#### Abstract

Quickly and accurately extracting information about a touched object's orientation is a critical aspect of dexterous object manipulation. However, the speed and acuity of tactile edge orientation processing with respect to the fingertips as reported in previous perceptual studies appear inadequate in these respects. Here we directly establish the tactile system's capacity to process edge-orientation information during dexterous manipulation. Participants extracted tactile information about edge orientation very quickly, using it within 200 ms of first touching the object. Participants were also strikingly accurate. With edges spanning the entire fingertip, edge-orientation resolution was better than $3^{\circ}$ in our object manipulation task, which is several times better than reported in previous perceptual studies. Performance remained impressive even with edges as short as 2 mm , consistent with our ability to precisely manipulate very small objects. Taken together, our results radically redefine the spatial processing capacity of the tactile system.

## Introduction

Putting on a necklace involves holding open a clasp while aligning it with a ring, a process that requires quickly and accurately determining and controlling each object's orientation. In this and many other fine manipulation tasks, information about an object's orientation is based largely on how its edges activate mechanoreceptors in the glabrous skin of the fingertips. Indeed, fingertip numbness due to events like cold exposure and nerve injury can degrade or even preclude fine manual dexterity ${ }^{1,2}$.

No previous studies have examined the speed and accuracy with which the neural system extracts and expresses tactile edge orientation information during object manipulation tasks that require fine manual dexterity. However, perceptual studies of tactile edge orientation have been done ${ }^{3-5}$, and for edges that span a large portion of the fingertip, the reported orientation acuity is $10-20^{\circ}$. For shorter edges, which only engage a small part of the fingertip, as is typical during fine manipulation tasks like buttoning, the reported perceptual orientation acuity is even cruder, around $90^{\circ}$ for a 2 mm long edge ${ }^{5}$. These psychophysical measures appear too crude to underlie the control of dexterous object manipulation and tell little about the speed by which the brain can extract and use tactile edge orientation information.

Here we used a novel experimental paradigm to establish the tactile system's ability to process edge-orientation information during object manipulation. In our main experiment, participants used their fingertip to contact a randomly oriented dial and, based on only tactile information gathered from a raised edge located on the dial, quickly rotated the dial to orient a pointer towards a target position (Fig. 1a-d). We found that participants oriented the pointer strikingly well. On average, participants were within $3^{\circ}$ of the target orientation for edges spanning the entire contact area of the fingertip, similar to their performance in a visually-guided version of the same task, and considerably better than the acuity of edge orientation processing previously reported in studies of tactile perception ${ }^{3-5}$. Performance remained impressive even
with much shorter edges, with participants orienting the unseen dial to within $11^{\circ}$ of the target orientation for a 2 mm long edge. We also found that participants gathered and processed the relevant tactile information quickly, initiating appropriate dial rotation within $\sim 200 \mathrm{~ms}$ of initially touching the edge. Based on a simple model, we propose that this exquisite capacity may reflect a previously largely overlooked feature of the peripheral tactile apparatus ${ }^{6-9}$ - namely, that first-order tactile neurons branch in the fingertip skin ${ }^{10-12}$ and have cutaneous receptive fields with multiple highly-sensitive zones (or "subfields") ${ }^{13-16}$.

