15 RRH: CALATAYUD ET AL.—REPRODUCTIVE BEHAVIORS IN SRM BOREAL TOADS

16

17 ABSTRACT: Loss of reproductive viability, physiologically and/or behaviorally,
18 can have profound effects on the fitness of a captive population and conservation efforts.
19 The southern rocky mountain (SRM) population of the boreal toad has declined over the
20 past 35 years, making captive breeding necessary to protect and augment the species in
21 the wild. In recent years, a notable reduction in the incidence of amplexus and viable
22 offspring from the captive breeding population has been observed. Hormone treatment
23 protocols to stimulate gamete release in males and females are established in this species
24 and *in vitro* fertilization has been performed successfully. However, successful hormone
25 stimulation of reproductive behaviors and natural fertilization has not been well
26 documented. During the breeding season of 2012, 24 males and 24 female toads were
27 selected from a population of over 600 captive animals. Both sexes were treated with
28 Human chorionic gonadotropin (hCG) and Gonadotropin Releasing Hormone (GnRH) or
29 phosphate buffered saline (PBS). Females were primed twice with 3.7IU/g hCG and then
30 injected with an ovulatory dose (OvD) of 13.5 IU/ g BW (Body weight) hCG and 0.4 µg/
31 g BW GnRH. Males were injected a single time with 10 IU/g BW hCG and 0.4 µg/ g
32 BW GnRH, 12 h after females received their OvD. In 2013, knowing the approximate
33 time when females oviposited after hormone treatments, we tested the best time to induce
34 amplexus and spermiation. Males were divided into 4 groups and injected at 4 different
35 times: (a) 12 h before females OvD; (b) at the same time as OvD; (c) 12 h after OvD; (d)
36 control injected with PBS. Results from 2012 indicated that oviposition was solely
37 dependent on females receiving hormone treatments not males. However, in 2013 we
38 found that the duration of amplexus significantly influenced oviposition ($P>0.05$), and
39 males injected 12 h prior to females spent more time in amplexus than males injected at

40 the same time or 12 h after the females received hormones. Promoting reproductive
41 behaviors and synchronizing gamete deposition continues to be imprecise and may
42 require more than exogenous hormones. The complexity of promoting breeding behaviors
43 may require a closer assessment of the captive environment.

44 **Key words:** Amplexus; Gonadotropin releasing hormone (GnRH); Human
45 chorionic gonadotropin (hCG); Oviposit hormone dose (OvD); Post hormone–treatment
46 (PT); Southern Rocky Mountain boreal toad (SRM).

47

48 LOW REPRODUCTIVE capacity is not uncommon in captive amphibian populations
49 and has recently been observed in a captive population of the Southern Rocky Mountain
50 boreal toad (SRM), *Anaxyrus boreas boreas*. Human chorionic gonadotropin (hCG) and
51 gonadotropin releasing hormone (GnRH) can induce amplexus and spermiation (Roth et
52 al. 2010) in male boreal toads, abdominal contractions and oviposition in the females
53 (Calatayud et al. 2015), and can be administered to collect gametes independently for *in*
54 *vitro* fertilization. However, there is little information about when hormones should be
55 administered to males and females to induce reproductive behaviors and synchronize
56 gamete deposition.

57 In the wild, boreal toads breed after a long period of brumation in the spring or
58 early summer, depending on elevation and the time of year when snow disappears
59 (McGee and Kenaith 2004). Breeding begins when males amplex females, which can last
60 for hours or days before eggs are deposited (McGee and Kenaith 2004; personal
61 observation). In the wild, females lay between 6000–12,000 eggs per clutch and may be
62 biennial breeders (Hammerson 1999; McGee and Kenaith 2004; Carey et al. 2005; Muth

63 et al. 2013). Biennial breeding is a parameter often overlooked in amphibian captive
64 breeding programs. In temperate amphibian species that inhabit high elevations,
65 particularly for females, breeding is determined by the availability of energy reserves, the
66 environmental conditions, and the risk breeding has on an individual's lifetime fitness
67 (Muths et al. 2010, 2013). Thus, it is likely that loss of reproductive behaviors in captivity
68 is associated with inappropriate environmental stimuli and inadequate or low nutrient
69 availability. Similar to other amphibian species, captive boreal toads of breeding age (≥ 6
70 years for females; ≥ 4 years for males) that fail to exhibit normal reproductive behaviors
71 after artificial brumation can be treated with exogenous hormones to stimulate
72 reproductive behaviors and promote gamete release (Johnson et al. 2002; Herbert 2004;
73 Michael et al. 2004; Browne et al. 2006a,b; Trudeau et al. 2010; Silla et al. 2011; Kouba
74 et al. 2009; Roth et al. 2010; Kouba et al. 2012; Calatayud et al. 2015; Theo Smith,
75 personal observation). In the last 10 years, SRM boreal toads at the Native Aquatic
76 Species Restoration Facility (NASRF, Alamosa, CO) were treated with hCG and
77 luteinizing hormone releasing hormone (LHRH; or alternatively, gonadotropin releasing
78 hormone, GnRH), when reproductive behaviors, such as amplexus and oviposition, did
79 not occur naturally (Theo Smith, personal communication).

