Abstract

The coordinated behaviour of populations of cells plays a central role in tissue growth and renewal. Cells react to their microenvironment by modulating processes such as movement, growth and proliferation, and signalling. Alongside experimental studies, computational models offer a useful means by which to investigate these processes. To this end a variety of cell-based modelling approaches have been developed, ranging from lattice-based cellular automata to lattice-free models that treat cells as point-like particles or extended shapes. It is difficult to accurately compare between different modelling approaches, since one cannot distinguish between differences in behaviour due to the underlying model assumptions and those due to differences in the numerical implementation of the model. Here, we exploit the availability of an implementation of five popular cell-based modelling approaches within a consistent computational framework, Chaste (`http://www.cs.ox.ac.uk/chaste`). This framework allows one to easily change constitutive assumptions within these models. In each case we provide full details of all technical aspects of our model implementations. We compare model implementations using four case studies, chosen to reflect the key cellular processes of proliferation, adhesion, and short- and long-range signalling. These case studies demonstrate the applicability of each model and provide a guide for model usage.

Introduction

Cells in eukaryotic organisms respond to physical and chemical cues through processes such as movement, growth, division, differentiation, death and secretion or surface presentation of signalling molecules. These processes must be tightly orchestrated to ensure correct tissue-level behaviour and their dysregulation lies at the heart of many diseases. The last decade has witnessed remarkable progress in molecular and live-imaging studies of the collective self-organization of cells in tissues. In combination with experimental studies, mathematical modelling is a useful tool with which to unravel the complex nonlinear interactions between processes at the subcellular, cellular and tissue scales from which organ- and organism-level function arises. The classical approach to modelling these processes treats the tissue as a continuum, using some form of homogenization argument to average over length scales much larger than the typical diameter of a cell. It can thus be difficult to incorporate heterogeneity between cells within a population, or investigate the effect of noise at various scales, within such models.

Facilitated by the reduction in cost of computing power, a number of discrete or 'individual-based' approaches have been developed to model the collective dynamics of multicellular tissues (Fig 1). Such models treat cells, or subcellular components, as discrete entities and provide natural candidates for studying the regulation of cell-level processes in tissue dynamics. However, they are less amenable to mathematical analysis than their continuum counterparts. The precise rules and methods of implementation differ between models and must be adapted to a particular biological system. However, they can be broadly categorised as on- and off-lattice, according to whether or not cells are constrained to lie on an artificial lattice. Each of the models described below have been helpful in furthering our knowledge but, like all models, they are simplifications and so have limitations.

Arguably the simplest individual-based models are cellular automata (CA), where each lattice site can contain at most a single cell (Fig 1(a)). The system is evolved discretely, using a fixed time-stepping [1] or event-driven [2] approach, with the new state of each cell determined using deterministic or stochastic rules and the state of the system at the previous time step. The computational simplicity of CA renders them amenable to simulating large numbers of cells.

Another class of on-lattice model is the cellular Potts (CP) model [3], which represents each cell by several lattice sites, allowing for more realistic cell shapes (Fig 1(b)). The shape of each cell is evolved via some form of energy minimization. Unlike CA, the CP model can
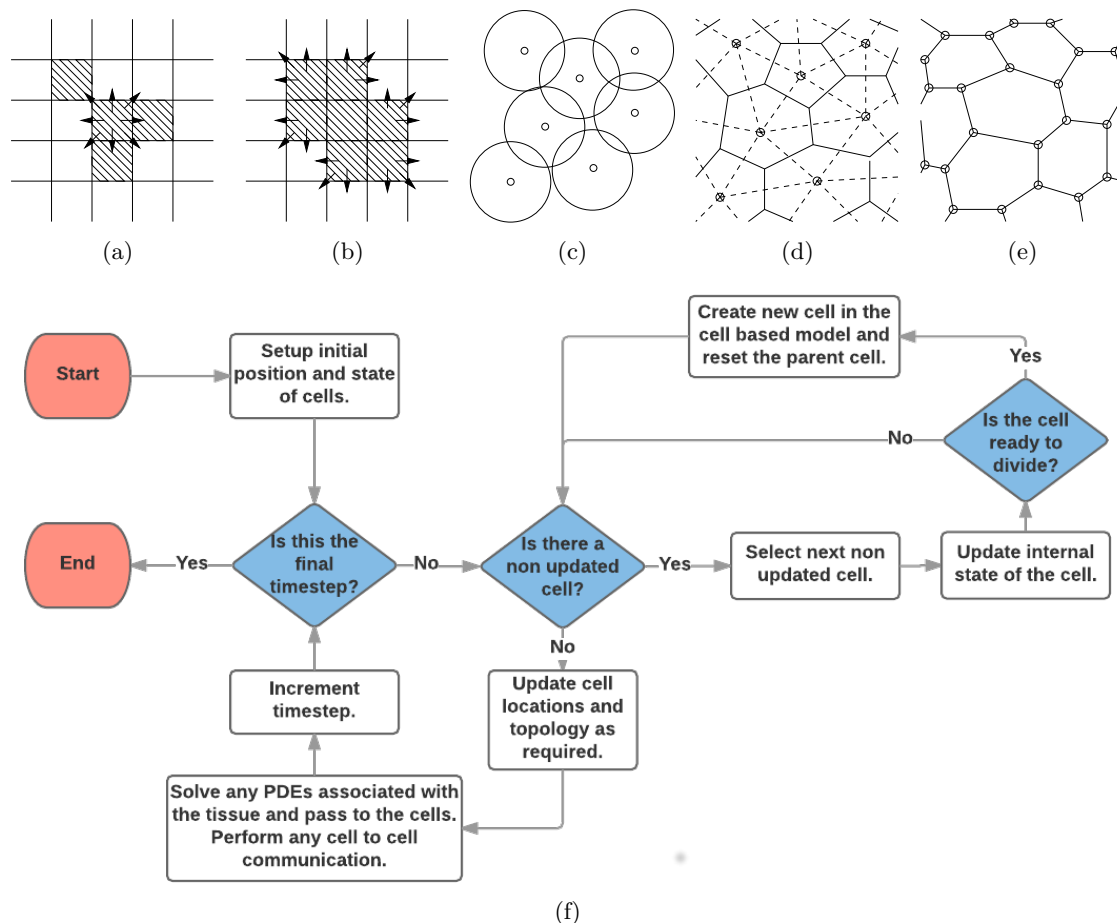

Fig 1. Schematics of the cell-based models considered in this study. (a) Cellular automaton (CA). (b) Cellular Potts (CP) model. (c) Overlapping spheres (OS) model. (d) Voronoi tessellation (VT) model. (e) Vertex model (VM). (f) Flow chart of cell-based simulation algorithm. See text for full details.

incorporate mechanical processes such as cell membrane tension, cell-cell and cell-substrate adhesion, chemotaxis and cell volume conservation. The CP model has been used to study biological processes ranging from cell sorting [4] and morphogenesis [5] to tumour growth [6].

The removal of a fixed-lattice geometry in off-lattice models enables the more detailed study of mechanical effects on cell populations. Two common descriptions of cell shape in off-lattice models are (i) 'overlapping spheres' (OS) or quasi-spherical particles [7] and (ii) through Voronoi tessellations (VT) [8]; in both approaches, the centre of each cell is tracked over time. In the former, cells are viewed as particles that are spherical in the absence of any interactions but which deform upon cell-cell or cell-substrate contact (Fig 1(c)). In the latter, the shape of each

cell is defined to be the set of points in space that are nearer to the centre of the cell than the centres of any other cell; a Delaunay triangulation is performed to connect those cell centres that share a common face, thus determining the neighbours of each cell [9] (Fig 1(d)). In either case, Monte Carlo methods or Langevin equations may be used to simulate cell dynamics.

An alternative off-lattice approach commonly used to describe tightly packed epithelial cell sheets are vertex models (VM), in which each cell is modelled as a polygon, representing the cell's membrane (Fig 1(e)). Each cell vertex, instead of centre, moves according to a balance of forces due to limited compressibility, cytoskeletal contractility and cell-cell adhesion. Additional rules govern cell neighbour rearrangements, growth, mitosis and death.

Several on- and off-lattice cell-based models have coupled descriptions of nutrient or morphogen transport and signalling to cell behaviour [10, 11, 12, 13, 14]. For example, a hybrid CA was used by Anderson and colleagues to study the role of the microenvironment on solid tumour growth and response to therapy [15], while Aegerter-Wilmsen et al. coupled a vertex model of cell proliferation and rearrangement with a differential algebraic equation model for a protein regulatory network to describe the interplay between mechanics and signalling in regulating tissue size in the *Drosophila* wing imaginal disk [10].

As the use of cell-based models becomes increasingly widespread in the scientific community, it becomes ever more useful to be able to compare competing models within a consistent computational framework, to avoid the potential danger of artifacts associated with different methods of numerical solution. To date there has not been a comparison of the classes of models described above, because it is difficult to identify in some cases corresponding processes but also that there has not been a common computational framework in which to carry out such a comparison. The development of Chaste, an open-source C++ library for cell-based and multiscale modelling [16, 17], now allows for the latter.

Here we present a systematic comparison of five classes of cell-based models through the use of four case studies. We demonstrate how the key cellular processes of proliferation, adhesion, and short- and long-range signalling can be implemented and compared within the competing modelling frameworks. Moreover, we provide a guide for which model is appropriate when representing a given system. We concentrate throughout on the two-dimensional case, but note that many of these models have also been implemented in three dimensions.

The remainder of this paper is structured as follows. We begin by presenting the five mathematical frameworks and discuss their implementation. Next, we use our four case studies to demonstrate

5

how the modelling frameworks compare. Finally, we discuss our results and present a guide to 74
which framework to use when modelling a particular problem. 75

Materials and Methods 76

In this study we compare the implementation and behaviour of: cellular automata (CA); cellular 77
Potts (CP); cell-centre, both overlapping sphere (OS) and Voronoi tessellation (VT); and vertex 78
(VM) models. We begin by briefly describing the governing rules and equations for each of these 79
models focussing on the way they implement the common processes of cell-cell interaction and 80
cell division. Throughout, full references are given to previous publications giving much fuller 81
details of the derivation and implementation of each of these models. We also present a consistent 82
numerical implementation for the models. 83

Cellular automaton (CA) model 84

There are several possible ways to represent cell movement in a CA. Here we focus on compact 85
tissues so consider movement driven by division and cell exchange, using a shoving-based 86
approach [18]. The spatial domain is discretised into a regular lattice with cells occupying the 87
individual lattice sites (Fig 1(a)). The area A_i of each cell i in this model is given by 1 squared 88
cell diameter (CD^2). 89

In common with all of the cell-based models presented here, cell proliferation is determined by a 90
model of how cells progress through the cell cycle, which in turn specifies when cells divide. Our 91
model of cell-cycle progression varies across the four examples considered. However, in all cases 92
a dividing cell selects a random lattice site from its Moore neighbourhood (the eight cells that 93
surround it), and all cells along the row, column or diagonal from the dividing cell's location are 94
instantaneously displaced or 'shoved' to make space for the new cell. 95

We use a Metropolis-Hastings algorithm to make additional updates to the state of the tissue 96
using asynchronous updating. At each time step Δt, after checking for and implementing any 97
cell divisions, we sample with replacement N_{Cells} cells, where N_{Cells} is the number of cells in the 98
tissue at time t (thus, it may be the case that a cell is sampled more than once in a time step, 99
while others are not sampled). This sweeping of the domain is also known as a Monte Carlo 100
Step (MCS). We randomly select a neighbouring lattice site from each sampled cell's Moore 101