## Results

In our main experiment, ten study participants stood at a table holding the tip of their right index finger at a home position located above a dial (Fig. 1a-1). An auditory signal instructed the participants to execute the task, which was to move their finger down from the home position to contact the dial at its center of rotation (Fig. 1a-2) and, based on tactile information gathered from a raised edge located on the dial (see below), to rotate the dial and orient a pointer, attached to the dial, from its initial position towards a center position (Fig. 1a-3). This action corresponds to touching, from above, the needle of a compass and, by rotating the fingertip, orienting it from some initial position, say northwest or northeast, to due north (labeled $0^{\circ}$ ). The initial orientation of the dial was randomized across the trials yielding six initial pointer positions relative to the due north target $\left( \pm 30^{\circ}, \pm 20^{\circ}, \pm 10^{\circ}\right)$. Hence, correctly orienting the dial required rotating the dial either clockwise or counter-clockwise by $10^{\circ}, 20^{\circ}$ or $30^{\circ}$. Shutter glasses prevented the participants from seeing the dial and pointer before and during the rotation. When the dial rotation ended, we measured the resultant pointer position and assessed the alignment error from due north (Fig. 1a-4). At the same time, the shutter glasses opened, which gave the participant visual feedback about their performance. If the resultant pointer position was off the due north target by more than $\pm 2^{\circ}$, participants were required to adjust, under visual guidance, the pointer to within $\pm 2^{\circ}$ of the due north target position. A raised edge on the contacted surface, the length of which constituted a key experimental variable, was oriented in the direction of the dial's pointer and provided tactile information about the dial's orientation relative to the fingertip (Fig. 1b-d). Figure 1e shows exemplar pointeralignment trials from one participant. When the participant contacted the dial, the normal force increased to a plateau-like force that was maintained until the trial ended. Typically, the rotation of the pointer started while the contact force was still increasing. The rotation velocity profile often showed one major velocity peak, but could also show two or more peaks indicating that one rotation could sometimes comprise two or even more sub-movements.

## Tactile edge orientation is extracted and processed very accurately in manipulation

Participants learned the tactile pointer-alignment task quickly during a practice block and there were no signs of further learning during the experiment (Fig. S1). Figure 2a shows the distribution of alignment errors for all pointer-alignment trials by all ten participants separated for each of the six edge lengths, ranging from a small dot of

Page 3

## Orientation processing during manipulation

zero length that provided no orientation information to an infinite edge spanning the entire area contacted by the fingertip (Fig. 1c). For the infinite edge, the resulting pointer positions were concentrated around the $0^{\circ}$ target position. As the edge length decreased, the distribution gradually became broader indicating that, on average, the alignment error increased. An increased frequency of trials with rotation in the wrong direction, that is, away from the target, contributed to this increase (gray segments of the distributions in Fig. 2a).

Figure 2b shows the absolute value of the alignment error for all trials (correct and incorrect rotation directions) as a function of edge length based on median values for individual participants. Edge length significantly affected the absolute alignment error ( $F_{5,45}=238.5, \mathrm{P}<10^{-6}$ ), which gradually decreased with increasing length. With the infinite edge, the error was $2.9 \pm 0.5^{\circ}$ (mean $\pm 1$ SD across participants) and with the 2 mm edge it was $11.1 \pm 2.9^{\circ}$, which was about one half of the error with the raised dot (i.e., 0 mm edge length) representing chance performance. Figure 2c illustrates how the sensitivity to edge orientation relates to the events at the fingertip by illustrating the 2,4 and 8 mm edges projected twice on a fingerprint at an angular difference of $4.0,5.9$ and $11.1^{\circ}$, respectively. These angular differences correspond to the average absolute alignment error with these edge lengths, and result in positional changes at the end of the edge of $0.28,0.21$ and 0.19 mm , respectively, if rotated around their centers.

One reason that alignment error increased with shorter edges was that participants more frequently rotated the dial in the wrong direction ( $\mathrm{F}_{5,45}=258.4$; $\mathrm{P}<10^{-6}$ ). The proportion of movements in the correct direction gradually decreased from nearly $100 \%$ with the infinite edge down to chance performance ( $\sim 50 \%$ ) with the raised dot (Fig. 2c). If $75 \%$ correct responses define threshold performance, as is common in two alternative forced choice (2AFC) tasks, the average threshold of edge length for correct rotation direction was around 2 mm .