80 However, no systematic studies have addressed the efficacy of the hormone
81 protocols, whether both males and females require hormone treatments, and how efficient
82 treatments are in promoting and enhancing reproductive behaviors and gamete production
83 in the SRM boreal toad.

84 To first explore the induction of reproductive behaviors in SRM boreal toad
85 females and the importance of the male presence for oviposition we examined: (1) the

86 induction of amplexus, oviposition, and tadpole production after administration of hCG
87 and GnRH to males alone, females alone or both sexes simultaneously compared to
88 control animals; and 2) the effect of hormone treatments on breeding when administered
89 to males at different time periods in relation to the female's ovulatory dose.

90

91

MATERIALS AND METHODS

92

Housing and Maintenance

93

94

95

96

97

98

99

Male and female boreal toads were housed together in groups according to the region from which original founders were obtained at the Native Aquatic Species Restoration Facility in Alamosa, Colorado (NASRF). NASRF toads were brumated between December and May at temperatures between 2–6°C in an EcoPro G2 1350 Liter upright refrigerated cabinet (Foster refrigerator, Corp., Hudson, New York, USA) in plastic boxes (33 x 13 x 15 cm) lined with a layer of activated carbon, moistened sand (3.81 cm deep) and moistened sphagnum moss.

100

101

102

103

104

105

106

The number of individuals per group ranged from 5 to 20 and often contained multiple generations from a particular region. During the active season (outside the brumation period), toads were housed in rectangular fiberglass tanks (121 x 60 x 30 cm) tilted at a 20° angle to allow constant drainage of free-flowing groundwater. Crickets and mealworms were gut-loaded with Bug Burger®, Hydro-load® water replacement gut-load (Allen Repashy's®, La Jolla, California, USA) and fresh carrots prior to being fed to the toads. Toads were fed live prey 3 times per week.

107

108

Before reintroducing animals to specific locations in the wild, individuals from the captive colony were selected for breeding according to age (≥ 4 years for males and \geq

109 6 years for females) and county of origin, and were interbred according to a particular
110 pedigree. Therefore, male:female ratios were dissimilar as were the numbers of animals
111 per experimental group. In addition, females were only selected for breeding if they had
112 not oviposited the previous year or had not been used for breeding in 2–4 years. The
113 water temperature in the tanks during the breeding season ranged from 15–18.3 °C. Toads
114 were exposed to natural rather than artificial lighting. Egg clutches were removed from
115 the breeding tank 24 h after oviposition was complete and were transported to a separate
116 rearing facility.

117 Hormones

118 Two exogenous hormones were used during this study: an LHRH analog ([des–
119 Gly10], D–Ala6 ethylamide acetate cat#: L4513; Sigma–Aldrich, St. Louis Missouri,
120 USA) and human chorionic gonadotropin (hCG; cat# C1063; Sigma–Aldrich, St. Louis,
121 Missouri, USA). hCG was reconstituted in sterile PBS at 2,500 IU or 5,000 IU per
122 milliliter and GnRH solution was prepared at 0.4µg / 5 µL. Priming and ovulatory doses
123 are described below. All doses were administered per gram body weight (g / BW). GnRH
124 solutions were stored in 1mL aliquots at –20°C hCG and thawed on the day of injection.
125 Hormones were injected intra–peritoneal (IP) using a 27–gauge needle. Females were
126 treated with two priming doses of hCG (3.7 IU/g BW) 72 h apart and the final OvD of
127 hCG (13.5 IU/g) and GnRH (0.4 µg/g) combined was administered 24 h after the second
128 priming dose (Calatayud et al. 2015). Males received a combination dose of hCG (10
129 IU/g) (Langhorne, CJ personal communication) and GnRH (0.4 µg/g) (Trudeau et al.
130 2010). Control males and females received injections of Phosphate buffered saline (PBS)
131 alone (200 µL).

