Abstract

One difficulty when identifying and analyzing alternative splicing (AS) events in plants is distinguishing functional AS from splicing noise. One way to add confidence to the validity of a splice isoform is to observe that it is conserved across evolutionarily related species. We use a high throughput method to identify junction based conserved AS events from RNA-Seq data across nine plant species including: five grass monocots (maize, sorghum, rice, *Brachpodium* and foxtail millet), plus two non-grass monocots (bananan and African oil palm), the eudicot *Arabidopsis* and the basal angiosperm *Amborella*. In total, 9,804 conserved AS events within 19,235 genes were identified conserved between 2 or more species studied. In grasses containing large regions of conserved synteny, the frequency of conserved AS events is twice that observed for genes outside of conserved synteny blocks. In plant-specific RS and RS2Z subfamilies, we observe both conservation and divergence of AS events after the whole genome duplication in maize. In addition, plant-specific RS and RS2Z subfamilies are highly connected with R2R3-MYB in splicing networks. Furthermore, we discovered that the network based on genes harboring conserved AS events is enriched for phosphatases, kinases and ubiquitylation genes, which suggests that AS may participate in regulating signaling pathways. These data lay the foundation for identifying and studying conserved AS events in the monocots, particularly across grass species, and this conserved AS resource identifies an additional layer between genotype to phenotype that may impact future crop improvement efforts.

Introduction

Alternative splicing (AS) is an important post-transcriptional process that can produce two or more transcript isoforms from a pre-mRNA. AS occurs in the spliceosome by removing introns and joining exons through the selective use of splice sites (Lee and Rio 2015) and is governed by *cis*- regulatory elements such as splicing enhancers/silencers, and *trans*- regulatory elements including SR proteins and hnRNP proteins (Busch and Hertel 2012, Wang and Burge 2008, Reddy et al. 2012, Reddy et al. 2013). AS isoforms that are translated can influence proteome diversity, while others that are not translated are purposefully non-functional and can act to post-transcriptionally modulate gene product levels (Fu et al. 2009, Hammond, Wachter, and Breaker 2009). AS participates in many important processes during the lifecycle of plants (Staiger and Brown 2013) and AS occurs in response to many abiotic stresses (Mastrangelo et al. 2012), for example red/blue light (Shikata et al. 2014, Wu et al. 2014), salt stress (Feng et al. 2015), drought (Thatcher et al. 2016), flooding (Syed et al. 2015) and temperature (Streitner et al. 2013, James et al. 2012).

RNA-Seq has become a standard tool to investigate transcriptomes and AS isoforms. While many studies have identified AS in individual species (Li, Xiao, and Zhu 2014, Thatcher et al. 2014, Shen et al. 2014, Filichkin et al. 2010, Mandadi and Scholthof 2015), few report investigating conserved AS across multiple plant genomes. Most published studies have focused on identifying conserved AS events between only two species. For example Severing et al. (2009) identified 56 protein-coding, conserved AS events between *Arabidopsis* and rice orthologous gene sets, and 30 conserved AS events leading to non-functional isoforms subjected to nonsense-mediated decay. Similarly, another study detected 537 AS events conserved between *Arabidopsis* and *Brassica*

(Darracq and Adams 2013) and 71 conserved AS events were identified between *Populus* and *Eucalyptus* (Xu et al. 2014). With respect to comparing more than two species, one study found 16 AS transcripts conserved between *Brachypodium*, rice, and *Arabidopsis* by performing all-vs-all BLAST between EST sequences (Walters et al. 2013). Recently, discovery and identification of AS events conserved broadly across eudicots has been reported (Chamala et al. 2015). Chuang et al. (2015) used available Sanger EST sets to characterize AS in grass species but did not focus on conserved AS events. There are no corresponding multi-species studies that leverage the deep NGS resources to characterize and identify conserved AS events within monocots and the grass family.

Many monocot species are economically important and grass species (Poaceae) are a particularly important source of calories. Within the grass family there are two major clades. The BEP clade is made up of the Bambusoideae, Ehrhartoideae, and Pooideae and contains rice and *Brachypodium* (Zhao et al. 2013); the PACMAD clade includes Panicoideae, Arundinoideae, Chloridoideae, Micrairoideae, Aristidoideae, and Danthonioideae, and includes maize, sorghum and foxtail millet (Cotton et al. 2015). In addition to these two major clades, there are three clades of basal grasses lineage Anomochlooideae, Pharoideae, and Puelioideae (Cotton et al. 2015). Published whole genome sequences exist for many monocot species including the grass species maize (Schnable et al. 2009), sorghum (Paterson et al. 2009), rice (Goff et al. 2002), *Brachypodium* (Vogel et al. 2010) and foxtail millet (Bennetzen et al. 2012), the non-grass species banana (D'Hont et al. 2012) and African oil palm (Singh et al. 2013).

To characterize AS and identify conserved events due to species shared ancestral a computational method was employed that identifies high confidence isoforms in any species with RNA-Seq data and a reference genome sequence, and then uses a junction based approach to identify conserved AS events across multiple species. In this analysis, we focused on seven monocot species that have available reference genome sequences and deep RNA-Seq data sets. Five of these are grasses (maize, rice, sorghum, foxtail millet and *Brachypodium*) that also have substantial retained gene collinearity which eases the identification of synteny and aids orthologue calls (Schnable, Freeling, and Lyons 2012). This analysis also includes banana and African palm oil, which extends the discovery of conserved events into non-grass monocot species. Although there are other non-grass monocot species that have available reference genomes, such as duckweed and orchid, there was not sufficient RNA-Seq data available for these species to be included in this analysis. Likewise, species representing basal grass lineages were excluded due to lack of reference genome sequences. Finally, the eudicot *Arabidopsis thaliana* and the basal angiosperm *Amborella* were included to provide outgroups for comparison. Therefore, the species studied allowed us to identify conserved AS events at specific reference points across the grasses and extends into non-grass monocots, eudicots and the sister species to all angiosperms.

Examination of conserved events uncovers likely functionally important AS isoforms of SR protein genes, stress-response transcription factors, and members of known protein-protein interaction networks. In addition the conserved AS event collection provides an opportunity to test the functional sharing hypothesis (Su et al. 2006) between single-copy vs. non-single-copy

genes, something that was not examined in previous studies of conserved AS events. This hypothesis predicts more instances of conserved alternative splicing events will be found in single copy genes than in non-single-copy genes. To measure to extent of selection pressure on AS, we examined Ka/Ks values on exons that flank conserved AS events. We also present network analysis based on the *Arabidopsis* protein-protein interaction data that provides evidence for a close association between splicing factors and stress responsive transcription factors that undergo conserved AS, and between splicing factors and R2R3-MYB across species. Finally, we discuss several noteworthy cases of conserved AS events across angiosperms including SPA3 possessing a conserved alternative donor site, a KH RNA-binding domain containing protein with a widely conserved exon skipping event, and the stress response NAC transcription factor RD26 that harbors an intron retention event conserved across the angiosperms.