6

neighbourhood for a potential swap. The swapping of cells is intended to model random motility and the affinity of cells to form and break connections with adjacent cells. Assigning the MCS to a time step Δt allows us to parametrize the timescale of the switching process and relate this to cell division. A probability per hour is assigned for the cells (or empty lattice site, which we refer to as a void) to swap locations, p_{swap}, which is calculated as

$$p_{\mathrm{swap}} = \begin{cases} \kappa_{\mathrm{swap}}, & \text{for} \quad \Delta H \leq 0, \\ \kappa_{\mathrm{swap}} \exp\left(-\frac{\Delta H}{T}\right), & \text{for} \quad \Delta H > 0. \end{cases} \tag{1}$$

where κ_{swap} represents the rate of switching and T represents the background level of cell switching, modelling random cell fluctuations. If $T = 0$ then only energetically favourable swaps happen, and we use this as the default value for our simulations; as T increases, more energetically unfavourable swaps occur. Finally, $\Delta H = H_1 - H_0$ denotes the change in adhesive energy due to the swap, with H_0 and H_1 being the energy in the original and changed configurations respectively, which is defined to be the sum of the adhesion energy between lattice sites:

$$H = \sum_{(i,j)\in\mathcal{N}} \gamma(\tau(i), \tau(j)), \tag{2}$$

where $\gamma(a, b)$ is a constant whose value depends on a and b, representing the adhesion energy between cells (or void) of type a and b, $\tau(k)$ is the type of cell k (or void if there is no cell on the lattice site) and $\mathcal{N}$ is the set of all neighbouring lattice sites. Here $\tau(k)$ takes the values 'A', 'B' and 'void', but can in principle be extended to more cell types.

Cellular Potts (CP) model

As in the CA, we discretize the spatial domain into a lattice. Although, as in the CA case, the structure and connectivity of this lattice may be arbitrary, for simplicity we restrict our attention to a regular square lattice of size $N \times N$. In contrast to the CA model, each cell is represented by a collection of lattice sites, with each site contained in at most one cell with the cell type of a lattice site being referred to as its spin. The area A_i of each cell i in this model is given by the sum of the area of all the lattice sites contained in the cell. In the present study, we take the area of each lattice site to be $1/16$ CD^2 and cells have a target area of 16 lattice sites i.e. 1 CD^2. This is illustrated in Fig 1(b).

7

In a similar manner to the CA, the system evolves by attempting to minimize a total 'energy' or $\quad$ 126
Hamiltonian, H, over discrete time steps using a Metropolis-Hastings algorithm. The precise $\quad$ 127
form of H varies across applications but can include contributions such as cell-cell adhesion, $\quad$ 128
hydrostatic pressure, chemotaxis and haptotaxis [5]. One iteration of the algorithm consists of $\quad$ 129
selecting a lattice site and a neighbouring site (from the Moore neighbourhood) at random and $\quad$ 130
calculating the change in total energy resulting from copying the spin of the first site to the $\quad$ 131
second, $\Delta H = H_1 - H_0$. The spin change is accepted with probability $\quad$ 132

$$p_{\text{swap}} = \min\left(1, e^{-\Delta H/\kappa T}\right), \tag{3}$$

where κ is the Boltzmann constant and T, referred to as the 'temperature', characterizes $\quad$ 133
fluctuations in the system; broadly speaking, at higher values of T cells move more freely, and $\quad$ 134
hence system fluctuations increase in size. At each time step, Δt we choose to sample with $\quad$ 135
replacement $N \times N$ lattice sites (thus, it may be the case that a cell is sampled more than once $\quad$ 136
in a time step, while others are not sampled). Note that this established algorithm for simulating $\quad$ 137
CP models permits cell fragmentation, in principle; however, recent work has overcome this $\quad$ 138
limitation [19]. $\quad$ 139

In this study, we use a Hamiltonian of the form $\quad$ 140

$$H = \sum_{i=1}^{N_{\text{Cells}}(t)} \left[\alpha\left(A_i - A_i^{(0)}\right)^2 + \beta\left(C_i - C_i^{(0)}\right)^2\right] + \sum_{(i,j)\in\mathcal{N}} (1 - \delta_{\sigma(i),\sigma(j)})\gamma(\tau(i),\tau(j)), \tag{4}$$

where the first and second terms on the right-hand side represent the area and perimeter constraint $\quad$ 141
energies, summed over each cell in the system, and the third term represents the adhesion energy. $\quad$ 142
Here $\sigma(k)$ denotes the index of the cell containing lattice site k (note we let $\sigma(k) = 0$ if no cell $\quad$ 143
is attached to the lattice site and we denote this to be the void), and $\delta_{a,b}$ is the delta function, $\quad$ 144
which equals 1 if $a = b$ and 0 otherwise. $\tau(k)$ denotes that cell's 'type' (with the type void if $\quad$ 145
$\sigma(k) = 0$), and γ denotes the interaction energies between cells occupying neighbouring lattice $\quad$ 146
sites i and j. Again $\mathcal{N}$ is the set of all neighbouring lattice sites and we allow γ to take different $\quad$ 147
values for homotypic and heterotypic cell-cell interfaces and for 'boundary' interfaces between $\quad$ 148
cells and the surrounding medium. Here $A_k^{(0)}$ and $C_k^{(0)}$ denote a specified 'target area' and $\quad$ 149
'target perimeter' for cell k, respectively, which can depend on internal properties of the cell, $\quad$ 150
allowing for cell growth to be modelled. Here we assume all cells are mechanically identical and $\quad$ 151
set $A_k^{(0)} = A^{(0)}$ and $C_k^{(0)} = C^{(0)}$. The parameters α and β influence how fast cells react to the $\quad$ 152

8

area and perimeter constraints, respectively.

Cell-centre models

Here cells are represented by their centres, which are modelled as a set of points $\{\mathbf{r}_1, \ldots, \mathbf{r}_{N_{\text{Cells}}}\}$ which are free to move in space. For simplicity, we assume all cells to have identical mechanical properties and use force balance to derive the equations of motion. We balance forces on each cell centre and making the standard assumption that inertial terms are small compared to dissipative terms (as cells move in dissipative environments of extremely small Reynolds number [20]), we obtain a first-order equation of motion for each cell centre, $\mathbf{r}_i$, given by

$$\eta \frac{\mathrm{d}\mathbf{r}_i}{\mathrm{d}t} = \mathbf{F}_i(t) = \sum_{j \in \mathcal{N}_i(t)} \mathbf{F}_{ij}(t), \tag{5}$$

where η denotes a damping constant and $\mathbf{F}_i(t)$ is the total force acting on a cell i at time t which is assumed to equal the sum of all forces, coming from the connections with all neighbouring cells $j \in \mathcal{N}_i(t)$ adjacent to i at that time, $\mathbf{F}_{ij}(t)$. The definition of $\mathcal{N}_i(t)$ varies between the OS and VT models; in the former, it is the set of cells whose centres lie within a distance $r_{\max}$ from the centre of cell i, while in the latter, it is the set of cells whose centres share an edge with the centre of cell i in the Delaunay triangulation. We solve this equation numerically using a simple forward Euler scheme with sufficiently small time step Δt to ensure numerical stability:

$$\mathbf{r}_i(t + \Delta t) = \mathbf{r}_i(t) + \frac{\Delta t}{\eta} \sum_{j \in \mathcal{N}_i(t)} \mathbf{F}_{ij}(t). \tag{6}$$

If the subcellular machinery causes cell i to divide then we generate a random mitotic unit vector $\hat{\mathbf{m}}$ and the daughters cells are placed at $\mathbf{r}_i \pm \epsilon \hat{\mathbf{m}}$, where ϵ is a constant division separation parameter and is dependent on the particular cell centre model being used.

Overlapping spheres (OS)

Here, each cell i has an associated radius R_i. Two cells i and j are assumed to be neighbours if their centres satisfy $||\mathbf{r}_i - \mathbf{r}_j|| < r_{\max}$ for a fixed constant $r_{\max}$, known as the interaction radius,

9

where $r_{\max} > 2R_i$ for all i. The area of the cell is defined as [21]

$$A_i = \pi \left(R_i^{\text{eff}} \right)^2, \tag{7}$$

where

$$R_i^{\text{eff}} = \frac{1}{6} \left[\sum_{j \in \mathcal{N}_i(t)} \frac{1}{2} (R_i - R_j + ||\mathbf{r}_{ij}||) + R_i(6 - \text{size}(\mathcal{N}_i(t))) \right]. \tag{8}$$

Here $\mathbf{r}_{ij}(t) = \mathbf{r}_j(t) - \mathbf{r}_i(t)$ is the vector from cell i to cell j at time t. An illustration of cell connectivity is given in Fig 1(c).

In the OS model we define the force between cells as [21]

$$\mathbf{F}_{ij}(t) = \begin{cases} \mu_{ij} s_{ij}(t) \hat{\mathbf{r}}_{ij}(t) \log \left(1 + \frac{||\mathbf{r}_{ij}(t)|| - s_{ij}(t)}{s_{ij}(t)} \right), & \text{for} \quad ||\mathbf{r}_{ij}(t)|| < s_{ij}(t), \\ \mu_{ij}(||\mathbf{r}_{ij}(t)|| - s_{ij}(t)) \hat{\mathbf{r}}_{ij}(t) \exp \left(-k_C \frac{||\mathbf{r}_{ij}(t)|| - s_{ij}(t)}{s_{ij}(t)} \right), & \text{for} \quad s_{ij}(t) \leq ||\mathbf{r}_{ij}(t)|| \leq r_{\max}, \\ 0, & \text{for} \quad ||\mathbf{r}_{ij}(t)|| > r_{\max}. \end{cases} \tag{9}$$

Here μ_{ij} is known as the "spring constant" and controls the size of the force (and depends on the cell types of the connected cells), by default $\mu_{ij} = \mu$ for all interactions, $\mathbf{r}_{ij}(t) = \mathbf{r}_i(t) - \mathbf{r}_j(t)$, $\hat{\mathbf{r}}_{ij}(t)$ is the corresponding unit vector, k_C is a parameter which defines decay of the attractive force, and $s_{ij}(t)$ is the natural separation between these two cells. For the OS model $s_{ij}(t)$ is the sum of the radii of the two cells, and here the cell's radius increases from 0.25 to 0.5 CDs over the first hour of the cell cycle, and hence is a function of time. Note that there is a cut off distance, $r_{\max}$, such that once $||\mathbf{r}_{ij}(t)|| > r_{\max}$ the cells are not connected so the force is zero.

Voronoi tessellation (VT)

In the VT model we represent cells by the Voronoi region of the cell centres (this is defined as the region of space that is nearer to one cell centre than any other). Example cell regions are shown as solid lines in Fig 1(d). In this model, the area A_i of a cell i is defined to be the area of the corresponding Voronoi region. Cell connectivity is defined by the dual of the Voronoi region, known as a Delaunay triangulation and this is shown by the dashed lines in Fig 1(d). Two cell centres are assumed to be connected if they share an edge in the Delaunay triangulation.