132 Experiment 1

133 In 2012, an experiment was designed to test the efficacy of hormonal induction of
134 amplexus in males, and oviposition in females. Reproductive responses in toads after
135 administration of hCG and GnRH were compared to control animals injected with PBS.
136 Females ($n = 24$) were randomly assigned to two groups, a hormone treatment or a
137 control group, of 12 females each.

138 During this experiment, the number of males' amplexing and the number of
139 females depositing eggs was recorded. The number of eggs was counted whether an
140 amplexed or an un-amplexed female deposited them. The experiment was terminated 7
141 days after the OvD if females had failed to oviposit. The experiment was also terminated
142 if a male and female in amplexus also failed to produce an egg clutch after 7 days. This
143 termination time point was based on previous observations that non-amplexed females
144 oviposit between 72–96 h after their OvD (Calatayud et al. 2015) and amplexed females
145 between 24–48 h post OvD (personal observation).

146 Experiment 2

147 In 2013, a second experiment examined the administration of hormone treatments
148 when administered to males at 3 different times, (a) hormone administration 12 h before
149 the female OvD ($n = 7$ males); (b) concurrently (at 0 h) with the female's OvD ($n = 6$
150 males); (c) 12 h post-OvD ($n = 4$ males); (d) controls (PBS) ($n = 5$ males). Five control
151 males were housed as follows: 2 male in groups A, 1 male in group C and 2 control males
152 in group B. In each group control males were injected with PBS at the same time as the
153 other males were injected in their respective groups. The uneven numbers of males in
154 groups A–C were the result of an unbalanced ratio of males to females in the colony, and

155 the particular combinations of pedigrees that were recommended for breeding. Therefore,
156 21 males were given access to 31 females and once a male had selected a female,
157 unpaired females were removed from the tank and housed separately. In this experiment,
158 all 31 females were treated with hormones as described in the 2012 experiment.

159 During this study, the percentage of males' amplexed post treatment (PT), the
160 duration of amplexus, and the number of females (whether amplexed or un-amplexed)
161 that oviposited was recorded. Males were first observed 1 h after the injection and then
162 monitored every hour for 12 h until midnight. Observations were resumed at 6am and the
163 percentage of males observed amplexing each morning was determined. Spermic urine
164 from amplexed males was collected by catheterization as described in Kouba et al. (2012).
165 However, to avoid over handling the animals during amplexus, the presence of sperm was
166 noted by collecting at least 5 μ L of spermic urine but concentration and motility were not
167 recorded.

168 Statistical analysis was carried out in R-studio (RStudio 0.99.489, © 2009–2014
169 RStudio, Inc., Cary, NC, USA) and the significance was set at $P < 0.05$. Data were
170 expressed as the mean \pm standard error. Shapiro–Wilks test for normality showed that all
171 our data sets were not normally distributed. The data were further analyzed using a
172 Levene's test to assess the equality of variances, which was found to be true for all data
173 sets. The effect of hormone treatment on males and females and the effect of amplexus on
174 mean oviposition rates were analyzed by ANOVA in relation to (1) hormone treatment of
175 males, females, or both compared to controls, and (2) amplexus and (3) time to
176 oviposition.

177 In 2013, a Shapiro–Wilks test for normality showed that all our data sets were not
178 normally distributed. Once again, a Levene’s test was performed and the assumption of
179 equal variances was found to be true for all data sets. The effect of hormone
180 administration on males and the, (1) time to amplexus, (2) duration of amplexus, (3)
181 oviposition with or without amplexus, and 4) time to oviposition in amplexed versus un–
182 amplexed females at 3 different times were analyzed by ANOVA.

191

192

193

194

Experiment 2

195

196

197

198

In 2012, hormone treatment significantly affected the number of females that oviposited ($P < 0.05$; Table 1) but oviposition was not affected by amplexus ($P > 0.05$). Oviposition in 7 hormone–stimulated amplexed females and 5 un–amplexed females was observed compared to 1 amplexed control female. Furthermore, there was a significant difference ($P < 0.05$) in the time to oviposition by non–amplexed (72 and 96 h post–OvD injections) and amplexed females (28 to 48 h post–OvD injections). Males began amplexing 6–10 h after they were injected. Treating males with hormones did not increase the probability that they would amplex females ($P > 0.05$). In 2013, experiments using hormones to induce amplexus were redesigned based on 2012 observations. In this study, males were separated into four groups and injected at different times with respect to female injections. Although hormone treatments did not have a significant effect on the induction of amplexus ($P > 0.05$) and amplexed males

199 were not more likely to induce oviposition ($P > 0.05$), the time spent in amplexus was
200 significantly influenced by the time at which they were treated with hormones ($P < 0.05$).