Materials and Methods

Genome Assemblies and Annotations

All analyses were performed on publicly available sequence and annotation collections for the following species: foxtail millet (*Setaria italica*), rice (*Oryza sativa L. ssp. Japonica*), *Brachypodium* (*Brachypodium distachyon*), the non-grass monocots banana (*Musa acuminata*) and African oil palm (*Elaeis guineensis*), the eudicot *Arabidopsis thaliana* and the basal angiosperm *Amborella* (*Amborella trichopoda*), which is a sister taxon to all angiosperms.

The Maize RefGen_v2 genome sequence and working gene set annotation were retrieved from MaizeGDB (Lawrence et al. 2004). Reference genome sequence and gene annotation for oil palm were retrieved from the Malaysian

Palm Oil Board (genomsawit.mpob.gov.my). Reference genome and annotation for Banana were retrieved from the banana genome hub (Droc et al. 2013). All remaining reference genome assemblies and annotations were retrieved from Phytozome v10 (Goodstein et al. 2012) (Table S1).

Transcriptome Data Collection

AS in maize (*Zea mays*) and sorghum (*Sorghum bicolor*) was previously identified based on public RNA-Seq data and described in (Mei et al. In Review), and available from figshare (http://10.6084/m9.figshare.4205079). Transcript sequences and annotations of *Arabidopsis thaliana* were retrieved from Araport11 PreRelease 20151202 (Cheng et al. 2016), which presents the updated TAIR10 annotation by inclusion of 113 RNA-Seq data sets. For the remaining 6 species, Illumina RNA-Seq, 454 and Sanger EST transcript sequences were downloaded from NCBI GeneBank. The sequence collections are described in Table S2.

Method to Detect Alternative Splicing

The process and software parameters used to assemble transcripts from Illumina short reads was described in full details (Mei et al. In Review). Briefly, three approaches were taken to assemble transcripts from Illumina short reads to maximize isoform detection. The assembly software used was annotation guided Cufflinks 2.2.1 (Trapnell et al. 2012), genome-guided Trinity 2.0.4 (Grabherr et al. 2011) and annotation guided StringTie 1.0.0 (Pertea et al. 2015). Isoforms built from cufflinks were required to have minimal expression FPKM value of 0.1 and required full reads support for the whole isoforms.

We masked vector and contaminant sequence in the Sanger ESTs using SeqClean (http://seqclean.sourceforge.net/). 454 transcripts were constructed using Newbler v2.8 (Roche 2010) with parameters "-cdna -urt". Cufflinks, Trinity and StringTie assembled isoforms were merged with the Newbler 454 assemblies and the cleaned ESTs. Each species specific sequence collection was aligned back to the appropriate reference genome sequence followed by additional assembly and clustering to remove redundancy using the PASA 2.0 package (Haas et al. 2003). Isoform quality control steps described in Mei et al. (In Review) were used on the PASA outputted transcript set to remove isoforms that were poorly supported and/or potentially poor quality/poorly assembled. Briefly, each splice junction in a final retained isoform was required to have a minimum entropy score of 2 (Sturgill et al. 2013). Retained introns that define potential intron-retention isoforms were expected over a minimum of 90% of their length with a minimal median coverage depth of 10, and a minimum intron retention isoform ratio of 10%. The intron retention rate was calculated as described in Marquez et al. (2012), where the median coverage of the retained intron was divided by the number of reads supporting the splice junction. Lastly, we required each isoform to have a minimum FPKM of 1 and compose at least 5% of the total isoform abundance for that gene in at least one tissue examined.

We performed the above methods to identify and define AS events in rice, foxtail millet, *Brachypodium*, banana, African oil palm, and *Amborella*. The transcripts from Araport11 PreRelease 20151202 for *Arabidopsis* were realigned to the *Arabidopsis* reference genome using PASA to identify and characterize the set of *Arabidopsis* AS events. AS isoforms defined previously within maize and

187 sorghum Mei et al. (In Review) were used to complete the AS isoforms sets
188 analyzed in this study.

189 ***Orthofinder Clustering Across Nine Species***

190 Orthologous sequences were defined and grouped in Orthogroups across
191 the nine species by OrthoFinder with default setting (Emms and Kelly 2015).
192 OrthoFinder was designed for plant genome orthogroup identification and
193 accounts for gene length bias.

194 ***Identify Sets of Syntenic Genes Across Five Grass Species***

195 Syntenic orthologs across five grass species (*Zea mays*, *Sorghum bicolor*,
196 *Setaria italica*, *Oryza sativa*, *Brachypodium distachyon*) were defined using the
197 methodology employed by (Schnable, Freeling, and Lyons 2012). Gene models
198 were updated according to new annotations from Phytozome 10 (Goodstein et al.
199 2012). 11,995 syntenic gene lists across five species (sorghum, rice, foxtail millet,
200 *Brachypodium*, either maize1/maize2 or both) were used for downstream
201 analysis.

202 ***Identification of Conserved Alternative Splicing***

203 AS was independently identified in each species (see above) and all AS
204 isoform sequences of the same event type (intron retention, exon skipping etc.)
205 for a given species were pooled. The computational methodology to detect
206 conserved AS relies on the creation of splice anchor sequence tags (SAST) for
207 each AS event and then comparing the SASTs for a given event type with the
208 SASTs defining the same event type between species. SASTs were generated for

each AS event by extracting up to 300bp of sequence from both sides of the splice junction that defines the AS event types described in Figure 1. The tags from a particular AS event (i.e. exon skipping SASTs) from each species were compared to one another using tBLASTx from WU-BLAST (Gish, W. (1996-2003) http://blast.wustl.edu) with an E-value cutoff of 1e-5. If the length of two matching tags were both less than 30bp, this matching was not considered. In the cases tags being compared were less that 100 bp, the default tBLASTx E-value cutoff value was used. To classify conserved AS, SASTs flanking a AS event splice junction are required to be conserved between genes across species, and those genes must belong to the same orthogroup. Conserved AS events identified by this process were clustered and each cluster may contain conserved AS events identified between orthologous genes across species (1:1) as well as between paralogs. In an ideal setting, one conserved AS cluster represents one ancient conserved AS event across multiple species. However, if a gene within sorghum is present in two copies (homeologues) in maize, and all three genes harbor a conserved AS event, all three events will be assigned to the same event cluster. Therefore, with respect to the gene in sorghum and the two homeologous copies in maize, this cluster identifies 1 conserved event defined by 2 homeologous events in maize and 1 event in sorghum. Therefore, the total number of events making up a cluster may be larger than the number of species harboring the event. Because we identify these individual events within each species as instances of a conserved event we generalize the AS event cluster as a "conserved AS event".