10

In the VT model we define the force between cells to be [8, 22],

$$\mathbf{F}_{ij}(t) = \mu_{ij}\hat{\mathbf{r}}_{ij}(t)\left(||\mathbf{r}_{ij}(t)|| - s_{ij}(t)\right). \tag{10}$$

Here μ_{ij} is the spring constant (which again defaults to $\mu_{ij} = \mu$), $\mathbf{r}_{ij}(t) = \mathbf{r}_i(t) - \mathbf{x}_j(t)$, $\hat{\mathbf{r}}_{ij}(t)$ is the corresponding unit vector and $s_{ij}(t)$ is the natural separation between these two cells. For the VT model this increases linearly from $s = \epsilon\ (= 0.1)$ to $s = 1$ over the first hour of the cell cycle.

When using a Delaunay triangulation to define cell connectivity, on a growing tissue, long edges can form between distant cells causing unrealistic connections to be made. There are two methods used to overcome this. The first is to introduce a cut-off length, r_{max}, such that cells further apart than the cut-off length are no longer connected (analogous to the OS model). The second method is to introduce *ghost nodes*, which are extra nodes introduced into the simulation which surround the tissue, which do not exert any forces on the cells, and preclude any long connections from forming. Moreover these ghost nodes ensure that the Voronoi regions, and therefore cell areas, are finite. In order for the ghost nodes to surround the tissue, as it grows, cells exert a force on the ghost nodes (and ghost nodes exert forces on other ghost nodes) causing them to move with the cells. The force applied is calculated using Equation (10). For more details on ghost nodes see [23].

Vertex model (VM)

In the VM a tissue is represented by a collection of non-overlapping connected polygons whose vertices are free to move, each polygon corresponds to a cell. In this model, the area A_i of a cell i is given by the area of the associated polygon. An illustration of cells in a VM is given in Fig 1(e). As in cell-centre models we consider a set of points $\{\mathbf{r}_1, \ldots, \mathbf{r}_{N_{\mathrm{Vertices}}}\}$ and we use force balance to derive an equation of motion [24]:

$$\eta_V \frac{\mathrm{d}\mathbf{r}_i}{\mathrm{d}t} = -\nabla_i\left[\sum_{j=1}^{N_{\mathrm{Cells}}(t)}\left(\alpha\left(A_j - A_j^{(0)}\right)^2 + \beta\left(C_j - C_j^{(0)}\right)^2 + \sum_{m=1}^{M_j}\gamma(\tau(j), \tau(j_m))L_{j,m}\right)\right], \tag{11}$$

where $\mathbf{r}_i$ is the position of vertex i, η_V is an associated drag constant, ∇_i is the gradient with respect to $\mathbf{r}_i$ and $N_{\mathrm{Cells}}(t)$ denotes the number of cells in the system at time t. The variables A_j and C_j denote the cross-sectional area and the perimeter of cell j, respectively, and M_j is the

11

number of vertices of cell j. $L_{j,m}$ is the length of the line connecting vertices m and $m+1$ in cell j and j_m is the neighbour of cell j which shares the edge connecting vertices m and $m+1$ in cell j. Similar to the CP model, $A^{(0)}$ is the cell's natural (or target) area, and $C^{(0)}$ is its natural perimeter. Finally, α and β are positive constants that represent a cell's resistance to changes in area or perimeter, respectively. γ again denotes the interaction energies between neighbouring cells. We allow γ to take different values for homotypic and heterotypic cell-cell interfaces and for 'boundary' interfaces between cells and the surrounding medium.

For simplicity here we set all cells to have a target area of $A^{(0)} = 1$ and therefore a target perimeter of $C^{(0)} = 2\sqrt{\pi}$. See [25] for a discussion on the other growth options and their influence on simulations.

To maintain a non-overlapping tessellation of the domain we need to introduce a process where cell edges can swap, known as a T1 transition. This process allows cell connectivity to change as cells grow and move and is instrumental in the process of cell sorting. When an edge between two cells, A and B, becomes shorter than a given threshold, l_r, we rearrange the connectivity so that the cells A and B are no longer connected and the other cells that contain the vertices on the short edge, C and D, become connected. Other processes may also be required, such as a T2 transition where small triangular elements are removed to simulate cell death. For further details of these elementary operations, see [26].

As with all of these models, other force laws could be used to define cell interactions [27]. For full details of the forces used in the vertex model, along with how they differ in both implementation and simulation results, see [26].

Implementation

Now we have briefly introduced all the cell-based models used in this study we proceed to discuss their implementation. Each simulation takes the form given in Fig 1(f). All components of this algorithm are the same for each simulation type except for the CA model where cells may also move due to the division of other cells. All models have been non-dimensionalised so that the units of space are cell diameters (CDs) and time is measured in hours.

We implement all model simulations within Chaste, an open source C++ library that provides a systematic framework for multiscale multicellular simulations [17]. Further details on the implementation of VM and CP models within Chaste can be found in [26] and [28], respectively.

12

Results 248

We now present a series of case studies that illustrate how cellular processes can be represented in 249
each cell-based model and how differences in representation may influence simulation results. 250

Adhesion 251

Cell-cell adhesion is a fundamental property of tissue self-organization. If embryonic cells of two 252
or more histological types are placed into contact with each other, they can undergo spontaneous 253
reproducible patterns of rearrangement and sorting. This process can, for example, lead to 254
engulfment of one cell type by another. Explanations for this phenomenon include the differential 255
adhesion hypothesis, which states that cells tend to prefer contact with some cell types more 256
than others due to type-specific differential intercellular adhesion [29]; and the differential surface 257
contraction hypothesis, which states that cells of different types instead exert different degrees 258
of surface contraction when in contact with other cell types or any surrounding medium [30]. 259
Computational modelling has played a key role in comparing these hypotheses [31]. 260

As our first case study, we simulate cell sorting due to differential adhesion in a monolayer of 261
cells in the absence of cell proliferation or respecification. We consider a mixed population of two 262
cell types, A and B, which we assume to exhibit differential adhesion. This is implemented in the 263
CA, CP and VM models by having different values of the parameter γ for different cell types. 264
Specifically, we choose $\gamma(A, A) = \gamma(B, B) < \gamma(A, B)$ and $\gamma(A, \text{void}) < \gamma(B, \text{void})$ to drive type-A 265
cells to engulf type-B cells. In the cell-centre (OS and VT) models, we instead assume that for 266
any pair of neighbouring cells located a distance farther apart than the rest length, the spring 267
constant, μ is reduced by a factor $\mu_{het} = 0.1$ if the cells are of different types. Additionally, in 268
the OS model we use a larger interaction radius, $r_{\max} = 2.5$, to encourage cell sorting. 269

In addition to the update rules and equations of motion outlined in the previous section, we 270
consider each cell to be subject to random motion. This random motion is intrinsic to the CA 271
and CP models and is adjusted by changing the parameter T in Eq (1) and Eq (3). For the OS, 272
VT and VM models we introduce an additional random 'diffusive' force acting on each cell or 273
vertex, 274

$$\mathbf{F}^{\text{rand}} = \sqrt{\frac{2\xi}{\Delta t}}\boldsymbol{\eta}, \tag{12}$$

13

where $\boldsymbol{\eta}$ is a vector of samples from a standard multivariate normal distribution and ξ is a 275
parameter that represents the magnitude of the perturbation [26]. This size is scaled by the time 276
step to ensure that when the equations of motion are solved numerically, the rate of diffusion is 277
independent of the size of time step. We simulate each model ten times, starting from an initial 278
rectangular domain of width L_x and height L_y, comprising 50% type-A cells and 50% type-B 279
cells. For all models, the edge of the domain is a free boundary. 280

The time step of the CA and CP models dictates how many MCS occur per hour and, along 281
with the temperature, T, can influence the dynamics of the simulation [28]. Here we perform an 282
ad hoc calibration of T and Δt so that the temporal dynamics of the CA and CP models match 283
those of the other models as far as possible [28]. A full list of parameter values is provided in 284
Tables 1 and 2. 285

The results of a single simulation of each model are shown in Fig 2. In each case, the tissue 286
evolves to a steady state where cells of each type are more clustered than the initial configuration. 287
In the CA, CP and VM models, type-A cells are eventually completely engulfed; note that for 288
other parameter values, each model can exhibit dissociation or checkerboard patterning [4, 31]. In 289
the other models, the tissue evolves to a local steady state that does not correspond to complete 290
engulfment. 291

A quantitative comparison of cell sorting dynamics is shown in Fig 3. In particular we show how 292
cell sorting is affected by the level of random motion applied to cells. This is demonstrated by 293
computing the fractional length, defined as the total length of edges between cells of different 294
types for each simulation. These are then normalised by the length at $t = 0$ for comparison. We 295
find that the CA and CP models undergo repeated annealing due to their stochastic updating, 296
and eventually end up at the global minimum (corresponding to complete engulfment). However, 297
large amounts of noise can cause disassociation of cells in the CP model. 298

As Fig 3 shows, for the off-lattice models the total energy of the system evolves to a local 299
minimum in the absence of noise; however, we can recover more complete engulfment through 300
the addition of random cell movement. A relatively large amount of noise is required to alter cell 301
neighbours in the Delaunay triangulation, illustrated by the flat lines in Fig 3(b). However, if 302
there is too much noise then cells can become dissociated and move amongst the ghost nodes; in 303
this case, if a cell reaches the edge of the ghost node region, its Voronoi area becomes ill-defined. 304
A similar sensitivity is exhibited by the VM; in this case, if the amount of noise is too high, cell 305
shapes can become inverted due to vertices randomly intersecting edges. 306

14

Table 1. Table of parameters used in the models across case studies.

Parameter	Description	Model(s)	Value	Reference
Δt	Time step	CA, CP	0.01 h	[28]*
		OS, VT, VM	0.005 h	[26][22]
$A^{(0)}$	Cell target area	CA	1 ls (1.0 CD^2)	–
		OS	$\pi/4$ CD^2	–
		CP	16 ls (1.0 CD^2)	–
		VT	$\sqrt{3}/2$ CD^2	–
		VM	1 CD^2	[26]
$\gamma(\text{cell}, \text{cell})$	Cell-cell adhesion coefficient	CA, CP	0.1	[28]*
		VM	1	[26]
$\gamma(\text{cell}, \text{void})$	Cell-boundary adhesion coefficient	CA, CP	0.2	[28]*
		VM	10	[26]
k_C	Decay of attraction force	OS	5	[21]
T	Temperature	CA	0.0	–
		CP	0.1	[28]
α	Volume deformation coefficient	CP	0.1	[28]
		VM	50.0	[26]
β	Surface deformation coefficient	CP	0.01	[28]
		VM	1.0	[26]
$C^{(0)}$	Cell target perimeter	CP	16 ls (4 CD)	[28]
		VM	$2\sqrt{\pi}$ CD	[26]
η	Drag coefficient	OS, VT	1.0	[22]
		VM	1	[26]
μ	Spring constant	OS, VT	50.0	[8, 32]
s	Mature cell spring rest length	OS, VT	1.0 CD	[22]
κ_{swap}	rate of cell switching	CA	1	–
r_{max}	Force cut-off length	OS	1.5	–
l_r	Cell rearrangement threshold	VM	0.1 CD	[26]

Asterisks (*) denote parameters whose values are taken for the CP model from the given reference, with the same value being assumed for the CA model.