Another reason for the increased alignment error with shorter edges was that the scaling of pointer displacement based on the initial dial orientation became poorer for trials in the correct direction. Figure $\mathbf{2 e}$ shows, for each initial dial orientation and edge length, the distribution of pointer displacements in the direction of the target for all trials by all participants (negative displacements indicate movements in the incorrect direction) and Fig. 2f shows the displacement for movements in the correct direction based on participants' medians. With the infinite edge, participants appropriately scaled pointer displacements in the sense that the alignment error was, on average, close to zero for each initial orientation (top panel in Fig. 2e). However, there was a tendency to undershoot the target with the $\pm 30^{\circ}$ initial orientations and overshoot the target with $\pm 10^{\circ}$ initial orientations. When the edge length decreased, for movements in the correct direction participants tended to increasingly undershoot the target for the $\pm 30^{\circ}$ and $\pm 20^{\circ}$ initial orientations, whereas they tended to overshoot with the $\pm 10^{\circ}$ orientations (Fig. 2f). Indeed, there was a significant interaction between edge length and initial orientation $\left(F_{25,225}=21.1\right.$; $\left.\mathrm{P}<10^{-6}\right)$ together with main effects of edge length ( $F_{5,45}=14.1 ; \mathrm{P}<10^{-6}$ ) and initial orientation ( $\mathrm{F}_{5,45}=77.5$; $\mathrm{P}<$

## Orientation processing during manipulation

$10^{-6}$ ) on the displacement in the correct direction. Post-hoc analyses failed to show a significant effect of sign of the initial orientation on the pointer displacement in the correct direction for the $\pm 10^{\circ}, \pm 20^{\circ}$ and $\pm 30^{\circ}$ orientations. For the raised dot, which provided no edge orientation information, participants nevertheless generated pointer movements of $\sim 15^{\circ}$. However, since these were in one direction or the other, with approximately equally probability and amplitude, virtually no pointer displacement occurred on average (bottom panel in Fig. 2e). Performance with the 1 mm edge was similar to that observed with the raised dot although some sensitivity to the initial dial orientation was apparent. For the 4 and 8 mm edges, we noted that the proportion of trials with movements in the wrong direction tended to be greater for the $\pm 10^{\circ}$ than for the $\pm 20^{\circ}$ and $\pm 30^{\circ}$ initial orientations (Fig. 2e). This impression was statistically supported by an interaction effect of initial orientation and edge length ( $F_{25,225}=3.0 ; P$ $=8 \times 10^{-6}$ ) on the proportion of movement in the correct direction, along with a main effect of the initial orientation ( $F_{5,45}=8.3 ; P=10^{-5}$ ).

Because the dial was initially oriented at one of six orientations in the main experiment, it is possible that participants may have learned six responses and then selected one of these responses based on coarse discrimination among the six initial orientations ( $10^{\circ}$ apart). There are at least two reasons why this situation is unlikely. First, participants showed no tendency to move in multiples of $10^{\circ}$ with short edges suggesting that they utilized tactile information about dial orientation in an analog manner to program the movement rather than attempting to categorize which of the six possible orientations was presented and then selecting the appropriate motion (Fig. 2e). Second, in a follow-up experiment performed with the infinite edge and involving 50 rather than 6 initial dial orientations (see Methods), the absolute alignment ( $2.7 \pm 0.4^{\circ}$; mean $\pm 1$ SD across participants) did not differ significantly from that recorded in the main experiment ( $2.9 \pm 0.5^{\circ} ; F_{1,18}=1.19 ; P=0.29$ ).

Taken together, we found that tactile information about edge orientation could effectively guide manipulation for edges that were 2 mm and longer and, with an edge of infinite length relative to the fingertip, alignment accuracy was, on average, better than $3^{\circ}$. We focused our remaining analyses on edges that were 2 mm and longer.

Tactile edge orientation is extracted and processed very quickly in manipulation

Manual dexterity depends not only on access to accurate spatial tactile information but also requires that it is quickly available. We investigated how quickly participants extracted and used tactile edge orientation information in our pointer-alignment task by examining the time between initial contact with the dial and the onset of the rotation as well as the development of contact force and rotation kinematics.