Measure Selection Pressure on Alternative Splicing

We looked for evidence of selection pressure on AS events that were conserved by examining the difference between pairwise non-synonymous substitution rates (Ka) vs. synonymous substitution rates (Ks) for residues defined by exon sequences flanking the conserved AS event in grass species. These are the same regions that were used to construct SASTs (Figure 1). Both upstream and downstream alignments required minimal alignment lengths of 40 codons. Selection pressure on AS events at the amino acid levels was measured by determining the Ka/Ks ratios using KaKs_Calculator2.0 through model averaging (Wang et al. 2010). To minimize errors introduced by alignments, or due to paralogs that may result when comparing loci across large phylogenetic distances, the Ka/Ks evaluation of conserved AS events was limited to those events originating within orthologous grass genome loci that also exhibit conserved synteny (defined above).

Testing the Functional Sharing Hypothesis: Whether Single Copy Genes Have More Conserved AS Events

The functional sharing hypothesis predicts that conserved AS events would have a higher incidence in single copy genes compared to non-single copy genes. We used a set composed of 2,717 multi-exon genes identified as "strictly" and "mostly" single copy identified across 20 flowering plant genomes by De Smet et al. (2013). We compared the number of single-copy genes exhibiting conserved AS events to the number of non-single copy genes with conserved AS events.

Conserved AS in SR and hnRNP Proteins

Maize SR protein genes were retrieved from Rauch et al. (2014); Sorghum SR protein genes were retrieved from Richardson et al. (2011). Maize hnRNP protein encoding genes were retrieved from PlantGDB (Duvick et al. 2008). The primary protein sequences of each SR protein gene in maize and sorghum were used for phylogeny analysis. Protein sequences were aligned with MUSCLE (version 3.8.31) using default parameters (Edgar 2004). The alignments were used to construct a maximum likelihood phylogenetic tree with RAxML (version 8.1.12) software using a gamma distribution and LG4X model (Stamatakis 2014, Le, Dang, and Gascuel 2012). A manual search along the phylogenetic tree was performed to determine conserved AS events in SR families between maize and sorghum based on conserved isoform structure. The exon-intron gene structure was visualized with Fancygene version 1.4 (Rambaldi and Ciccarelli 2009) with AS events further labeled.

Network Analysis in Stress Responsive Transcription Factors and Conserved Splicing Genes

3,150 *Arabidopsis* transcription factors (TFs) responsive to 14 diverse stresses were retrieved from STIFDB V2.0 (Naika et al. 2013) and we were focused on five major stresses (ABA, drought, cold, NaCl and light). Protein-protein interaction networks based on transcription factors (TFs) in *Arabidopsis* with conserved AS in response to five major stresses were built with using STRING v10 (Szklarczyk et al. 2014). In addition, a network based on *Arabidopsis* genes demonstrating conserved AS in *Amborella*, *Arabidopsis* and at least one monocot species was also constructed. The cluster of networks constructed was identified and analyzed in Cytoscape v3.3.0 (Shannon et al. 2003).

Go Term Annotation

Genes harboring conserved AS events between *Amborella*, *Arabidopsis*, and at least one monocot species were further evaluated for functional annotation and GO term enrichment based on the *Arabidopsis* gene name using the agriGO analysis toolkit (Du et al. 2010). We use the Fisher's exact test in singular enrichment analysis, followed by multiple test corrections with the Hochberg FDR test. Only associations with a minimum corrected p-value of 0.05 were considered.

Data Availability

AS events table and GFF files for the AS isoforms in seven species (*Setaria italica*, *Oryza sativa L. ssp. Japonica*, *Brachypodium distachyon*, *Musa acuminate*, and *Elaeis guineensis*, the eudicot *Arabidopsis thaliana* and the basal angiosperm *Amborella*) are made available to the community via figshare (figureshare address will made immediately available once the manuscript has been accepted). In addition, a table detailing the AS events identified as conserved during this study will be made available. The *Zea mays* and *Sorghum bicolor* are already available community via figshare (http://10.6084/m9.figshare.4205079).

Results

Up to 54.6% of Expressed Multi-Exon Genes Exhibit Evidence of AS Among Nine Species

Five types of AS events were considered during this study: Intron retention (IntronR), Alternative acceptor (AltA), Alternative donor (AltD), Exon skipping (ExonS) and Alternate terminal exon (AltTE) (Figure 1). The percentage of expressed multi-exon genes that exhibit AS was determined for each species. The nine species evaluated exhibit AS across a range of 28.7% to 54.6% of multi-exon genes (Table S3). The largest proportion of expressed multi-exon genes with evidence of AS was in *Amborella* (54.6%). Over 60% of the intron retention events in *Amborella* were removed during the filtering process (described in Materials and Methods). Although the number of *Amborella* genes that exhibit AS is similar to that of other species examined during this analysis, *Amborella* has a lower proportion of multi-exon genes in the genome relative to other species. Therefore, despite the similar number of multi-exon genes that undergo AS, *Amborella* exhibits a high fraction of multi-exon genes that produce AS transcripts compared to the other species considered here. Intriguingly, *Amborella* genes that undergo AS produce the highest average number of isoforms/gene compared to other species (Table S3). Whether this feature reflects the evolutionary position of *Amborella* in angiosperm, or is the result of the absence of lineage specific whole genome duplication events – whereas species with additional lineage specific WGD events have lost or partitioned AS isoforms among paralogues through sub-functionalization (Jiang et al. 2013) – remains to be investigated. Maize has the largest collection of RNA-Seq data among the nine species examined and also has the largest number of AS events, but the percentage of multi-exon genes that undergo AS is similar to other species. While the proportions of genes that undergo AS and the total number of AS events is higher than previously reported for many plant species (Amborella

326 Genome Project 2013, Campbell et al. 2006, Panahi et al. 2014, Abdel-Ghany et al.
327 2016, Walters et al. 2013), a substantially lower fraction of plant multi-exon
328 genes undergo AS relative to human genes where a reported 95% of multi-exon
329 genes undergo AS (Pan et al. 2008). Similar to previous genome-wide AS studies
330 (Thatcher et al. 2014, Li, Xiao, and Zhu 2014, Mandadi and Scholthof 2015,
331 Chamala et al. 2015), intron retention was the most commonly observed AS
332 event type in monocots. Sorghum and *Amborella* were found to have the lowest
333 percentage of intron retention events, 35.6% and 37.2%, respectively, while
334 African oil palm and *Brachypodium* have the highest proportion of intron
335 retention events, 61.4% and 57.6%, respectively (Table S3).