To summarise, we find that the degree of cell sorting observed in our simulations depends on how much random cell movement can be accommodated within each model. We note that there is no reason *a priori* to suppose that the configuration corresponding to the global minimum

ξ	Level of noise	OS	0.05	*
		VT	0.1	*
		VM	0.1	*

Asterisks (*) denote parameters whose values in the CA and CP models are chosen to ensure that engulfment occurs over a similar timescale to that observed in the OS, VT and VM models.

is biologically realistic; this depends on how the typical time scale over which complete sorting 310 occurs compares to other embryogenic processes. 311

Proliferation, death and differentiation 312

Embryonic development and adult tissue self-renewal both rely on careful control of cell prolifer- 313 ation, differentiation and apoptosis to ensure correct cell numbers. The intestinal epithelium 314 offers a particularly important example of such tightly orchestrated cell dynamics. It is folded 315 to form invaginations called crypts and (in the small intestine) protrusions called villi. The 316 disruption of cell proliferation and migration in intestinal crypts is the cause of colorectal cancers. 317 Experimental evidence indicates a complex pattern of cell proliferation within the crypt, in which 318 cells located at the base of the crypt cycle significantly more slowly than those further up. One 319 possible explanation for this is contact inhibition, in which stress due to overcrowding causes a 320 cell to proliferate more slowly, enter quiescence or even undergo apoptosis [34]. The biological 321 mechanism through which shear stress affects the expression of key components in the Wnt 322 signalling pathway, which in turn plays an important role in cell proliferation and adhesion in 323
Fig 2. Simulations of cell sorting due to differential adhesion. Snapshots are shown at selected times for each model. Cells of type A and B are shown in purple and green, respectively. Engulfment of type-B cells occurs most readily in the CA, CP and VM models. Parameter values are given in Tables 1 and 2.
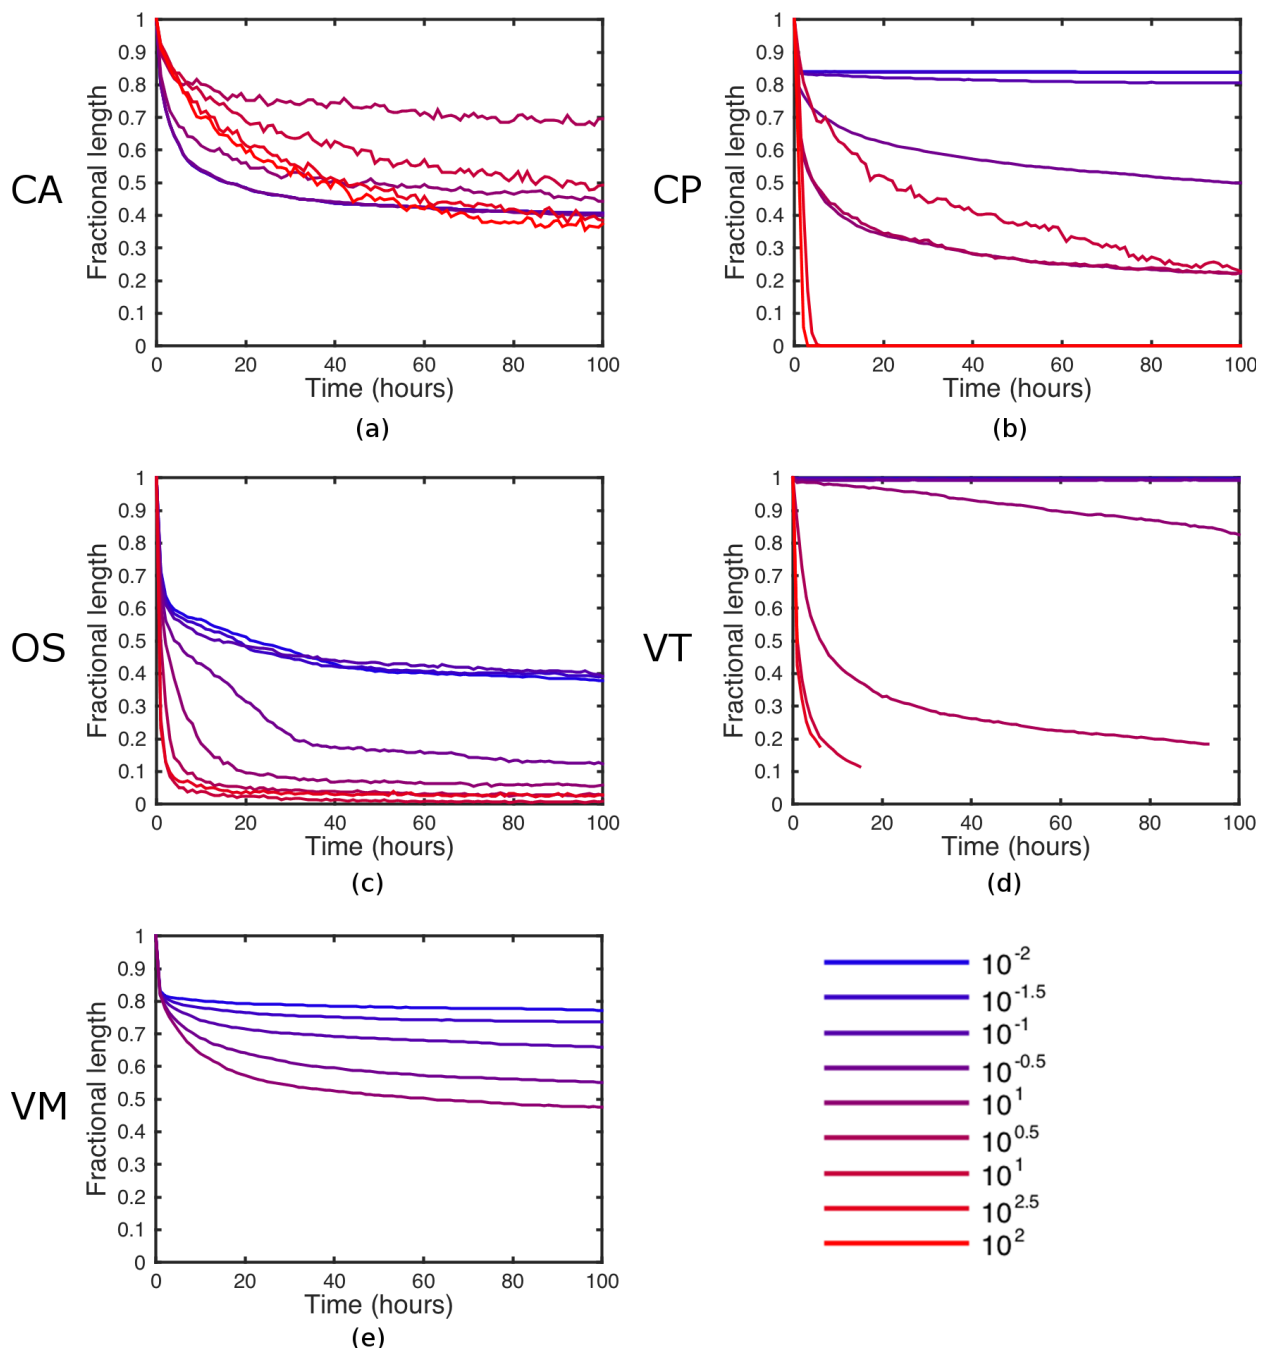

Fig 3. Comparison of cell sorting dynamics across differential adhesion simulations. As a measure of sorting, the fractional length is computed as a function of time for each model: (a) CA; (b) CP; (c) OS; (d) VT; (e) VM. Results are shown for varying multiples of the baseline level of noise, ξ, whose value is defined for each model in Table 2. Each line is the mean value of 10 simulations. Parameter values are given in Tables 1 and 2.

this tissue, has been elucidated through a number of studies [35, 36].

A variety of cell-based models have been developed to study aspects of intestinal crypt dynamics [37], including defining the role of the Wnt signalling pathway [38]. The process and consequences of contact inhibition have also been described using cell-based modelling approaches in a more general setting [39, 40, 41]. A recent study used a cell-centre modelling approach to investigate how combined changes in Wnt signalling response and contact inhibition may induce altered proliferation in radiation-treated intestinal crypts [33].

As our second case study, we simulate the spatiotemporal dynamics of clones of cells within a single intestinal crypt. This example demonstrates how multicellular models and simulations (in particular Chaste) can include the coupling of cell-level processes to simple subcellular processes and deals with cell proliferation, death and differentiation.

Our underlying model of a colonic crypt has been described in detail previously [23, 42, 43]. We restrict cells to lie on a fixed cylindrical crypt surface, defined by the two-dimensional domain $[0, L_x] \times [0, L_y]$, where L_x and L_y denote the crypt's circumference and height, respectively. Periodicity is imposed at the left- and right-hand boundaries $x \in \{0, L_x\}$. We impose a no-flux boundary condition at the crypt base ($y = 0$) and remove any cell that reaches the crypt orifice ($y = L_y$). In each simulation, we start with a random tessellation of cells occupying this domain; the crypt is then evolved for a duration t_{start} to a dynamic equilibrium, before cell clones are recorded and the crypt evolved for a further duration t_{end}.

For each cell-based model considered, we implement cell proliferation and differentiation as follows. Any cell located above a threshold height y_{prolif} from the crypt base is considered to be terminally differentiated, and can no longer divide. Any cell located below y_{prolif} can proliferate. On division a random cell cycle duration is drawn independently for each daughter cell. Specifically, we draw the duration of each cell's G1 phase, t_{G1}, from a truncated normal distribution with mean $\mu_{\text{G1}} = 2$, variance $\sigma^2_{\text{G1}} = 1$ and lower bound $t_{G1_{\min}} = 0.01$, and we set the remainder of the cell cycle as $t_S = 5$, $t_{G2} = 4$ and $t_M = 1$, for the durations of the S phase, G2 phase, and M phase, respectively.

In addition the duration of G1 phase depends on the local stress, interpreted as the deviation from a cell's preferred area. A cell pauses in the G1 phase of the cell cycle if

$$A_i < r_{CI} A_{Ti}, \tag{13}$$

19

where r_{CI} is the quiescent area fraction and A_i is as earlier defined for each model [44]. This description allows for quiescence imposed by transient periods of high compression, followed by relaxation. If a cell is compressed during the G2 or S phases then it will still divide, and thus cells whose areas are smaller than the given threshold may still divide.

The dimensions of the crypt domain are chosen in line with [32] but are scaled to decrease simulation time. A full list of parameter values is provided in Tables 1 and 3.

Table 3. Table of parameters specific to the colonic crypt simulations.

