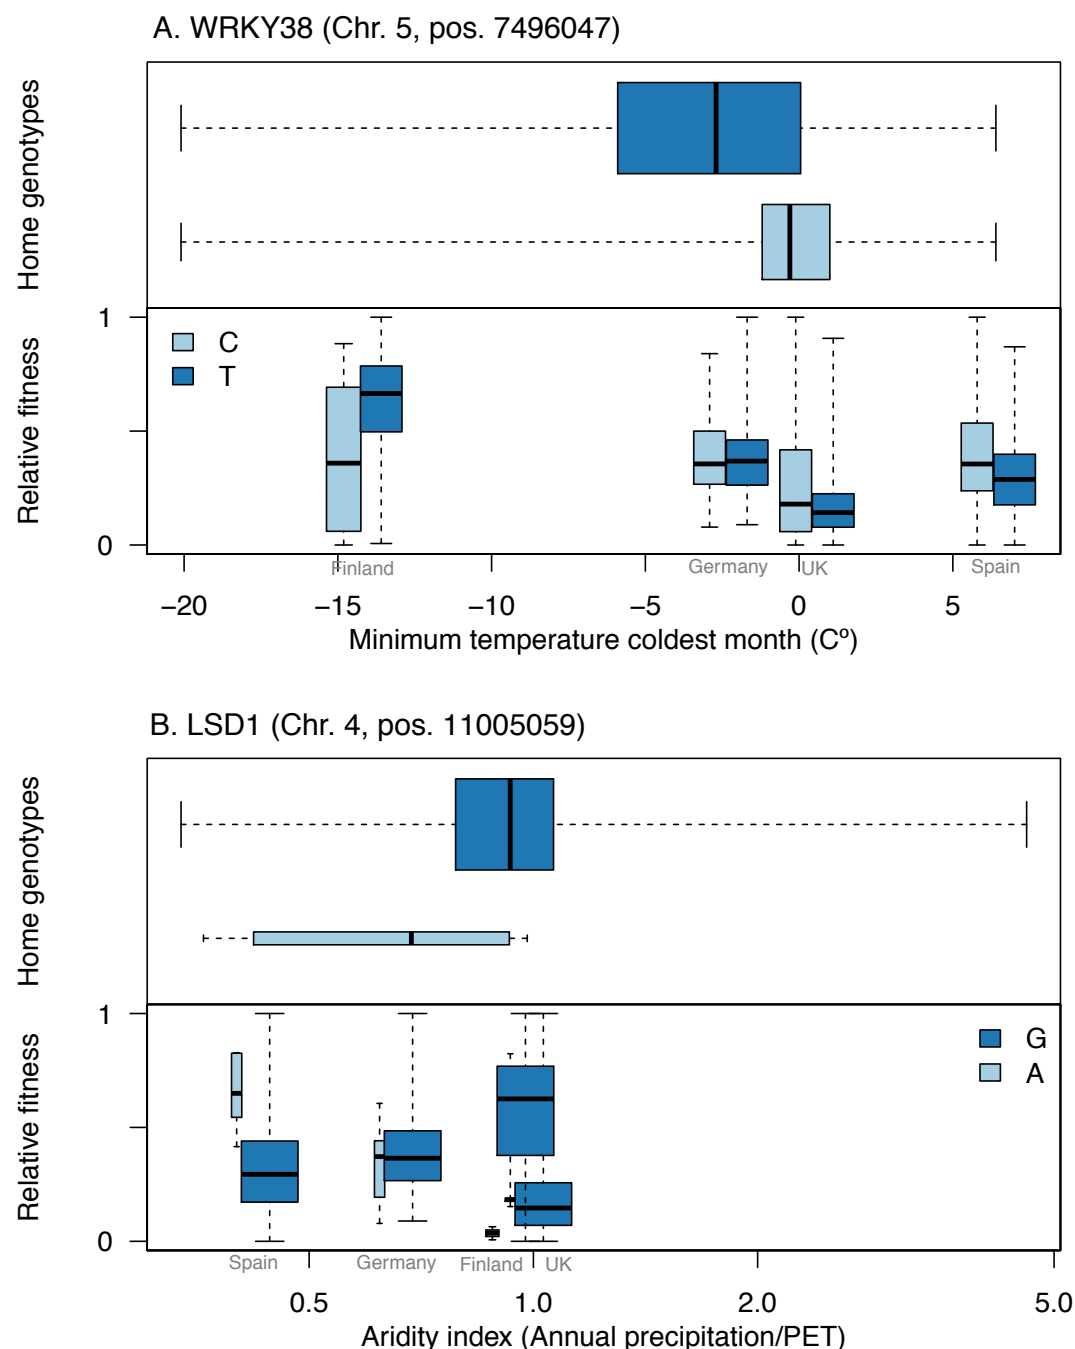

535 climate in Lasky *et al.* (2012) (Figure 5). The top SNP associated with variability in growing season precipitation interaction effects on fitness (chr. 2, position 18504858) falls 380 bp from ABA HYPERSENSITIVE GERMINATION 11, AHG11, which mediates the effect of abscisic acid (ABA), a major hormone of abiotic stress response, on germination (Murayama *et al.* 2012). The fifth highest SNP (and second highest locus)

540 associated with growing season cold interaction effects on fitness (chr. 3, position 8454439) fell within ABERRANT LATERAL ROOT FORMATION 5, ALF5, a gene

that confers resistance to toxins (Diener *et al.* 2001) belonging to the MATE gene family,
which play a variety of roles responding to environment (Shoji 2014).

545

Figure 5. Example SNPs with the strongest associations (i.e. lowest p-value) with cold winter temperatures (A) and aridity (B). Top subpanels show the climate distribution of alleles in home genotypes (i.e. natural geographic patterns), known as genotype-environment associations. Bottom subpanels show relative fitness of alleles in four common gardens, where common gardens' climates determine position on x-axes. Each SNP falls within the coding region of indicated genes (WRKY38 and LSD1). Boxes are scaled to number of accessions with each allele. In both (A) and (B), the allele with the greatest relative fitness in common gardens changes along the environmental gradient consistent with change in allele frequency in native accessions (i.e. ecotypes).

Discussion

Genetic variation in environmental responses ($G \times E$) is ubiquitous but poorly understood at large spatial scales, *e.g.* across a species range. Replicated common garden

560 experiments and genome scans for loci exhibiting evidence for local adaptation have been important in understanding the genetic basis of $G \times E$ and local adaptation (Hancock *et al.* 2008; ECKERT *et al.* 2010; Turner *et al.* 2010; Fournier-Level *et al.* 2011a; Lasky *et al.* 2012a, 2015; Ågren *et al.* 2013; Evans *et al.* 2014). However, the complementary information in common gardens and geographic variation in allele frequency have not