336 ***AS Events Conserved Between Monocots, Arabidopsis and Amborella***

337 We identified 9,804 conserved AS event clusters in nine species (Table 1).
338 59.0% of conserved AS events represent intron retention. Approximately 68.7%,
339 18.6%, 7.3% and 5.4% conserved AS events are conserved across two species,
340 three species, four species and at least five species, respectively (Table 1). 1,816
341 conserved AS event clusters were found to include *Amborella*. Of these, 1,015
342 involved conserved intron retention events, 450 alternative acceptor events, 205
343 alternative donor events, 114 exon skipping events and 32 alternative terminal
344 exon events (Table 2). In addition, we identified 80 conserved AS events
345 conserved only between *Amborella* and *Arabidopsis* and absent from seven
346 monocot species examined. These 80 AS events likely represent AS events lost
347 after the divergence of eudicots and monocots including 34 intron retention, 31
348 alternative acceptor, 11 alternative donor, and 4 exon skipping events (Table 2).
349 Analysis of nine species revealed 9,804 conserved AS event belong to 19,235

genes (Figure 2), with an apparent increased number of genes with conserved AS events within grass species (Figure 2); *Arabidopsis* had the least (944) number of genes harboring conserved AS events while maize had the most (3,687).

GO term enrichment analysis was performed on *Arabidopsis* genes with AS events that are conserved within *Amborella*, *Arabidopsis* and monocots to identify whether genes with conserved AS events participated in particular biological processes. 129 AS events meet this criteria. These 129 conserved AS events represent 64 intron retention events, 43 alternative acceptor events, 11 alternative donor events, 10 exon skipping events and 1 alternative terminal exon events (Table 2). GO term enrichment based on the *Arabidopsis* genes producing these 129 conserved AS events suggest an over-representation of kinase and phosphorylation activity (Figure S1). This result is consistent with the proposal that AS impacts protein kinase mediated signaling pathways (Reddy et al. 2013), which may modulate the transfer of developmental or environmental cues.

TFIIIA possesses an exon skipping event conserved across land plants (Fu et al. 2009, Barbazuk 2010). This event was also identified in all species examined in our study, although our stringent depth requirements initially filtered it out of the banana analysis. In addition, a widely conserved AS event was discovered within SPA3, a member of the SPA protein family, that plays a pivotal role in light signaling as a suppressor of photomorphogenesis (Laubinger and Hoecker 2003). Initial investigation by Shikata et al. (2014) identified an intron retention event and an alternative donor event within *Arabidopsis* SPA3; both splice isoforms harbor premature terminal codons that result in truncated protein products. These truncated proteins retain interaction with

375 CONSTITUTIVE PHOTOMORPHOGENIC 1 (COPI) but lose the ability to bind to
376 DAMAGED DNA-BINDING PROTEIN 1 (DDB1). Evidence suggests the
377 phytochrome could mediate the production of AS transcripts of SPA3 in response
378 to some light conditions, thus promoting plant photomorphogenesis (Shikata et
379 al. 2014). Both the intron retention and alternative donor AS events were
380 identified in our analysis: the alternative donor event is conserved across all nine
381 species examined and the intron retention event is conserved in four species:
382 maize, foxtail millet, African oil palm and *Arabidopsis*. The absence of the intron
383 retention event in the other species examined could be due to limited data depth
384 or tissue sampling. Further investigation is required to determine whether or not
385 this intron retention is conserved broadly across the angiosperms.
386 Alternative donor and acceptor events were reported to be significantly
387 enriched among events conserved between *Brassica* and *Arabidopsis* (Darracq
388 and Adams 2013). We found significant enrichment of alternative donor and
389 alternative acceptor events conserved across at least three species relative to
390 events conserved in only two species ($P<0.0001$, Fisher's exact test, Table 1),
391 similar enrichment patterns were observed for exon skipping events conserved
392 across at least four species relative to clusters conserved in only two species
393 ($P<0.05$, Fisher's exact test, Table 1). Expectedly, the overall numbers of AS
394 events that are conserved decreases as the number of species they are conserved
395 within increases. In addition, when considering AS conserved across multiple
396 species, as the number of species that harbor the conserved AS increase, the
397 proportion of conserved AS that are intron retention decrease relative to the
398 other event types. This suggests that requiring an AS event to be conserved
399 between species selects for biologically relevant and important events, and that

400 the trend we observe with intron retention might imply that intron retention
401 suffers a higher proportion of 'noisy' or non-relevant splicing relative to other AS
402 types.

403 Examining the lengths of conserved retained introns relative to the non-
404 conserved retained introns across 9 species does not reveal a universal trend. In
405 *Arabidopsis*, *Brachypodium*, and foxtail millet, the length of conserved retained
406 introns is significantly shorter than that of non-conserved (i.e. unique to only one
407 species) retained intron (Table 3). However, in *Amborella* and African oil palm,
408 the length of conserved retained introns is significantly longer than that of non-
409 conserved retained introns. In banana, maize, sorghum and rice, there is no
410 significant difference in retained intron length between conserved and non-
411 conserved retained introns. However in the related grass species maize, rice and
412 sorghum that exhibit large segments of genome co-linearity (Gale and Devos
413 1998) the mean length of conserved retained intron is shorter than non-
414 conserved retained introns, while the median lengths of conserved retained
415 introns are similar or larger than those of non-conserved retained introns (Table
416 3). A previous report suggested that the lengths of retained introns within
417 *Arabidopsis* that are conserved in *Brassica* are shorter than non-conserved
418 retained introns (Darracq and Adams 2013). We observed the same length trend
419 in *Arabidopsis*, but this is not consistent in other species.

420 *Arabidopsis* TFs responsive to 14 diverse stress signals were retrieved
421 from STIFDB V2.0 (Naika et al. 2013). TFs responsive to oxidative stress,
422 dehydration, ABA, NaCl, drought, light, and cold have more AS relative to TFs
423 responsive to the other 7 stresses (Table S4). Since the oxidative stress and
424 dehydration responsive TFs only have 1 and 8 TFs with conserved AS,

425 respectively, we focus on the five major stresses where AS appears to play a
426 significant role: ABA, NaCl, drought, light, and cold. The absolute number and
427 percentage of AS in these TFs responsive to five major stresses are described in
428 Table S4 together with the number and the percentage of conserved AS in these
429 TFs. Two genes are particularly interesting, AT4G27410 (NAC transcription
430 factor RD26) and AT1G78070 (Transducin/WD40 repeat-like superfamily
431 protein). These two genes have conserved AS events and are responsive to all
432 five stresses based on the data (Figure S2). RD26 has a conserved intron
433 retention event across 7 of the 9 species we examined (absent in sorghum and
434 *Brachypodium*). AT1G78070 has a conserved alternative terminal exon between
435 sorghum, banana and *Arabidopsis*. These results indicate that there are AS events
436 in stress-response TFs conserved among species across large phylogenetic
437 distances, which suggests that AS may play an important role in the activity of
438 some TFs during stress response.