Parameter	Description	Model(s)	Value	Reference
t_{start}	Pre-simulation duration	All	100 h	–
t_{end}	Simulation duration	All	1000 h	–
r_{CI}	Quiescent volume fraction	All	$0 - 1$	–
L_x	Width of crypt	All	15 CD	Scaled from [32]
L_y	Height of crypt	All	12 CD	Scaled from [32]
h	Height at which cells are sloughed	All	12 CD	Scaled from [32]
μ_{G1}	G1 phase duration mean	All	2 h	–
σ^2_{G1}	Cell cycle variance	All	1 h	–
$t_{G1_{\min}}$	Minimum G1 Phase duration	All	0.01 h	–
t_S	S Phase duration	All	5 h	–
t_{G2}	G2 Phase duration	All	4 h	–
t_M	M Phase duration	All	1 h	–
y_{prolif}	Proliferation height threshold	All	6 CD	Scaled from [32]

The results of a single simulation of each model are shown in Fig 4. In each case, the number of clones decreases over time as the crypt drifts to monoclonality. A more quantitative comparison of clonal population dynamics is shown in Fig 5. For each simulation we compute the number of clones remaining in the crypt as a function of time. All models exhibit the same qualitative behaviour, with a sharp initial drop as all clones corresponding to cells outside the niche are rapidly lost, followed by a more gradual decay in the number of clones at the crypt base due to neutral drift. However, we note that the number of clones reduces more slowly in the VM than other models, since the implementation of the 'no flux' boundary condition at the crypt base causes cells to remain there for longer in this model. This highlights the effect that the precise implementation of boundary conditions can have in such models. Finally, we note that for models where contact inhibition can be imposed, we see a slight effect of the degree of contact inhibition on the clonal population dynamics. In most of the models contact inhibition slows the process of monoclonal conversion, due to there being more compression at the crypt base. In contrast, in the VM the number of clones present in the crypt decreases more quickly when

20

r_{CI} is larger. This effect is due to there being higher rates of division, resulting in cells more frequently being 'knocked' from the crypt base; in the other models this effect is counteracted by compression from above.

A quantitative comparison of cell velocity profiles up the crypt is shown in Fig 6. This extends the comparison previously made of cell-centre and vertex models of crypt dynamics in [42]. For each simulation we compute the vertical component of cell velocity at different heights up the crypt, averaging over the x direction. We find that all models are similar when considering a 'position-based' cell-cycle model (in which cell proliferation occurs below a threshold height up the crypt, corresponding to a threshold Wnt stimulus). However we see more pronounced differences when incorporating more restrictive contact inhibition into the cell-cycle model.

Short-range signalling

In many developmental processes, distinct states of differentiation emerge from an initially uniform tissue. Lateral inhibition, a process whereby cells evolving towards a particular fate inhibit their immediate neighbours from doing so, has been proposed as a mechanism for generating such patterns. This process is known to be mediated by the highly conserved Notch signalling pathway, which involves ligand-receptor interactions between the transmembrane proteins Notch and Delta or their homologues [45].

Lateral inhibition through Notch signalling has been the subject of several mathematical modelling studies [46, 47, 48, 49, 50, 51]. Such models have largely focused on the conditions for fine-grained patterns to occur in a fixed cell population; little attention has been paid to its interplay with cell movement, intercalation and proliferation. To illustrate how cell-based modelling approaches may be utilised to investigate such questions, as our third case study we simulate Notch signalling in a growing monolayer, with cell proliferation dependent on Delta levels. This example demonstrates how intercellular signalling may be incorporated within each cell-based model.

In this example, cells proliferate if located within a radius R_P from the origin, and are removed from the simulation if located more than a radius $R_S > R_P$ from the origin. For each proliferative cell, we allocate a probability p_{div} of division per hour, once the cell is above a minimum age, t_{min}. This is implemented by independently drawing a uniform random number $r \sim U[0,1]$ for each cell at each time step and executing cell division if $r < p_{\mathrm{div}}\Delta t$.

This description is coupled to a description of Notch signalling between neighbouring cells that

21
Fig 4. Simulations of monoclonal conversion in the colonic crypt. Snapshots are shown at selected times for each model. In each simulation at time $t = 0$, every cell is regarded as a clonal population and given a different colour, which is inherited by its progeny. These populations evolve in time due to cell proliferation and sloughing from the crypt orifice, resulting in a single clone eventually taking over the entire crypt. Parameter values are given in Tables 1 and 3.
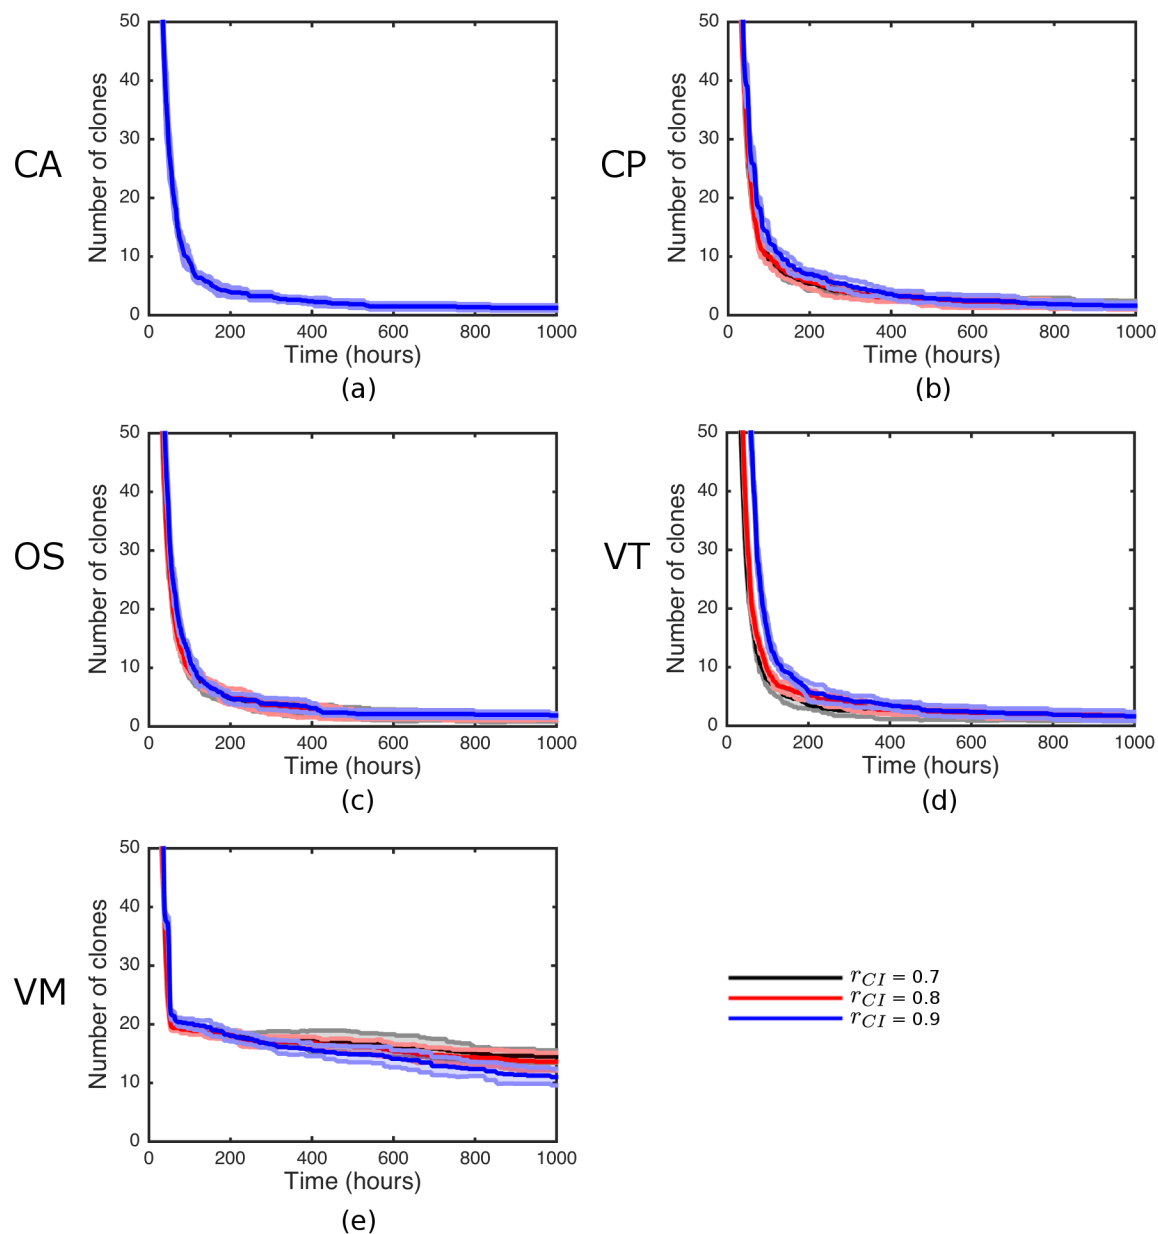

Fig 5. Comparison of clonal population dynamics across crypt simulations for varying levels of contact inhibition. The number of clones remaining in the crypt is computed as a function of time for each model: (a) CA; (b) CP; (c) OS; (d) VT; (e) VM. For each model, the mean and standard error from 10 simulations are shown for three levels of contact inhibition, quantified by the parameter r_{CI}. Parameter values are given in Tables 1 and 3.

23
Fig 6. Comparison of crypt cell velocity profiles across simulations. The vertical component of cell velocity is computed for each model: (a) CA; (b) CP; (c) OS; (d) VT; (e) VM. For each model, the mean and standard error from 10 simulations are shown for three levels of contact inhibition, quantified by the parameter r_{CI}. Parameter values are given in Tables 1 and 3.

is based on a simple ordinary differential equation model previously developed by Collier et al. [46]. This represents the temporal dynamics of the concentration of Notch ligand, $N_i(t)$, and Delta receptor, $D_i(t)$, in each cell i in the tissue. A feedback loop is assumed to occur, whereby

activation of Notch inhibits the production of active Delta. Signalling between cells is reflected in the dependence of Notch activation on the average level of Delta among a cell's immediate neighbours. The precise set of equations for this signalling model takes the form

$$\frac{\mathrm{d}N_i}{\mathrm{d}t} = \frac{\bar{D}_i^{n_N}}{k_N + \bar{D}_i^{n_N}} - N_i, \tag{14}$$

$$\frac{\mathrm{d}D_i}{\mathrm{d}t} = r_{DN}\left(\frac{k_D}{k_D + N_i^{n_D}} - D_i\right), \tag{15}$$

where $\bar{D}_i$ denotes the average value of $\{D_j(t) : j \in \mathcal{N}_i(t)\}$, and $\mathcal{N}_i(t)$ is the set of neighbours of cell i. A full list of parameter values is provided in Tables 1 and 4. At the start of the simulation, values of each N_i and D_i are independently drawn from a $U[0,1]$ distribution. Upon division, the values of N_i and D_i are inherited by each daughter cell.

Table 4. Table of parameters specific to the lateral inhibition simulations.

Parameter	Description	Model(s)	Value	Reference
t_{end}	Simulation duration	All	1000 h	–
p_{div}	Cell division rate	All	$\{0.01, 0.05, 0.1\}$ cell^{-1} h^{-1}	–
t_{min}	Minimum division age	All	1 h	–
k_N	Dependence of Notch on Delta	All	0.01	[46]
k_D	Dependence of Delta on Notch	All	0.01	[46]
n_N	Notch Hill coefficient	All	2	[46]
n_D	Delta Hill coefficient	All	2	[46]
r_{DN}	Relative rate of Delta activity	All	1 h^{-1}	[46]
R_S	Removal zone radius	All	5 CD	–
R_P	Proliferative zone radius	All	15 CD	–
r_{max}	Force cut-off length	OS	1.0	–

Eq (14) and Eq (15) are coupled to the cell-based models using the following algorithm. At each time step, having updated the cell-based model, we calculate $\bar{D}$ based on the current connectivity and, assuming $\bar{D}$ remains constant on the short interval Δt, we solve the Notch signalling model numerically over the interval $[n\Delta t, (n+1)\Delta t]$ using a Runge-Kutta method.