201 The average time taken for a male to amplex was 12–14 h PT. The time spent in
202 amplexus was significantly different (26 h PT; $P < 0.05$) between males in group A
203 (injected 12 h prior to OvD) compared to the other three groups, B (injected at the same
204 time as OvD), C (injected 12 h after OvD) and control, (injected with PBS according to
205 the treatment group with which they were housed A, B or C). The percentage number of
206 males in amplexus at 12 h PT was greater in group A (57 %) than in groups B (17 %), C
207 (25 %) and control (20 %), and remained higher than other groups after 26 h PT. At 26 h
208 PT, group A had 57 % of males still amplexed, while group B and C had 0% males
209 amplexed and the control group had 50 % (Table 2). Males in group A spent more
210 consecutive hours in amplexus with a mean of 34 ± 4.36 h before oviposition occurred,
211 compared to males in the control group and groups B, C which had a mean of 18.38 h
212 ± 3.06 h. The total number of eggs oviposited in group A was higher than in other groups but the
213 mean number of eggs oviposited among the groups was not significantly different (Fig. 1).
214 Collection of spermic urine was performed to verify a complete reproductive response to
215 hormones. Hormone-treated males showed an initial production of sperm at 3 h PT
216 before becoming amplexic indicating a faster spermiation than behavioral response to the
217 hormone. In three control males, sperm was first detected between 9–12 h after PBS
218 injection, when amplexus was first detected. The presence of sperm in control males,
219 continued to be observed in samples collected at 24 and 48 h PT the same duration as
220 hormone-treated males.

244 of amplexus. Sexual receptivity in female anurans has been correlated with elevated
245 gonadal steroids, readiness to oviposit and egg maturity (Wilczynski et al. 2005, review).
246 Therefore, initial female resistance to a potential mate may decrease as circulating
247 estrogen and progesterone reach peak levels (Lynch and Wilczynski 2006). Female
248 receptivity would increase as egg maturation and ovulation was induced by hormone
249 treatment and may provide a strong signal to nearby mates regardless of whether the
250 males have received a hormone treatment.

251 As mentioned in our previous study, it is likely that priming doses of hCG caused
252 a gradual rise in circulating LH levels in treated females, which culminated in an LH
253 surge and increased progesterone production in developed oocytes, resulting in ovulation
254 (Amsterdam et al. 1989; Fernandez and Ramos 2003; Calatayud et al. 2015). However,
255 we suggest that amplexus with a male causes the female to oviposit faster.

256 Results from 2013 indicated that females that were amplexed by males that had
257 been injected 12 h prior to the female receiving an OvD oviposited at significantly earlier
258 times. Although amplexus did not significantly affect oviposition, the external stimulation
259 provided by the male may provide a physical mechanism that increased the rate at which
260 the eggs travelled through the oviduct, compared exclusively to the abdominal
261 contractions observed in the females. Nevertheless, it is unclear whether the influence of
262 amplexus on oviposition was overshadowed by the stronger influence of hormones, since
263 we did observe oviposition by one control female after becoming amplexed.

264 In anurans such as *Bufo japonicus*, under normal conditions, amplexus causes an
265 LH surge, which in turn stimulates spermiation (Ishii and Itoh 1992). GnRH stimulates
266 the brain to produce LH and FSH in the pituitary and, as shown in *Bufo cognatus*, the

267 testes produce sperm and the associated Leydig cells produce increased levels of
268 testosterone (Propper and Dixon 1997). The induction of spermiation before amplexus in
269 hormone treated toads may be the result of hCG acting directly on the testes before GnRH
270 can act on the brain to elicit an LH surge. In this instance, amplexus may occur after
271 spermiation because hCG stimulates protein secretion by Sertoli cells which, in turn
272 stimulate Leydig cell steroid biosynthesis increasing testosterone and with it reproductive
273 behaviors as reported in mice (Onoda et al. 1991; Langhorne 2016). While hCG may be
274 directly affecting earlier spermiation in the testis, hCG may also enhance GnRH induced
275 LH surge, which results in amplexus after spermiation. The detection of sperm at 24 and
276 48 h PT suggests that, once the behavior has been elicited, amplexus is sufficient to
277 maintain the complete reproductive responses of the male. This theory supports our
278 results, which show that males injected 12 h before females remained in amplexus for
279 longer than males that were injected at the same time or 12 h after females. This is not
280 surprising because males in group A would have to wait longer for the females they
281 amplexed to be ready to oviposit, compared to males that were injected at the same time
282 or 12 h after females.