439 ***AS Conserved Between Monocot Grass and Non-Grass Species***

440 There are 239 AS events conserved between banana, African oil palm, and
441 at least one of the five grass species examined (Table 2). 34 out of 239 conserved
442 AS events are conserved across banana, African oil palm and five grass species
443 (Table 2). 204 conserved AS events exist within the banana and African oil palm
444 lineages but are absent from the grass species studied. 224 conserved AS events
445 are conserved across the five grass species examined, and these are comprised of
446 60 intron retention events, 106 alternative acceptor events, 37 alternative donor
447 events and 21 exon skipping events (Table 2). Within the PACMAD clade, 1,544,
448 1,488 and 1,323 AS events are conserved between maize vs. sorghum, maize vs.

449 foxtail millet, and sorghum vs. foxtail millet, respectively. In the BEP clade, 1,658
450 conserved AS events are conserved between rice and *Brachypodium*. 4,333
451 conserved AS events are conserved in at least one species in the BEP clade and
452 one species in the PACMAD clade (Table 2). Maize clock genes (i.e circadian
453 rhythm) GRMZM2G033962 (pseudoresponse regulator protein 37, *PRR37*) and
454 GRMZM2G095727 (pseudoresponse regulator protein 73, *PRR73*) share a
455 conserved intron retention that is also conserved across rice, *Brachypodium*, and
456 foxtail millet. Our data suggests that this intron retention event is likely specific
457 to members of the grass family; the role of intron retention in *PRR37* and *PRR73*
458 controlling photoperiodic flowering needs further experimental investigation.
459 Since syntenic genes were more likely to transcribe transcripts and
460 translate proteins than non-syntenic regions (Walley et al. 2016), we tested the
461 hypothesis that AS and conserved AS is enriched in syntenic regions across grass
462 species compared to non-syntenic regions. There are 11,996 syntenic gene
463 clusters across five grass species including maize, sorghum, foxtail millet, rice,
464 and *Brachypodium*. Since maize has undergone an additional whole genome
465 duplication relative to the others, syntenic genes could be maize1 gene, maize2
466 gene or both. In each of five grass species, we compared the proportion of genes
467 within syntenic relationships that undergo AS vs. non-syntenic genes, and the
468 proportion genes within syntenic relationships that have conserved AS events vs.
469 the proportion of non-syntenic genes that have conserved AS events. The
470 proportion of genes with syntenic relationships that exhibit AS is approximately
471 twice that of genes in non-syntenic relationships (Figure 3). This trend is
472 consistent across five grass species. Similarly, the proportion of genes that have
473 conserved AS events that reside in syntenic regions is approximately twice that

474 of genes with conserved AS events that do not reside within syntenic regions
475 (Figure 3). This suggests that genes within conserved syntenic blocks between
476 present within the five grass species studied are enriched in both AS, and
477 conserved AS events.

478 We examined selection pressure at the amino acid level on AS events
479 conserved within grasses by performing pairwise comparisons of Ka/Ks ratios
480 across the exonic regions flanking each conserved AS event (Figure 4). In total
481 4,083 flanking exonic regions were examined, 1,999 from upstream exons and
482 2,084 from downstream exons. We separated the Ka/Ks values for the flanking
483 upstream and downstream portions of each alternative splicing type and plotted
484 these values (Figure 4). In general, Ka/Ks values of exonic regions flanking
485 conserved AS events are smaller than 1 (Figure 4), which suggest these regions
486 are under purifying selection. There are 161 pairwise flanking region pairs with
487 Ka/Ks value above 1, indicative potential candidate for positive selection. These
488 include 67 from intron retention, 41from alternative acceptor, 40 from
489 alternative donor, 8 from exon skipping and 5 from terminal alternate exon. We
490 did not detect a statistically significant difference in Ka/Ks between exons
491 upstream and downstream of conserved intron retention, alternative acceptor,
492 and exon skipping events. However, a significant difference in Ka/Ks was
493 observed between upstream and downstream exons flanking conserved
494 alternative donor events ($P < 0.001$, Wilcoxon Rank-Sum Test) and alternate
495 terminal exon ($P < 0.001$, Wilcoxon Rank-Sum Test). In general, these results
496 suggest that the regions flanking conserved AS events in grasses are undergoing
497 purifying selection, which may be maintaining *cis*- signals required for AS and
498 somewhat responsible for maintaining sequence conservation across species.

499 ***Conserved AS is More Common Among Single Copy Genes***

500 We tested the functional sharing hypothesis between single copy genes
501 vs. non-single copy genes by measuring the number of genes within each
502 category that exhibit conserved AS events. 2,985 single copy genes including
503 strict and mostly single copy were described in *Arabidopsis* (De Smet et al. 2013).
504 Han et al. (2014) suggested single copy genes had increased levels of AS relative
505 to genes from large gene families and a decreased proportion of AS compared to
506 genes from small gene families. Similarly, Su and Gu (2012) suggested that single
507 copy genes had more isoforms per gene compared to the genes from large gene
508 families but similar average isoform counts per gene compared to the genes from
509 small gene families.

510 We compared the number of conserved AS genes between single copy
511 genes vs. non-single copy genes irrespective of gene family size. 2,717 out of
512 2,985 single copy genes are multi-exon genes. 1,113 out of the 2,717 multi-exon
513 genes have evidence of AS in *Arabidopsis* based on the Araport11 transcripts. In
514 the 19,700 non-single copy multi-exon genes, there are 6,751 that exhibit AS.
515 Among multi-exon genes, the single copy genes have significantly more AS
516 compared to the rest of multi-exon genes ($P < 0.0001$, Chi-square with Yates'
517 correction). Among the 944 *Arabidopsis* genes with conserved AS events in our
518 analysis, 173 were from 1,113 single copy AS genes, while the remaining 771
519 were from the 6,751 non-single copy AS genes. Single copy genes in *Arabidopsis*
520 showed significantly enriched in conserved AS events ($P < 0.0001$, Chi-square
521 with Yates' correction). These results suggest that among multi-exon genes in

522 *Arabidopsis*, a greater proportion of single copy genes both undergo AS and
523 harbor conserved AS events than do non-single copy genes.