Simulation snapshots for each model are shown in Fig 7. In each case, we see that lateral inhibition successfully leads to patterning of cells in 'high delta' steady state surrounded by cells in a 'low delta' steady state in the outer ring of non-proliferating cells. This patterning is disrupted in the inner proliferating region, as cells frequently change neighbours and hence are unable to synchronise their delta-notch dynamics. The degree of this disruption increases with cell division rate and is most apparent in the VM simulation. This may be due to cells

exchanging neighbours more frequently, even in regions without proliferation, in the VM; a 423
similar disruption is observed in the CP simulation. A lattice-induced anisotropy is clearly visible 424
in the CA simulation, where cell shoving causes significantly more cell rearrangements and, as a 425
result, less patterning along diagonals. This phenomenon also occurs, to a lesser extent, in the 426
CP simulation. 427
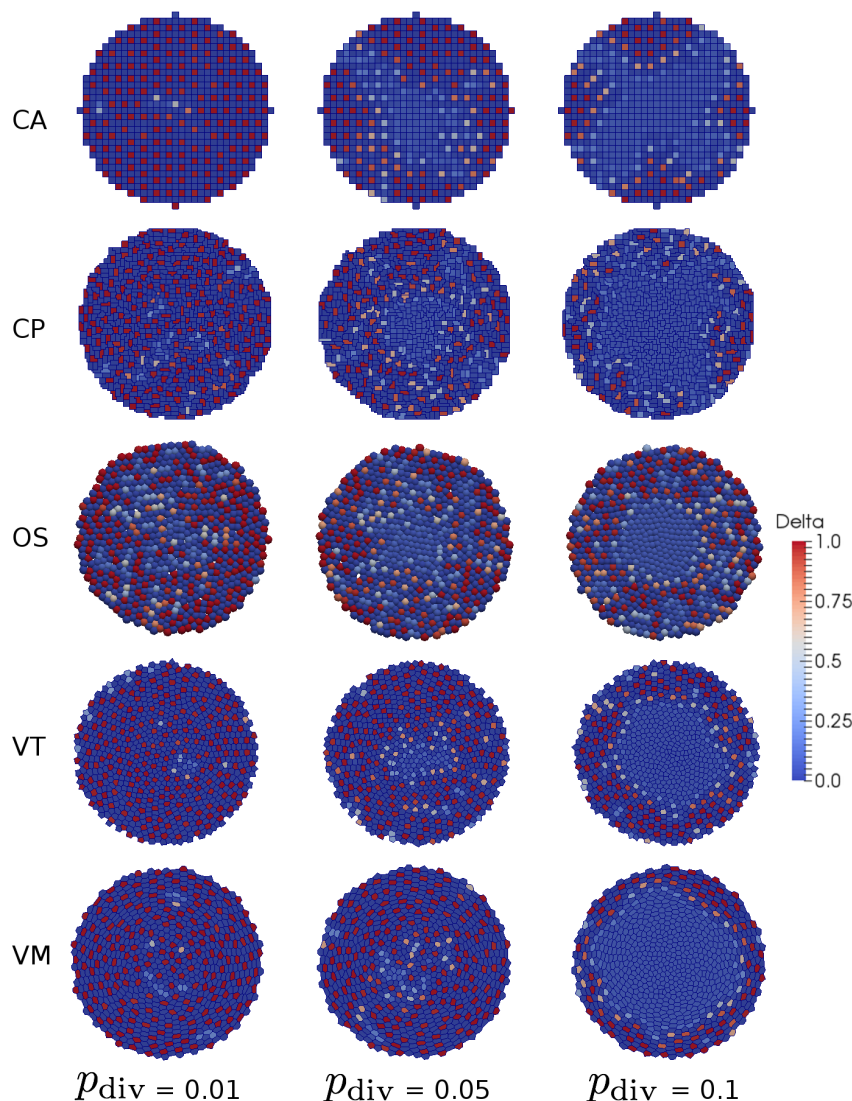

Fig 7. Simulations of lateral inhibition in a proliferating tissue. For each model,
snapshots are shown for three levels of cell proliferation, quantified by the parameter p_{div}.
Parameter values are given in Tables 1 and 4.

A quantitative comparison of the patterning dynamics across models is shown in Fig 8. As a 428
measure of patterning we plot the ratio of cells in the heterogeneous steady state to those not in 429

26

this state at the end of each simulation, computed as a radial distribution across the tissue. Note that the 'kinks' observed in the CA results (Fig 8(a)) are due to the presence of discrete cells on a fixed lattice. We see that there is significantly less patterning in the proliferative region for all models and that as the rate of division is increased the difference is exaggerated.

Long-range signalling

Morphogens are secreted signalling molecules that provide positional information to cells in a developing tissue and act as a trigger for cell growth, proliferation or differentiation. The processes of morphogen gradient formation, maintenance and interpretation are well studied, most notably in the wing imaginal disc in the fruit fly *Drosophila* [52], a monolayered epithelial tissue. A key morphogen called Decapentaplegic (Dpp) forms a morphogen gradient along the anterior-posterior axis of this tissue. Dpp is known to determine the growth and final size of the wing imaginal disc, although the mechanism by which its gradient is established remains unclear.

A number of cell-based models have been proposed for the cellular response to morphogen gradients and mechanical effects in developing tissues such as the wing imaginal disc [53, 54, 11]. As our final case study, we simulate the growth of an epithelial tissue in which cell proliferation is coupled to the level of a diffusible morphogen. This case study represents an abstraction of a wing imaginal disc and illustrates how continuum transport equations may be coupled to cell-based models.

Our description of morphogen-dependent cell proliferation is based on that proposed by [12] and is implemented as follows. The probability of a cell dividing exactly n time steps after its last division is given by $p_{\text{div}} u_n \Delta t$, where p_{div} is a fixed parameter and the weighting u_n satisfies the recurrence relation

$$u_{n+1} = u_n \left(1 + \Delta t g (1 + \lambda c_n)(1 - u_n)\right), \tag{16}$$

with $u_0 = u_N/2$ where u_N denotes the parent cell's weighting value immediately prior to division. Here λ is a fixed parameter quantifying the effect of the morphogen on cell growth, c_n denotes the morphogen concentration at that cell at that time step, and g is a random variable independently drawn upon division from a truncated normal distribution with mean μ_g, variance σ_g^2 and minimum value g_{min}.

27
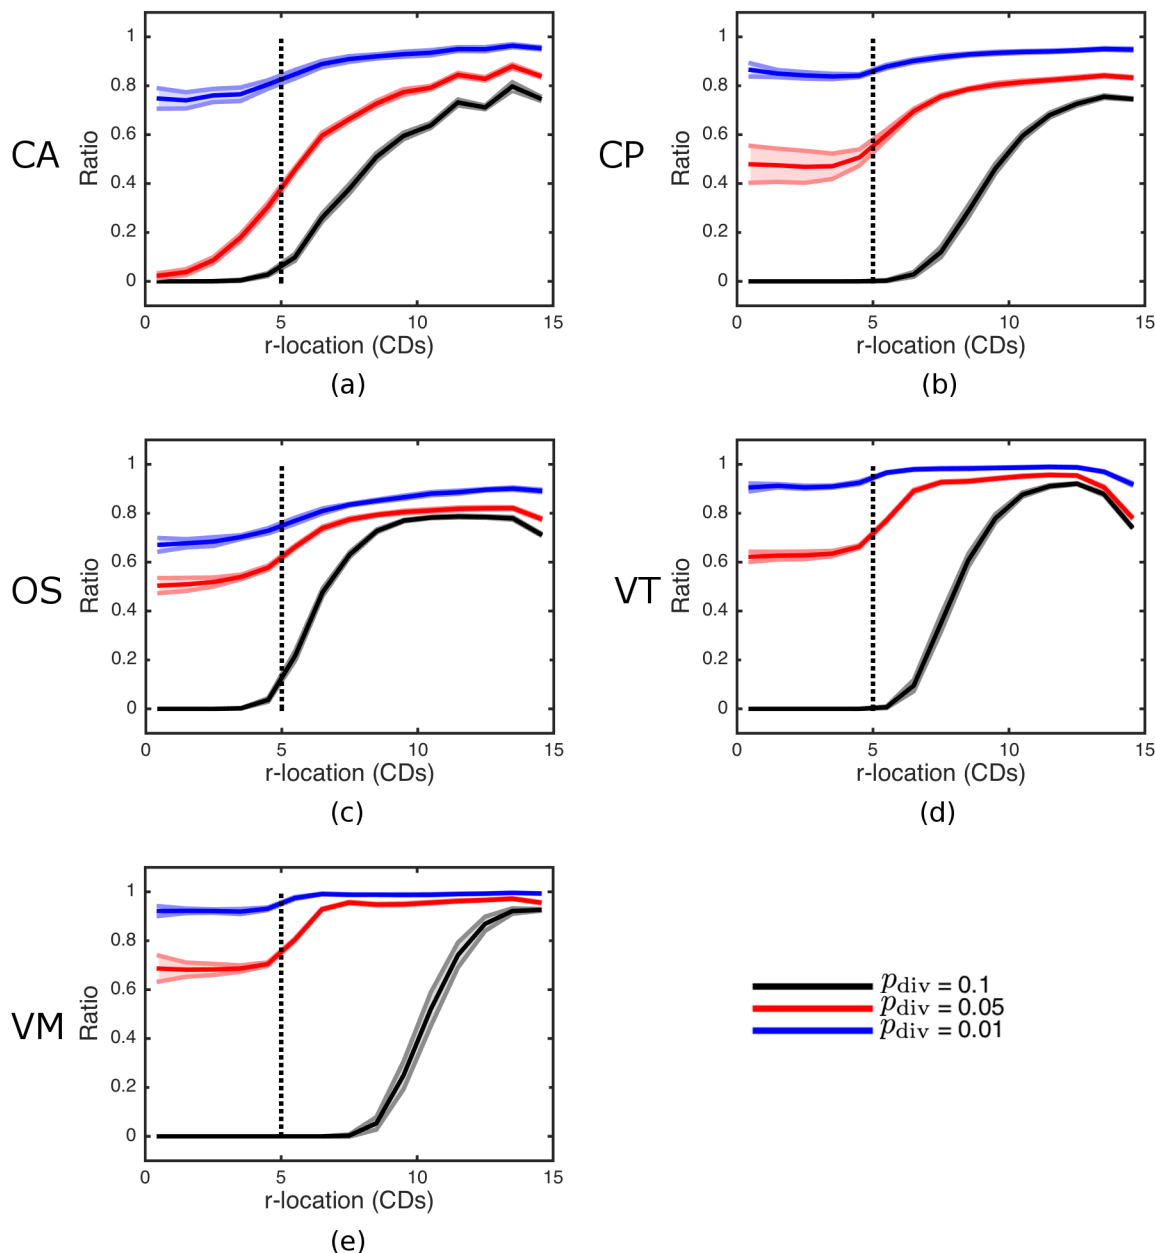

Fig 8. Comparison of cell fate patterning across lateral inhibition simulations. As a measure of patterning, the ratio of cells in the heterogeneous steady state to those not in this state is computed at time t_{end}, as a radial distribution across the tissue (calculated using a bin size of 0.5 CDs), for each model: (a) CA; (b) CP; (c) OS; (d) VT; (e) VM. For each model, the mean and standard error from 10 simulations are shown for three levels of cell proliferation, quantified by the parameter p_{div}. Parameter values are given in Tables 1 and 4.