565 been coherently synthesized. Previous association studies of $G \times E$ have modeled discrete, categorical environmental effects (Murcay *et al.* 2009; Thomas 2010; Korte *et al.* 2012; Marigorta and Gibson 2014). Here, we demonstrated an approach to association study of $G \times E$ for fitness and an imputation technique that allowed us to coherently synthesize evidence from common gardens and genome-environment associations. Our imputation
570 method relied on making explicit the often implicit assumption of local adaptation that underlies genome-environment association studies (Coop *et al.* 2010; Hancock *et al.* 2011; Lasky *et al.* 2012a). Using simulation, we demonstrated that this imputation can increase power to identify SNPs causing $G \times E$ for fitness and local adaptation. Our approach also identified strong candidate genes in *Arabidopsis* associated with SNPs that
575 exhibit fitness tradeoffs along climate gradients such that locally common alleles had greater relative fitness. An advantage of studying *Arabidopsis* was that we had published measures of fitness, whereas below we discuss how our approach could be applied when only data on components of fitness or adaptive traits are available.

580 *Model extensions*

Above we described a method of imputation based on the assumption of local adaptation, *i.e.* home genotypes had greater fitness than away genotypes. However, local adaptation in nature is typically imperfect, such that the optimal genotype for a given location might not be the home genotype (Leimu and Fischer 2008; Hereford 2009). Local adaptation
585 may fail due to immigration of maladaptive alleles (Slatkin 1973), limited genetic variation (Barton 2001), and other processes (Bridle and Vines 2007). Thus our imputation can be considered a heuristic to be improved by further development.