283 In amphibians, the administration of hormones and their influence on egg
284 maturation is not well understood, nor are the effects of repeated, long-term hormone
285 treatment. Management should also consider the possibility that females may not breed
286 every year and may skip two or more breeding seasons before ovipositing again (Carey et
287 al. 2005; Muths et al. 2010). Additionally, we have not explored the effects of age,
288 breeding history and frequency of hormone use on the reproductive health of these
289 animals. Analyzing egg quality in females of different ages may be necessary to

290 determine if breeding females over a certain age results in low fertilization rates or poorer
291 quality offspring. Age assessments, with regards to male contribution to fertilization,
292 should also be studied in the future.

293 This study demonstrated that, although exogenous hormones are not required to
294 induce amplexus in the captive boreal toad, injecting males may; (1) be beneficial in
295 increasing the length of time they amplex and spermiate and (2) increase the chances of
296 synchronizing gamete deposition.

297

298 CONCLUSIONS

299 It appears that it is not necessary to hormonally treat male boreal toads to induce
300 amplexus or spermiation. However, males that are hormonally treated 12 h before
301 females receive an OvD amplexed for longer, which implies that hormone treatment may
302 be important for gamete synchronization in captive breeding efforts. It may also be
303 favorable to expose males to females when they are receiving priming doses, to allow
304 males' time to respond to the female's physiological response.

400 TABLE 1.—Shows the number of females in control and hormone treated groups, the number and percentage that oviposited,
401 were amplexed, oviposited with or without the aid of a male (without amplexus). In 2012, no significant differences were
402 observed between the females that oviposited after amplexus and those that oviposited without amplexus. However, there
403 was a significant difference between the number of eggs oviposited between control and hormone treated females.

415

416

	Treatment		<i>P</i> -value
	Control	Hormone	
Total number of females	12	12	
Number of amplexed females	2	7	
Percentage amplexed	17	58	
Number of females ovipositing	2	4	
Percentage females oviposited	17	33	
Total eggs produced	3,726	15,987	
Mean number of eggs	1,863	3,997	<i>P</i> < 0.05
Total number of eggs with male amplexus	3,726	4,525	
Mean number of eggs with male amplexus	1,863	2,284	<i>P</i> > 0.05
Total number of eggs without male amplexus	0	11,462	
Mean number of eggs without male amplexus	0	2,292	<i>P</i> > 0.05

418 TABLE 2.—Male hormone treatment summary shows number of males treated with hormones in each group, the number and
 419 percentage that amplexed a female and the number of eggs that resulted from those pairings.

	Male number	Amplexed pairs	% Amplexed pairs	Total eggs
Control	5	1	20	5,926
Group A	7	4	57	9,646
Group B	6	1	17	1,852
Group C	4	1	25	2,436

420

421

422 FIGURE CAPTIONS

423 FIG. 1.—Total number of eggs deposited by amplexed pairs during the breeding season of
424 2013. Treatment groups reflect the differences in the time at which males were injected, since all
425 females received their injection at the same time (with male group B). Male treatment group's
426 A) hormone administration 12 h before the female OvD ($n = 7$ males); group; B) concurrently (at
427 0 h) with the female's OvD ($n = 6$ males); group; C) 12 h post-OvD ($n = 4$ males); D) control
428 males (PBS) ($n = 5$ males). Although significantly more egg clutches were oviposited by pairs
429 from group A (3 clutches) compared to groups' B (1 clutch), C (1 clutch) and control (1 clutch),
430 the mean number of eggs deposited per clutch was not significantly different between treatment
431 groups.

432
433
434 FIG. 2.—Shows the time to oviposition by amplexed pairs in 2013. The time to
435 oviposition in groups A, B, C and control was significantly different most likely due to the time
436 at which the females were injected. Males' from group A were already amplexed when females
437 housed with them received their OvD therefore, group A males spent more time amplexed before
438 females (stimulated by hormones) were able to oviposit.

439
440
441 FIG. 3.—The total number of amplexed males in each experimental group (A—group A,
442 B—group B, C—group C and D—controls) during 2013. The five time points shown (0, 12, 24, 36,
443 48 h) reflect the number of hours post-treatment that males were observed in amplexus and egg

444 clutch represents the time post–male treatment at which egg masses were first detected. Only
445 results for egg clutches deposited by amplexing pairs are represented.
