14 generation sequencing

15

16 **Abstract**

17 DNA extracted from herbarium specimens is highly fragmented and decays at a faster
18 rate than DNA from ancient bones. Therefore, it is crucial to utilize extraction
19 protocols that retrieve short DNA molecules. Improvements in extraction and library
20 preparation protocols for animal remains have allowed efficient retrieval of molecules
21 shorter than 50 bp. We adapted those improvements to extraction protocols for
22 herbarium specimens and evaluated their performance by shotgun sequencing, which
23 allows an accurate estimation of the distribution of fragment lengths. Extraction with
24 PTB buffer decreased median fragment length by 35% when compared to CTAB.
25 Modifying the binding conditions of DNA to silica allowed for an additional decrease
26 of 10%. We did not observe a further decrease in length when we used single-
27 stranded instead of double-stranded library preparation methods. Our protocol enables
28 the retrieval of ultrashort molecules from herbarium specimens and will help to
29 unlock the genetic information stored in herbaria.

30 **Method summary**

31 We optimized the extraction procedure for isolating ultrashort DNA fragments from
32 herbarium specimens through combination of PTB lysis buffer and modifications
33 previously used for ancient bones. We show the advantage of this protocol over others
34 by estimating the DNA fragment length through shotgun sequencing.

35

36 Since ancient DNA (aDNA) is highly fragmented, it is particularly important to
37 employ extraction protocols that retrieve ultrashort molecules (< 50 bp). It has been
38 shown that a recently developed extraction protocol for animal remains efficiently

39 recovers those molecules (1), which has allowed sequencing highly fragmented
40 hominin (2) and cave bear remains (1) that are hundreds of thousands of years old.
41 DNA retrieved from herbarium specimens is also highly fragmented because it decays
42 six times faster than in bones (3). Consequently, DNA from century-old herbarium
43 specimens is as short as that of thousands of years old animal remains. To take full
44 advantage of the genetic information stored in those samples it is important to
45 optimize the extraction of ultrashort molecules from desiccated plant tissue.

46 We assessed the impact of extraction and library preparation methods on the
47 distribution of DNA fragment lengths in 20 *Arabidopsis thaliana* herbarium
48 specimens, which were collected between 1839 and 1898 (Table S1). We used a
49 hierarchical experimental design that includes three different phases due to limited
50 availability of tissue per sample (Figure 1). In phase one and two we used 10 *A.*
51 *thaliana* samples (~20 mg of leaf tissue each), which were subjected to two different
52 extraction protocols (~10 mg of tissue per treatment), followed by double-stranded
53 library preparation. To compare the performance of double- and single-stranded
54 library preparation methods, in phase three we applied single-stranded library
55 preparation method to DNA extracts produced by the most efficient DNA extraction
56 protocol in phase two. In each phase we evaluated the performance of the methods by
57 sequencing the genomic libraries with the Illumina MiSeq platform (Table S2).

58 Extraction buffers used for ancient bones and teeth are commonly composed
59 predominantly or exclusively of EDTA and proteinase K (4), reagents that are not
60 optimal for DNA extraction from plant tissue. Hence, in the first phase we tested two
61 commonly used DNA extraction buffers for historical plant specimens, which contain
62 either cetyl-trimethyl ammonium bromide (CTAB), or a mixture of N-
63 phenacylthiazolium bromide (PTB) and dithiothreitol (DTT) (5) (Figure 1). CTAB is

64 a strong detergent that under high salt concentrations binds to polysaccharides and
65 aids their removal from the solution (6). Although CTAB is highly used in DNA
66 extractions from modern plants, it has been shown that it does not have a detectable
67 effect when applied to non-carbonized archaeobotanical remains (7). PTB is a
68 substance that cleaves glucose-derived protein cross-links (8) and can help to release
69 DNA trapped within sugar-derived condensation products (9); it has been effectively
70 used to retrieve DNA from archaeobotanical remains (10). DTT digests disulfide
71 bonds releasing thiolated DNA from cross-link complexes (11). In order to allow
72 better comparison of the CTAB and PTB protocols, we replaced the ethanol
73 precipitation step of the CTAB method with silica column binding (12) provided with
74 the DNeasy® Plant Mini Kit. Subsequently, libraries were prepared using a double
75 stranded DNA library protocol (13).

76 Based on qPCR measurements on unamplified libraries, the PTB protocol
77 recover a higher number of unique library molecules than CTAB protocol (paired t-
78 test $p = 0.007$) (Figure 2F and Table S3). We found that PTB decreases the median
79 fragment length by 35% (from 88 to 57 bp) (paired t-test $p = 2.8e-06$) when compared
80 to CTAB (Figure 2A and 2B). This decrease in length was also manifested as a higher
81 proportion of damaged sites (λ) (paired t-test $p = 1.3e-06$) (Figure 2C), which
82 represents the fraction of bonds broken in the DNA backbone (14, 15). In addition,
83 DNA molecules extracted with PTB buffer showed more cytosine (C) to thymine (T)
84 substitutions at the 5' end (paired t-test $p = 1.2e-06$; Figure 2G). C-to-T substitutions
85 are typical damage patterns of aDNA and result from spontaneous deamination of C
86 to uracil (U), which is read as T by the polymerase (16, 17). It is possible that shorter
87 and more damaged fragments of DNA were released after cross-links were resolved
88 by PTB and DTT, since there is a strong negative correlation between median

89 fragment length and C-to-T substitutions at first base ($R^2 = 0.44$; $p = 1.5e-07$; $N = 50$)
90 (Figure S4). Alternatively, the observed variation in fragment length distribution
91 could be explained by unknown chemical incompatibilities of lysis and binding
92 buffer, i.e. certain reagents could in principle reduce DNA-binding properties of the
93 buffer. Finally, in the CTAB protocol we apply a chloroform-isoamyl alcohol wash,
94 which could also reduce recovery of short molecules.