524 ***Conserved AS is More Common Among SR Protein Genes Relative to hnRNP***
525 ***Proteins***

526 Similar to previous observations (Kalyna et al. 2006, Rauch et al. 2014,
527 Chamala et al. 2015), AS events were detected in SR proteins. 19 out of 21 SR
528 proteins in maize demonstrate AS, and 13 out of 19 alternatively spliced SR
529 protein genes in maize showed 24 conserved AS events with other species
530 including 13 intron retention events, 4 alternative acceptor events, 4 alternative
531 donor events and 3 exon skipping events (Table S5). 10 out of 24 conserved AS
532 events are present in at least five species. Richardson et al. (2011) identified two
533 SR proteins (GRMZM2G110143 and GRMZM2G170365) in maize with evidence
534 of positive selection (Supplemental Table5). These two genes also have
535 conserved AS events across 2 and 4 species, respectively. Zm-SCL30
536 (GRMZM2G065066), previously identified in maize, responds to both cold and
537 heat response (Mei et al. In Review). SCL30 has alternative acceptor, alternative
538 donor, and exon skipping events conserved across grass species and *Amborella*,
539 as well as two intron retention events only conserved within the grass lineage.
540 Altogether, there are 4 maize SR proteins (2 in the RS subfamily, 1 in the SC
541 subfamily, and 1 in the SCL subfamily) that demonstrate 6 conserved AS events
542 with *Amborella* (Table S5), which supports the existence of a deeply conserved
543 splicing mechanism in SR proteins. 10 out of 40 hnRNP proteins in maize exhibit
544 evidence for 17 conserved AS events, 10 of which are intron retention events, 4
545 alternative acceptor events, 2 alternative donor events, and 1 exon skipping

546 events (Supplemental Table5). None of these 17 conserved AS events are
547 conserved across more than four species. 3 of the 17 conserved AS events from 3
548 hnRNP genes in maize are conserved with *Amborella* (Table S5), while 6 out of
549 24 AS events from 4 SR proteins in maize are conserved with *Amborella*. These
550 results suggest that the signals for AS within SR protein genes across species are
551 better conserved than those within the hnRNP protein encoding genes.

552 ***Conservation and Subfunctionalization of SR Proteins After Whole Genome***
553 ***Duplication***

554 We used a phylogenetic approach to identify conserved AS across the SR
555 protein subfamilies in maize and sorghum. An ancestral exon skipping event is
556 conserved across all members of this subfamily in maize and sorghum (Figure
557 5A). Intriguingly, all three maize SR subfamily genes were reduced to one copy
558 after whole genome duplication; one gene lost a homeologous copy from maize
559 subgenome1, and two genes lost their homeologous copies from subgenome2.
560 The plant-specific RS subfamily also has a shared exon skipping in the second
561 long intron region coding RRM domain both in maize and sorghum (Figure 5A).
562 The exon skipping isoform generates a complete RRM domain. Kalyna et al.
563 (2006) suggested this long intron is conserved from green algae to angiosperms,
564 and the splice site is retained between monocot and eudicot lineages. Our
565 analysis suggests that this exon skipping event is preserved in maize, sorghum,
566 rice, *Brachypodium*, foxtail millet and *Amborella*. In the plant-specific RS2Z
567 subfamily, maize maintained both copies of the genes after whole genome
568 duplication. Remarkably, two sorghum genes Sobic.009G022100 and
569 Sobic.009G022200 are next to each other but in opposite directions on the

chromosome, which suggests one copy may be the result of a tandem duplication. Based on phylogenetic evidence Sobic.009G022200 might be the older copy (Richardson et al. 2011). Not only did Sobic.009G022200 and two duplicate genes in maize retain an exon skipping event, but they also contain two intron retention events surrounding the skipped exon (Figure 5B). Sobic.009G022100 and the two duplicate genes in maize (GRMZM2G099317 and GRMZM2G474658) apparently diverged their AS isoforms (Figure 5B). Sobic.009G022100 only preserved the exon skipping isoform, which would generate a complete RRM domain. GRMZM2G099317 retained the intron retention event on the right side, and the exon skipping event. For the second copy, GRMZM2G474658, the intron retention event on the left side is retained as well as an alternative acceptor event. There is one additional sorghum gene Sobic.003G064400 without conserved synteny in maize, which suggests maize might have lost both syntenic copies that had represented orthologues of this sorghum gene. The AS pattern of this gene is similar to AS pattern of GRMZM2G474658 (Figure 5B). The alternative long intron in the RS2Z subfamily is also conserved from mosses to angiosperms (Kalyna et al. 2006).

R2R3-MYB is Tightly Connected with a Plant-Specific SR Protein Subfamily

We used a network building approach to identify the degree of interactivity of TFs with conserved AS in response to five stresses (ABA, drought, cold, NaCl and light) based on protein-protein interactions in STRING v10 (Szklarczyk et al. 2014). Several interesting relationships showed up in the network (Figure S3). Ubiquitin genes such as UBQ10, UBQ11, and UBQ14 are centralized in the network, which suggests AS might play a role in the

susceptibility of translated isoforms to ubiquitin mediated degradation. Ubiquitin genes are closely associated with splicing related genes (such as RS2Z33, RS41, RS2Z32, RS40, U2AF65A, SR45, SCL33) via *Glycine Rich Protein 7* (GRP7). GRP7 is part of the circadian clock and negatively auto-regulates its own protein abundance by producing a non-productive AS isoform that is subject to the nonsense-mediated decay (NMD) pathway (Schöning et al. 2007, Schöning et al. 2008). In addition, we identified the MYB gene network is associated with splicing network genes through the proline-rich spliceosome-associated protein (AT4G21660) (Figure S3). The MYB genes identified in this network belong to the R2R3-MYB family. The R2R3-MYB family has undergone expansion in plants (Du et al. 2014) and plays many important plant-specific roles. Furthermore, there are many kinase and phosphatase related genes in close association with genes responsible for phosphorylation and dephosphorylation of splicing regulators, such as serine-threonine protein kinase (CIPK3), calcium-dependent protein kinase 29 (CPK29), CBL-interacting protein kinase 9 (CIPK9), and calcineurin b-like protein (CBL1). CBL1 has been identified as a salt-tolerance gene and connects with components of the spliceosome (Feng et al. 2015). CBL2 and CBL3 together with CIPK3 and CIPK9 can form a calcium network to regulate magnesium levels, while CBL1 is a calcium sensor (Tang et al. 2015). Here, AS of CBL1 and CIPK3, CIPK9 could potentially participate in regulating magnesium levels through a feedback loop sensitive to calcium concentration.

We also examined the networks containing genes in *Arabidopsis* with conserved AS events with *Amborella* and at least one species of monocot. Most of the genes present in the network were from the plant-specific SR protein subfamily, such as RS2Z, RS, and SR45a. In addition, TFIIIA is connected to the

splicing protein network via RNA-binding protein (AT4G35785). TFIIIA has an exon skipping event that is conserved across the land plants (Barbazuk 2010, Fu et al. 2009). Similar to the network based on TFs in response to stress, we identified a close connection between the R2R3-MYB class with a splicing protein network via TFIID-1 (AT3G13445) and proline-rich spliceosome-associated family protein (AT4G21660) (Figure 6). These R2R3-MYBs are involved in many important functions, such as glucosinolate biosynthesis, phenylpropanoid pathway, conical epidermal cell outgrowth, drought and pathogens ABA- and JA- mediated, and cuticular wax biosynthesis (Table S6).