We consider two approaches that would extend the generality of our approach by treating relative fitness as a parameter rather than imputed data. First, instead of assuming
590 that each sequenced genotype is most fit in its home environment, an alternative approach could treat the unobserved fitness of home genotypes as a free parameter. To constrain estimates of unobserved fitness one could use informative priors, such that the prior probability of relative fitness at home for each genotype would be monotonically increasing, *i.e.* local adaptation is the most likely state, but minor maladaptation is
595 expected to be common. Inferences about unobserved fitness could be further constrained using hierarchical models, such that home fitness parameters for multiple genotypes arise from a distribution (GELMAN and HILL 2007). Second, for situations in which fitness is not measured, components of fitness (*e.g.* survival) or traits thought to be locally adaptive (*e.g.* physiological or behavioral) can be measured and used to infer the genomic basis of
600 local adaptation. For example, instead of modeling SNP×environment associations with fitness, one could model SNP×environment associations with components of fitness or adaptive traits measured in common gardens, and estimate unobserved traits for

sequenced genotypes using informative priors. To be clear, in our case study of Arabidopsis, we had near but not complete lifetime fitness data (missing germination
605 stage). Here we do not attempt to parameterize these model extensions, given the current computational challenge of fitting many more parameters in a Bayesian framework.

Genotype-by-environment interactions in genome-wide association studies

Recent advances in association models have included explicit modeling of $G \times E$ (Murcray
610 *et al.* 2009; Thomas 2010; Korte *et al.* 2012; Marigorta and Gibson 2014; Li *et al.* 2014; Kooperberg *et al.* 2016; Windle 2016), but to our knowledge there are no published genome-wide association studies accounting for SNP interactions with continuous environmental gradients. Some of the aforementioned categorical treatments of $SNP \times environment$ interactions were used in association studies for human disease.

615 However, many of the environmental variables that may mediate genetic risk of disease are continuous in nature, *e.g.* exposure to ultraviolet radiation and tobacco smoke. Future research on local adaptation and human disease may benefit from exchange of approaches given the shared importance across disciplines of understanding the genomic basis of $G \times E$.

Case study on Arabidopsis thaliana

Our approach leveraged information from both common gardens and geographic patterns in allele frequency, which simulations indicated can increase power and accuracy to detect variants driving local adaptation. Furthermore, although there was overlap with
625 signal identified by previous approaches using the same data (Hancock *et al.* 2011;

Lasky *et al.* 2012a, 2014), overlap was generally weak, indicating our approach identified distinct loci as causing local adaptation. In our case study on *Arabidopsis*, the SNPs that exhibited the strongest evidence for SNP×climate interaction effects on fitness often fell within the coding regions of strong candidate genes based on known roles in environmental responses, suggesting our approach is a useful for identifying loci underlying local adaptation.

Our approach identified many SNPs where allelic variation was associated with rank-changing relative fitness tradeoffs along climate gradients (*e.g.* all 214 of the SNPs with strongest interaction, *i.e.* 0.001 quantile, with winter minimum temperature association for fitness), loci where selective gradients may maintain population differentiation (Anderson *et al.* 2011b; Ågren *et al.* 2013). Studies of local adaptation genomics often find limited evidence for loci with antagonistic pleiotropy. A previous study of the common garden data used here (Fournier-Level *et al.* 2011a) found that the SNPs with the strongest association with fitness in one common garden were rarely among those with the strongest associations in another garden, which may be evidence for conditional neutrality. By contrast with previous approaches that model phenotypes at a single site, our model was explicitly focused on detecting alleles with the strongest evidence for SNP×climate interactions favoring home alleles. Thus using our model, loci with patterns indicative of antagonistic pleiotropy were most likely to be detected. Additionally, local adaptation to many climate gradients may involve evolution of complex traits governed by variants at many loci. Thus loci exhibiting antagonistic pleiotropy and loci exhibiting G×E but no tradeoffs may both underlie genome-level local adaptation. Note that our study, like that of (Fournier-Level *et al.* 2011a) is based on

association mapping, which may suffer from identification of more false positives

650 compared with linkage mapping approaches (HALL *et al.* 2010; ANDERSON *et al.* 2013; Ågren *et al.* 2013). Follow-up experimental study of phenotypic effects of variation at individual loci is required to confirm the results of association mapping (*e.g.* Verslues *et al.* 2014; Broekgaarden *et al.* 2015).

We found evidence that SNP×climate interaction effects on fitness were enriched
655 in genic regions, suggesting that our model captured a signal of local adaptation rather than population structure. We found that enrichments in genic SNPs only emerged after using a mixed model to control for the putative effects of population structure (*i.e.* genome-wide similarity), suggesting that the genic-enriched patterns of divergence we modeled were not simply associated with overall patterns of among-population
660 divergence. This enrichment is consistent with other findings in *Arabidopsis* (Hancock *et al.* 2011; Lasky *et al.* 2012a) and other species ((Coop *et al.* 2009; Fumagalli *et al.* 2011; Lasky *et al.* 2015), but see (Pyhäjärvi *et al.* 2013)). We do not interpret this enrichment as indicating that changes in amino acid sequences are more important than regulatory evolution in local adaptation, but rather as supporting the hypothesis that local adaptation
665 is more likely to involve sequence evolution near genes as opposed to at locations farther from genes, where many intergenic SNPs are found.