95 In the second phase, to further increase the recovery of short fragments, we
96 used PTB/DTT, which was the most successful extraction buffer in phase 1, and
97 evaluated two systems for binding DNA to silica. We tested DNeasy® mini spin
98 columns (Qiagen) in combination with the binding buffer used in the Plant Mini kit
99 and MinElute® silica spin columns in conjunction with a binding buffer optimized for
100 the recovery of short molecules from animal remains (1) (Figure 1). We found that the
101 latter method decreased the median fragment length by 10% (from 60 to 54 bp)
102 (paired t-test $p = 1.9e-04$), which shows that it is suitable to recover very short
103 sequences also from herbarium specimens (Figure 2A and B). The frequency of C-to-
104 T substitutions at the first base differed significantly between the two DNA binding
105 methods (paired t-test $p = 3.3e-03$) (Figure 2G), with a decrease in median fragment
106 length again being accompanied by an increase in C-to-T substitutions.

107 To investigate whether library preparation has an effect on fragment length
108 distribution, in the third phase we produced single-stranded DNA (ssDNA) libraries
109 using the extracts from the modified PTB/DTT extraction (18,19) and compared them
110 to the dsDNA libraries constructed from the modified PTB extraction material of
111 phase 2 (Figure 1). We did not observe a significant decrease of the median of the
112 fragment length distribution in ssDNA libraries (paired t-test $p = 0.44$) (Figure 2A and
113 B). Instead, the shape of the distribution changed towards larger numbers of longer

114 and shorter molecules at the cost of intermediate-size molecules, which is reflected in
115 decreased lambda (Figure 2C) and congruent with previous findings (19). Similarly to
116 Gansauge and Meyer (2013), we also detected a reduction of GC content in ssDNA
117 libraries when compared to dsDNA (Figure 2D). This phenomenon can be attributed
118 to a known bias in dsDNA libraries towards molecules with higher GC content
119 (20,21). We detected uniform GC content across the distribution of fragment lengths,
120 which suggests that the ssDNA library preparation protocol excels in reducing those
121 biases (Figure S8). In contrast to previous reports (19), the ssDNA library method did
122 not produce an increase in the proportion of endogenous DNA (Figure 2E, Figure S1,
123 S6). However, it has been suggested that increase in the proportion of endogenous
124 DNA occurs only when the initial content of endogenous DNA is lower than 10% (22,
125 23). Our *A. thaliana* samples have endogenous DNA between 16% and 94%, which
126 could explain why we did not detect a gain in endogenous DNA.

127 In summary, we demonstrate that the choice of extraction buffer has a great impact on
128 the length distribution of molecules recovered from herbarium specimens. Ultrashort
129 molecules are most efficiently retrieved using a combination of PTB/DTT mixture for
130 DNA extraction and the buffers and conditions suggested by Dabney *et al.* (2013) for
131 DNA binding. The two library preparation methods tested here appear to be equally
132 efficient in retaining short DNA fragments, however, while single stranded method
133 reduces GC bias in library it also decreases the fraction of endogenous DNA. We
134 present the DNA extraction protocol that increases the recovery of short fragments
135 and thus the accessibility of precious herbarium specimens for genetic analyses.

230 **library preparation protocols on properties of sequenced libraries from**
231 **herbarium specimens.** Experiments were conducted in three phases. In phase one we
232 subject 10 herbarium specimens of *Arabidopsis thaliana* to extraction with two
233 different lysis buffers and compare sequencing results. In phase two we tested two
234 DNA-binding methods on second set of 10 *A. thaliana* specimens. In phase three we
235 compared the libraries constructed with double- and single-stranded methods.

236 **Figure 2. The effect of DNA extraction and library preparation protocols on**
237 **different properties of DNA sequencing libraries.** The figure depicts the results
238 from experiments in phases 1-3 (Figure 1). (A) Distribution of fragment lengths of
239 merged reads mapped to the *Arabidopsis thaliana* reference genome. The y-axis
240 shows the kernel density estimates. (B-G) Distributions represented as box and
241 whisker plots; medians are depicted by thick black lines, boxes represent data
242 between quartile Q1 and Q3, whiskers extend to 1.5 times the interquartile range
243 between Q1 and Q3, and points symbolize outliers. Comparisons within experiments
244 that result in significant differences in a paired t-test are connected with black lines
245 ('***' indicates an alpha level of 0.005) (B) Fragment length medians. (C)
246 Proportion of broken DNA fragments (λ). (D) Proportion of GC content. (E)
247 Proportion of endogenous DNA (proportion of reads mapped to *A. thaliana* reference
248 genome). (F) Number of unique molecules per base of *A. thaliana* reference genome
249 (molecule coverage of DNA extract) calculated from qPCR measurements on
250 unamplified libraries. (G) Percentage of cytosine to thymine substitutions at first base
251 at the 5' end.