28

When initialising the simulation, a value of g is drawn independently for each cell from a truncated normal distribution (as on division), and a value of u_0 is drawn independently from a $U[0.5, 1]$ distribution. 458 459 460

Each cell-based model is coupled to a continuum model of morphogen transport based on that proposed by [12]. We assume that the morphogen is secreted in a central 'stripe' of tissue and diffuses throughout the whole tissue, being transported by the cells, while being degraded. In this description, the morphogen concentration $c(\mathbf{x}, t)$ is defined continuously for times $t \geq 0$ in the spatial domain $\mathbf{x} \in \Omega_t$ defined by the boundary of the cell population (see below). This concentration evolves according to the reaction-advection-diffusion equation 461 462 463 464 465 466

$$\frac{\partial c}{\partial t} + \mathbf{w} \cdot (\nabla c) - \nabla \cdot (D \nabla c) = f(\mathbf{x}) - k_c c, \tag{17}$$

with zero-flux boundary conditions at the edge of the domain. The vector field $\mathbf{w}$ denotes the velocity of the cells moving in the tissue (and is found in the weak formulation in [12]). Its inclusion in Eq (17) denotes the advection of Dpp with the cells. The parameters D and k_c denote the morphogen diffusion coefficient and degradation coefficient respectively. Finally, the function f specifies the rate of production of morphogen in the central stripe of tissue, and is given by 467 468 469 470 471 472

$$f(x, y) = \begin{cases} f_{\text{prod}} \text{ for } x \in (-L_{\text{prod}}, L_{\text{prod}}), \\ 0 \text{ otherwise.} \end{cases} \tag{18}$$

To solve Eq (17) numerically, we first discretise the spatial domain defined by the cells to make a computational mesh. For the VT model we use the triangulation defined by the dual of the Voronoi tessellation; for the vertex model we use the triangulation defined by dividing each polygon cell into a collection of triangles (made up from the set of vertices and the centre of the polygon) as in [12]; and for the CA, CP and OS models we create a triangulation by calculating the constrained Delaunay triangulation of the centres of the cells. This tessellation changes over time as the tissue grows. 473 474 475 476 477 478 479

We solve Eq (17) using a method of lines approach along the characteristic lines 480

$$\frac{dc}{dt} = \frac{\partial c}{\partial t} + \mathbf{w} \cdot (\nabla c), \tag{19}$$

and a continuous Galerkin finite element approximation to the spatial derivatives. 481

29

We approximate the solution of Eq (17) using a Forward Euler discretization for time and a linear finite element approximation in space. As we generate the computational mesh from the cells, the mesh moves with velocity **w**. We can therefore account for the advective term of Eq (17) by moving the solution with the moving cells. Finally in each model when a cell divides it creates a new node in the mesh and the solution at the new node is defined to be the same as the node attached to the parent cell. A full list of parameter values is provided in Tables 1 and 5.

Table 5. Table of parameters specific to the morphogen-dependent proliferation simulations.

Parameter	Description	Model(s)	Value	Reference
Δt	Time step	All	0.005 h	–
t_{end}	Simulation duration	All	100 h	–
L_r	Initial radius of tissue	All	5 CD	[12]
D	Dpp diffusion coefficient	All	10^{-4} CD^{2}h^{-1}	[12]
k_c	Dpp degradation rate	All	0.01 h^{-1}	[12]
f	Maximal Dpp production rate	All	0.01 h^{-1}	[12]
W_{Dpp}	Width of Dpp production zone	All	4 CD	[12]
p_{div}	Average baseline cell division rate	All	0.1 h^{-1}	[12]
λ	Morphogen effect on cell growth	All	0.01	[12]
f_{prod}	Level of production of Dpp in sripe	All	0.01	[12]
L_{prod}	Half the width of stripe of Dpp production	All	2	[12]
μ_g	Cellular growth rate mean	All	0.05	–
σ_g^2	Cellular growth rate variance	All	0.000 1	–
g_{min}	Minimum cellular growth rate	All	0.01	–

Simulation snapshots for each model are shown in Fig 9. As expected, over time the morphogen biases the shape of the tissue, which exhibits greater growth in the y direction. This is confirmed in Fig 11, which shows a quantitative comparison of tissue shape dynamics across models. A quantitative comparison of the spatio-temporal morphogen dynamics across models is shown in Fig 10. In each case, the morphogen distribution is plotted at different times as an average over the x direction and over 20 simulations. While the mean behaviour is conserved across models, the CA exhibits significantly greater variation about this mean. This is due to the discrete nature of cell movement, and hence morphogen advection, in these models. Looking at the snapshots in Fig 9 we see that despite being an off lattice model the VT model exhibits some regularity in shape through growth, witnessed by straighter than expected edge segments. This is due to the method for calculating connectivity in VT model and can introduce artefacts when considering freely growing domains as seen here.