We found evidence that loci we identified as candidates for local adaptation were enriched in evidence for partial selective sweeps (PHS and iHS statistics), suggesting that recent local sweeps in particular environments are an important mode of local adaptation
670 (Voight *et al.* 2006; Toomajian *et al.* 2006). That many locally adaptive variants were swept recently may be expected based on the range dynamics of *Arabidopsis*, which has

colonized much of its Eurasian range following the retreat of glaciers (Sharbel *et al.* 2000), a process that may have involved recent local adaptation. It is important to note that extended haplotype patterns suggestive of partial sweeps may occur at the shoulders
675 (*i.e.* away from causal loci) of complete sweeps (Schridder *et al.* 2015), thus caution is warranted in attributing our observed PHS and iHS enrichment to localized sweeps versus global sweeps at nearby loci.

Finally, we found significant overlap between SNPs associated with G×E for fitness along growing season cold gradients and SNPs associated with G×E for
680 flowering time across growing season temperature treatments (Li *et al.* 2014). Our findings suggest that evolution of plasticity in flowering time is a mechanism of local adaptation along growing season cold gradients and that our model has captured the signal of this adaptation. For organisms inhabiting seasonal environments, timing of the life cycle may have large impacts on fitness. Previous common garden
685 experiments have provided strong evidence that flowering time is a central trait involved in local adaptation (Hall and Willis 2006; Franks *et al.* 2007; Keller *et al.* 2012; Lowry *et al.* 2014) with molecular study further supporting the role of flowering time (Stinchcombe *et al.* 2004; Caicedo *et al.* 2004; Shindo *et al.* 2005; Lovell *et al.* 2013) and the role of plasticity (Fraser 2013; Lasky *et al.* 2014) in local
690 adaptation.

Conclusions

Local adaptation to environment involves genotype-by-environment interactions for fitness. Genome-wide association studies are a promising approach for identifying the

genomic basis of local adaptation and G×E. Additional approaches, *e.g.* genome-wide expression profiling, may also be useful for uncovering the genomic basis of local adaptation (Des Marais *et al.* 2013). Future approaches that use a principled basis for quantitative synthesis of these data types may enhance our ability to characterize adaptation in an integrative fashion.

Supplemental material

1000 **Tables S1-S4 (attached csv files).** List of genes within 1 kb of SNPs in the lower 0.001 quantile for p-values for SNP×environment interactions for each climate variable, including imputed observations and accounting for kinship.

1005 **Table S5.** Rank correlation among SNPs for SNP×environment effect p-values

comparing the three tested approaches with Arabidopsis.

	<i>Random effect, no imputation</i>	<i>Random effect, imputation</i>
Min. temp. growing season		
<i>No random effect, including imputation</i>	0.396	-0.001
<i>Random effect, no imputation</i>		0.041
Aridity		
<i>No random effect, including imputation</i>	0.318	0.008
<i>Random effect, no imputation</i>		-0.032
Min. temp. coldest month		
<i>No random effect, including imputation</i>	-0.021	-0.012
<i>Random effect, no imputation</i>		0.104
CV growing season prec.		
<i>No random effect, including imputation</i>	0.178	0.090
<i>Random effect, no imputation</i>		-0.006

Table S6. Overlap (one-tailed permutation tests) and rank correlations (Spearman's rho)

1010 between different approaches to identifying SNPs associated with local adaptation in
Arabidopsis. Citations are given for the original publication of previous approaches. For
partial Mantel and RDA, we used absolute value of SNP scores to rank SNPs.

Climate var.	Mixed model, overlap in 0.01 tail strongest associations	Mixed model, rank correlation between associations	Partial Mantel, overlap in 0.01 tail strongest associations	Partial Mantel, rank correlation between associations	First axis of RDA, overlap in 0.01 tail strongest associations	First axis of RDA, rank correlation between associations	First axis of RDA after removing spatial structure,, overlap in 0.01 tail strongest associations	First axis of RDA after removing spatial structure, rank correlation between associations