Discussion

In this study, we utilized a bioinformatics scheme to detect AS events and identify those which are conserved across 9 plant species by mining publicly available RNA-Seq data. In total, across all 9 species, 9,804 AS events conserved between 2 or more species are defined within 19,235 genes. New sequenced plant genomes and vast amounts of RNA-Seq are increasingly deposited into NCBI's Sequence Read Archive (SRA). These are treasure troves of data waiting to be mined for new discoveries. Many are already tapping into this wealth, as exemplified by (Nellore et al. 2016) who examined splice junction variants in the human genome, and Chamala et al. (2015) who examined conserved AS events across several species of eudicots. The method we describe here can be used to mine to identify conserved AS events within any species with an available genome sequence and deep RNA-Seq data.

642 ***AS Shows Widely Conserved Across Species but Likely Undergone***

643 ***Complicated Patterns of Gain and Loss***

644 Each species examined has one to three thousand genes with evidence of

645 conserved AS. *Arabidopsis* has least number of genes with conserved AS (944),

646 while maize has the greatest number of genes (3,687) (Figure 2). The smallest

647 percentage of conserved AS genes among genes that undergo AS is *Arabidopsis*

648 (12.0%), while foxtail millet has the greatest percentage of conserved AS genes

649 among genes with AS (36.2%). We identified 1,413 genes with conserved AS

650 events in *Amborella*, which account for 18.3% of the genes in *Amborella* with

651 evidence of AS. One conserved exon skipping event occurs within the gene

652 encoding an RNA-binding KH domain-containing protein. This conserved AS

653 event was detected in 8 of the 9 species RNA-Seq data examined, but was

654 apparently absent in *Arabidopsis*. However, this isoform is reported within the

655 AtRTD *Arabdiopsis* transcriptome data (Zhang et al. 2015) indicating that it is

656 broadly conserved across all species investigated here. RNA-binding KH domain

657 proteins are vital for heat stress-responsive gene regulation (Guan et al. 2013).

658 The alternatively spliced exon within this RNA-binding KH domain-containing

659 protein has high sequence similarity across nine species studied (Figure 7) and

660 this AS event is likely conserved broadly across angiosperms. Similar to a

661 previous study that identified that alternative donor and alternative acceptor

662 events were found to be significantly enriched between *Arabidopsis* and *Brassica*

663 (Darracq and Adams 2013), we identified a significant enrichment of alternative

664 donor and alternative acceptor events that were conserved in at least three

665 species relative to those conserved in only two species, and a significant

666 enrichment of exon skipping events conserved in at least four species relative to

667 those conserved in only two species. We observed that *Arabidopsis*,
668 *Brachypodium* and foxtail millet retained introns that are conserved have
669 significantly shorter lengths compared to non-conserved retained introns, which
670 is consistent with a previous report in *Arabidopsis* (Table 3) (Darracq and Adams
671 2013). However, this trend is not observed across all the species examined.
672 Conserved retained introns in *Amborella* and African oil palm are longer than
673 those retained introns that were not conserved, and there are no significant
674 differences in the lengths of conserved retained introns vs. non-conserved
675 introns in banana, maize, rice, and sorghum.

676 The plant specific RS and RS2Z subfamilies associate with the R2R3-MYB
677 class within the network built from *Arabidopsis* genes demonstrating conserved
678 AS with *Amborella* and at least one species of monocots. Many R2R3-MYB genes
679 are represented in this network and possess plant-specific functions (Table S6).
680 Li et al. (2006) identified conserved AS events within MYB59 and MYB48. Both
681 genes are represented within our network and associate with SR proteins via a
682 proline-rich spliceosome-associated protein AT4G21660 (Figure 6). Together,
683 these results suggest a conserved connection between splicing factors and R2R3-
684 MYB transcription factors. These two protein classes may cooperate during
685 developmental processes and stress response in plants.

686 ***Grass Lineage Enriched for Conserved Alternative Splicing***

687 Within monocots we identified lineage-specific conserved AS events.
688 There are 204 conserved AS events between banana and African oil palm that
689 are absent in the grass species examined, likely lost in the grass family, and 239
690 conserved AS events conserved in banana, African oil palm and at least one grass

691 species. The number of conserved AS between two species in the PACMAD clade
692 (maize, sorghum, and foxtail millet) is similar to the number of conserved AS
693 events between two species within the BEP clade (rice and *Brachypodium*). 224
694 conserved AS events were found conserved across five grass species examined
695 (maize, sorghum, foxtail millet, rice, and *Brachypodium*). In addition, the
696 proportion of genes within syntenic blocks with AS events in the grasses is
697 approximately twice that compared to those outside of syntenic blocks, and this
698 trend is also mirrored across those genes with conserved AS events (Figure 3).
699 In general, the average values of Ka/Ks across different AS events are less
700 than 1, which suggests that the flanking exonic regions are undergoing purifying
701 selection for conserved AS events. In contrast, previous studies have suggested
702 only moderate selection pressure on the alternative vs. the constitutive regions
703 (Xing and Lee 2006, Chen et al. 2006, Xing and Lee 2005). However, the selection
704 on the flanking region of conserved AS is less explored, particularly in plants. In
705 intron retention, alternative acceptor and exon skipping, there is no significant
706 difference in Ka/Ks between flanking upstream and downstream exonic regions
707 (Figure 4); however, we did observe significantly higher Ka/Ks in the upstream
708 compared to downstream flanking regions in alternative donor and alternative
709 terminal exon. These results indicate that the flanking downstream regions have
710 stronger purifying selection compared to the upstream regions in AltD and ATE
711 events, which suggest that a proportion of flanking upstream and downstream
712 exonic regions of conserved AS events might harbor splicing regulatory
713 elements.
714 We observed both conserved and subfunctionalization patterns of AS
715 within SR protein encoding genes after the whole genome duplication event in

716 the maize lineage. The plant-specific RS subfamily in maize and sorghum harbor
717 conserved exon skipping although the maize orthologue has been reduced to a
718 single copy after whole genome duplication (Figure 5A). In the RS2Z family,
719 Maize has retained both homeologous copies of the RS2Z subfamily genes. In one
720 case, it has maintained the conserved AS events in both maize homeologues
721 including exon skipping and intron retention events (Figure 5B), however, in
722 another case, the AS events have diverged between the sorghum gene and its two
723 maize homoelogous (Figure 5B).