30

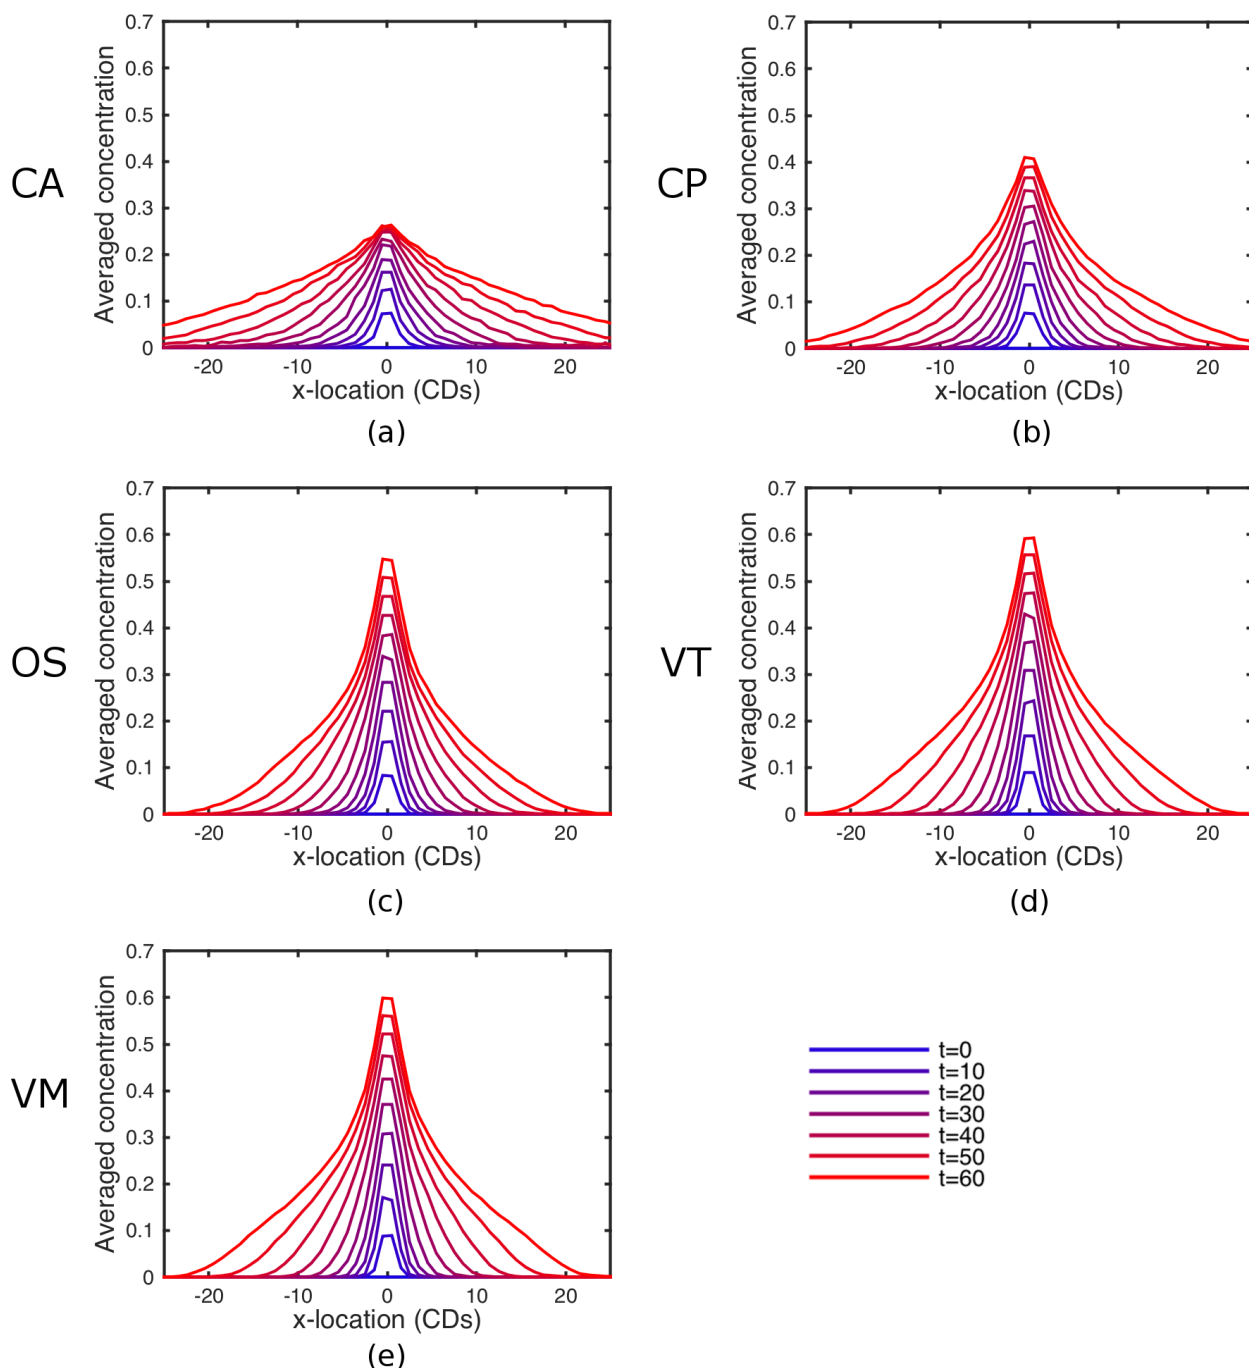

Fig 10. Comparison of spatio-temporal morphogen dynamics across simulations.
Results are shown for each model: (a) CA; (b) CP; (c) OS; (d) VT; (e) VM. In each case, the morphogen distribution is plotted at selected times as an average over the x direction and over 20 simulations. Parameter values are given in Tables 1 and 5.
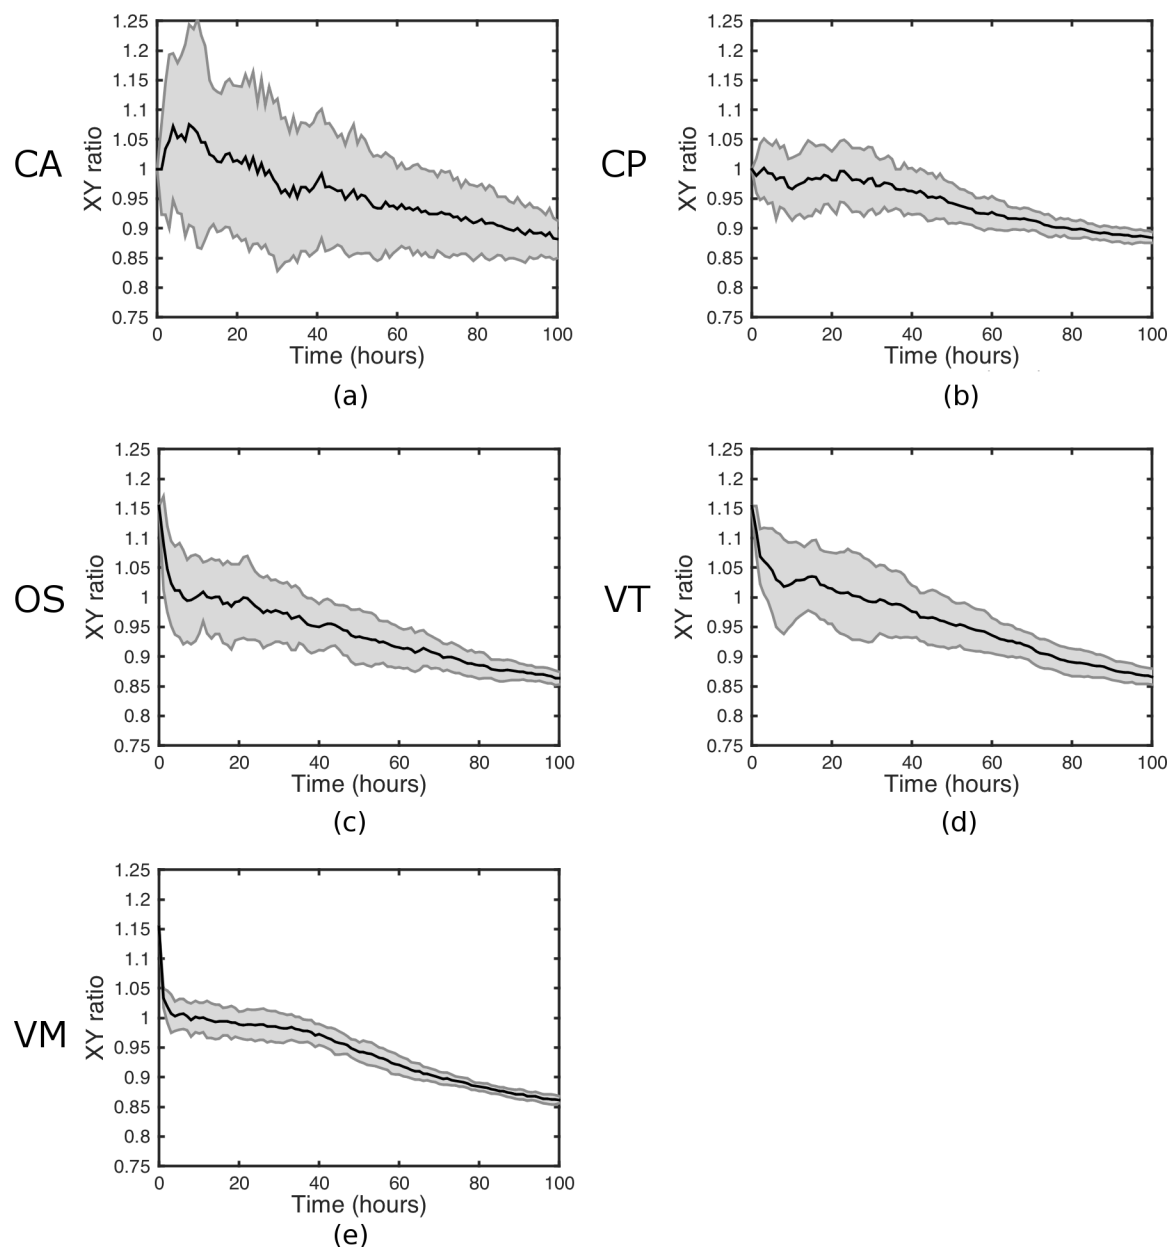

Fig 11. Comparison of tissue shape dynamics across morphogen-dependent proliferation simulations. As a measure of tissue anisotropy, the ratio of the widths of the tissue in the x and y directions is computed as a function of time for each model: (a) CA; (b) CP; (c) OS; (d) VT; (e) VM. For each model, we plot the mean and standard error of this ratio across 10 simulations. Parameter values are given in Tables 1 and 5.

Discussion

The field of mathematical modelling in biology has matured beyond recognition over the past decade. One indication of this is the move towards quantitative comparison with data taking

500

501

502

33

precedence over qualitative comparison. In this context, we must investigate if the model 503 framework chosen might amplify or diminish the effects of certain processes. To this end, the 504 present work seeks to advance our comparative understanding of different classes of models in 505 the context of cell and tissue biology. 506

A variety of cell-based approaches have been developed over the last few years. These models 507 range from lattice-based cellular automata to lattice-free models that treat cells as point-like 508 particles or extended shapes. Such models have proven useful in gaining mechanistic insight 509 into the coordinated behaviour of populations of cells in tissues. However, it remains difficult 510 to accurately compare between different modelling approaches, since one cannot distinguish 511 between differences in behaviour due to the underlying model assumptions and those due 512 to differences in the numerical implementation. Here, we have exploited the availability of an 513 implementation of five popular cell-based modelling approaches within a consistent computational 514 framework, Chaste. This framework allows one to easily change constitutive assumptions within 515 these models. In each case we have provided full details of all technical aspects of our model 516 implementations. 517

We compared model implementations using four case studies, chosen to reflect the key cellular 518 processes of proliferation, adhesion, and short- and long-range signalling. These case studies 519 demonstrate the applicability of each model and provide a guide for model usage. While on 520 a qualitative level each model exhibited similar behaviour, this was mainly achieved through 521 parameter choice and fitting. Parameters were chosen to give consistent behaviour where possible. 522 When choosing which model to use, one should bear in mind the following. 523

Certain examples presented in this study are more aligned with particular models. For example, 524 in the adhesion example the CP and VM models are designed to explicitly represent cell sorting 525 (through cell boundary energy terms) whereas the other models needed modification to represent 526 the same phenomena. In fact, in the OS and VT (and to some extent the VM) models, the ability 527 to sort completely was limited by the presence of local energy minima and a noise component of 528 cell motion was required to mitigate this. However, as the level of noise was increased, artefacts 529 can be introduced into the models, for example the tessellation may become non conformal 530 leading to voids in the tissue. 531

The implementation of other features such as boundary conditions can also influence simulation 532 outcomes. This was observed in the proliferation example where the rate of neutral drift was 533 significantly different in the VM compared to the other models, due to additional adhesion of 534

34

cells to the bottom of the domain. In this study we did not implement contact inhibition for the CA model as our definitions of contact inhibition required cells to be for different sizes. It is possible to implement an alternative form of contact inhibition in the CA model by restricting division events to only occur when there is sufficient free space [55]; however, this would again result in a different behaviour to our simulations.

A key difference between the models we considered lies in the definition of cell connectivity. It is possible for cells in the same configuration to have different neighbours under different models. For example, when under compression cells in the OS model can have more neighbours than similarly sized cells in CP, VT or VM models. The effects of this can be seen in the short-range signalling example with a high degree of proliferation.

In terms of understanding and software development time, one can code up a simple CA model in a few hours and the models increase in complexity from there in order CP, OS, VT, with VM being the most involved. While the focus here has been on epithelial layers and two spatial dimensions, all the models have also been utilised in 3D and for the CA, CP, OS, and VT, models the extension is relatively natural. For the VM model the extension is not trivial, as multiple rearrangements need to be considered in order to maintain a confluent tissue.

Finally, the models differ vastly on how long they take to simulate. In their original uncoupled forms, the least computationally complex model to simulate is the CA, followed in order by the CP, OS, VT and VM. However, this complexity depends on what is coupled to the models, at both the subcellular and tissue levels. Specifically, in order to make the CP model equivalent to the other models when coupling to subcellular and tissue level processes, we have chosen to use a time step that is smaller than that typically used in CP simulations, increasing the computation time. Table 6 shows how long typical simulations took for each example across the models considered in the present study. We see that (except for the CP model) the level of computational time is roughly as expected, increasing with complexity with the OS and VT models being similar. There are exceptions to this. For example, the CA and CP simulations of the long-range signalling example take longer than may be expected. This is due to the method used to calculate the growing PDE mesh in our computational implementation in Chaste, which is optimal for off-lattice models; future work will involve developing optimised numerical techniques that exploit the lattice structure of the on-lattice models. On the other hand, the VM simulation of the proliferation example is quicker than may be expected; this is due to the choice of parameters leading to there being slightly fewer cells in the VM simulation for this example, reducing the computational demands.

35

Table 6. Table of approximate simulation times. Run time (in seconds, on a single core i7 processor) for typical single runs for each problem considered here.

Example	CA	CP	OS	VT	VM
Adhesion	34	1638	168	625	321
Proliferation	44	4336	1218	2752	2419
Short-range signalling	166	7536	2837	4433	9983
Long-range signalling	1393	23741	804	789	5803

Parallelisation is one way to both decrease computational time and to also be able to solve larger problems. Of the models considered, the CA model is simplest to parallelise. While more more advanced, the CP model has been parallelised in publicly available software packages [56], as has the OS model [57]. In the VT and VM cases, the implementations are much more involved. 568 569 570 571

The present study provides a starting point for a number of further avenues for research. First, there remains a need for theoretical and computational tools with which to easily perform quantitative model comparisons. Our results indicate that for many of the sorts of questions these types of model are currently being used to address, there is likely to be little difference in model predictions. However, such models are nevertheless moving toward a more quantitative footing, particularly as the resolution of experimental data at the cell to tissue scale improves. Further progress in this area will be accelerated by advances in automating the process of model specification and implementation, for example through extended use of mark-up languages such as SBML, FieldML and MultiCellDS. 572 573 574 575 576 577 578 579 580

Here we have made use of a consistent simulation framework, Chaste, within which to compare different classes of cell-based model. A longer-term challenge is to extend such comparison studies across simulation tools, of which there is an increasing ecosystem (CompuCell3d, Morpheus, EPISIM, CellSys, VirtualLeaf, Biocellion, BioFVM). We emphasize here the lack of 'benchmarks' on which to make such comparisons; the present study offers four examples that could offer such benchmarks. 581 582 583 584 585 586

Throughout this study we have concentrated on 2D studies. However, many of the models considered have also been implemented in three dimensions both in previous studies and in the Chaste modelling framework, for example in the case of overlapping spheres models of the intestinal crypt [33, 58] or 3D vertex models of the mouse blastocyst [59]. Of the models considered in the present study, vertex models are arguably the most technically challenging to extend to three dimensions, due to the complexity of the possible cell rearrangements and force 587 588 589 590 591 592

calculations. 593

Work has also been done to model individual cells at a finer resolution by considering them 594
to be composed of mesoscopic volume elements, which enables cell geometry and mechanical 595
response to be emergent, rather than imposed, properties. These include the subcellular element 596
model [60], which may be thought of as a natural extension of the cell centre model, and the 597
finite element model [61] and immersed boundary model [62], which use alternative approaches 598
to decompose cell shapes into volumetric or surface elements in a much more detailed manner 599
than vertex models. 600