724 ***Important Functional Conserved AS in SR Protein in Response to***
725 ***Environment Stress***

726 Many stress responsive TFs have conserved AS. We focused on identifying
727 conserved AS in stress responsive TFs during five major stresses: ABA, salt
728 (NaCl), drought, light, and cold. Two genes AT1G78070 (Transducin/WD40
729 repeat-like superfamily protein) and AT4G27410 (RD26) are expressed during
730 all five stresses. RD26 encodes a NAC transcription factor induced in response to
731 desiccation. In our data, RD26 has conserved AS in 7 out of the 9 species we
732 examined (except sorghum and *Brachypodium*), however we don't have data to
733 test whether this conserved AS is stress responsive. As illustrated in Figure S4,
734 the exonic flanking sequence of this intron retention event has the highest
735 sequence conservation across species than any other region of the gene,
736 although there remains some similarity between maize and sorghum in the
737 conserved intron region. This conserved intron retention event is likely broadly
738 conserved across angiosperms.

739 Within the protein-protein interaction network based on *Arabidopsis*
740 stress response TFs with conserved AS events identified in our data sets, we
741 detect phosphatases, kinases and several ubiquitin genes in the center of the
742 network (Figure 6). This result is in line with the recent discovery that
743 alternative exons and exitrons (exon-like introns) have more phosphorylation
744 sites and ubiquitination sites compared to constitutive exons (Marquez et al.
745 2015). In these conserved AS genes across the angiosperms, AS may be involved
746 in signaling pathways responsible for de/phosphorylation and protein
747 degradation pathways, which suggests an important regulatory role in plants.
748 Furthermore, we detected an association between plant-specific RS2Z and RS
749 subfamily splicing proteins and R2R3-MYB proteins via proline-rich
750 spliceosome-associated proteins, suggesting the R2R3-MYB family and splice
751 regulators may interact during abiotic stress responses (Figure 6). Another
752 interesting finding in the network is SPA3 (Figure 6). In moss, red and blue light
753 photoreceptors were shown to regulate AS and intron retention was mis-
754 regulated in moss mutants defective in the red light sensing phytochromes (Wu
755 et al. 2014), which suggests an ancient connection between light regulation and
756 conserved AS in land plants. We found both conserved alternative donor and
757 intron retention events in SPA3, which acts as a negative regulator during light
758 signaling via suppression of photomorphogenesis (Laubinger and Hoecker
759 2003). The truncated protein produced by two AS events in SPA3 will properly
760 interact with COPI but loses the ability to bind to DDB1 (Shikata et al. 2014).
761 SPA3 is connected to 9 additional kinase genes in the network, all of which have
762 conserved AS across the angiosperms (Figure 6). This suggests that AS of kinases
763 might play an important role in the regulation of the light signal, perhaps by

affecting a kinase mediated signal cascade linked to SPA3. Inclusive, our study suggests the conserved AS landscape in plants is complicated and needs further functional study to link the phenotype to conserved AS events and identify the regulatory code for functional relevant AS.

Authors' Contributions

WM, WBB designed the work. WM, WBB, LB, GF, JCS analyzed the data. WM and WBB wrote the manuscript with input from LB, GF and JCS.

Acknowledgements

We thank Daniel Gates and Emily Josephs provide helpful comments for the manuscript. This work was supported by Department of Biological Sciences at University of Florida, Florida Genetics Institute, Graduate Student Fellowship and College of Liberal Arts and Sciences Dissertation Fellowship from University of Florida awarded to WM and National Science Foundation grants IOS-0922742 & IOS-1547787 (WBB).

Figure Legends

Figure 1. Pipeline to identify conserved alternative splicing events.

Up to 300bp on either side of a splice junction were extracted. These extracted sequences were binned together with all other similarly extracted and binned sequences flanking the same type of event for each species (eg. one bin with sequences flanking junctions involved in intron retention, one bin with sequences flanking junctions involved in exon skipping, etc.). Sequences within each bin were compared with tBLASTx to bins of the same evet from other species to identify similar tags. Cases were the sequence tags were similar and the parent genes are from different species but represent orthologs as evidenced by being within the same orthogroup (see Methods) defined conserved alternative splicing events.

Figure 2. Genes with conserved alternative splicing events across nine species.

We calculate the number of genes with conserved alternative splicing events in each species. Tetraploidy and Hexaploidy are labeled on the phylogenetic trees. The length of the phylogenetic tree is not proportional to the phylogenetic distance.

Figure 3. Alternative splicing and conserved alternative splicing enriched across grass syntenic genes.

We calculated the percentage of AS in syntenic and non-syntenic genes (the percentage of AS genes are labeled in blue). In addition, we calculated the

percentage of conserved AS in syntenic AS genes and non-syntenic AS genes (the percentage of conserved AS genes are labeled in black).

Figure 4. Violin plot of Ka/Ks value from flanking upstream and downstream in different alternative splicing events across syntenic genes within grass species.

We calculated the pairwise Ka/Ks ratio within exonic regions upstream and downstream of conserved alternative splicing events in five grass species. Only those exonic regions aligned at a>= 120bp were considered in Ka/Ks calculation. The dotted lines within the violin plot represented the first, second and third quartile.

Figure 5. Phylogenetic tree and gene structure of SR, RS and RS2Z subfamilies in maize and sorghum.

A) Phylogenetic tree representing the relationship of genes from SR and RS subfamilies in maize and sorghum; associated gene structures are illustrated by Fancygene to the right. Constitutive exons are shaded blue and alternative region are indicated with orange. Transcript structure is indicated by exons connected via dashed lines; orthologous exons are indicated with grey lines. B) Phylogenetic tree and gene structure of RS2Z subfamily in maize and sorghum are illustrated by Fancygene. Annotation and shading is described above; intron retention regions are indicated in clear boxes.

Figure 6. Protein-protein network of *Arabidopsis* genes with evidence of conserved alternative splicing with *Amborella* and at least one species of monocot.

The arrow in the network indicates the direction of the protein-protein network.

Figure 7. Sequence conservation within a gene encoding an RNA-binding KH domain-containing protein that produces an exon skipping even conserved across species.

An example of sequence conservation of the alternative exons in a RNA-binding KH domain-containing protein. The exon skipping in *Arabidopsis* is not included in the Araport11, but detected in AtRTD. Vista plots of pair-wise alignments between the RNA-binding KH domain protein encoding gene from *Brachypodium* and its orthologue in *Amborella*, *Arabidopsis*, banana, African oil palm, rice, foxtail millet, sorghum and maize. The alternative exon (boxed in red) is highly conserved between *Brachypodium* and its orthologues in eight other plant species. Levels of sequence identity between *Brachypodium* and its orthologues in eight other plants species displayed are depicted as blue peaks. Pink bars signify segments that pass the alignment criteria of 70% identity over 100bp window.