Averaged across participants' medians, the time between touch and rotation onset was $0.20 \pm 0.02 \mathrm{~s}$ (Fig. 3a). Rotation onset typically occurred while the contact force was still increasing towards its plateau-like state (Figs. 1b and 3b), which, on average, was reached $0.31 \pm 0.09 \mathrm{~s}$ after initial contact with the dial. Accordingly, the contact force at rotation onset ( $1.15 \pm 0.44 \mathrm{~N}$, Fig. 3c) was typically smaller than the
plateau force ( $1.64 \pm 0.83 \mathrm{~N}$, Fig. 3d; $F_{1,9}=11.5 ; P=0.008$ ). Edge length and initial dial orientation showed no statistically significant effect on any of these measures.

The duration of dial rotation tended to increase with the required rotation amplitude but the size of this effect depended on the edge length. Shorter edges that yielded smaller pointer displacements also yielded shorter rotation durations (Fig. 3e). This was reflected statistically as main effects of both edge length and initial dial orientation on the rotation duration $\left(F_{3,27}=6.2, P=0.002\right.$ and $F_{5,45}=15.0, \mathrm{P}<10^{-6}$, respectively) as well as an interaction between these factors ( $\mathrm{F}_{15,135}=4.5, \mathrm{P}<10^{-6}$ ).

Although the task explicitly emphasized accuracy, participants initiated the rotation movement much sooner after contact ( $\sim 0.2 \mathrm{~s}$ ) than the maximum permitted delay (see Methods). By exploiting the within-participant variability in rotation onset time (SD ranged from 0.046 s to 0.055 s across participants), we examined whether participants improved performance by taking more time to accumulate and process tactile information. For each participant, we ran an ANCOVA with absolute alignment error as the dependent variable and rotation onset time as a continuous predictor and edge length and initial dial orientation as categorical predictors. None of the participants showed a significant relationship between the absolute alignment error and the rotation onset time ( $0.01<\mathrm{F}_{1,399}<3.86 ; 0.05<\mathrm{P}<0.93$, uncorrected for multiple comparisons). In a corresponding analysis, we found that none of the participants showed a significant relationship between rotation duration and absolute alignment error ( $0.07<\mathrm{F}_{1,399}<3.41 ; 0.07<\mathrm{P}_{\text {uncorrected }}<0.79$ ). Likewise, we found no reliable effect of the whole trial duration (that is, the entire time from touch to the end of the rotation) on absolute alignment error ( $0.01<\mathrm{F} 1,399<6.17 ; 0.01<\mathrm{P}_{\text {uncorrected }}<0.92$ ).

We also tested if sub-movements during dial rotation improved alignment accuracy
(Fig. 1, Fig. S2a-d). We reasoned that tactile processing of edge orientation might continue while the first movement was executed, which could improve the programming of subsequent movements (the second sub-movement, on average, commenced $0.22 \pm 0.02 \mathrm{~s}$ after rotation onset). We found sub-movements in $44 \%$ of all trials. The frequency distribution of trials with and without sub-movements was similar for all edge lengths (Fig. S2c) and trials with sub-movements were present in all participants (Fig. S2d). Repeated measures ANOVAs with edge length, initial dial orientation, and presence of sub-movements as factors failed, however, to indicate a significant effect of sub-movements on the absolute alignment error (Fig. S2e) or on the proportion of rotations in the correct direction (Fig. S2f).

Taken together, these results suggest that study participants generated the dial rotation action based on tactile information extracted and processed essentially within ~200 ms of initial contact.

## Touch is nearly as good as vision

To benchmark pointer alignment accuracy based on touch, we had the same participants as in the main experiment to perform a visual version of the pointer alignment task. The experiment was identical to the main experiment with two exceptions. First,
the shutter glasses opened at the onset of the auditory signal that instructed the participant to execute the task and remained open until the dial was contacted, which in practice implied that the participants could view the pointer position and the target location for $0.64 \pm 0.20 \mathrm{~s}$ before rotation onset. Second, only the raised dot was used. Hence, in contrast to the main experiment where participants obtained information about the initial dial orientation solely by touching the dial, in the visual pointeralignment task they obtained this information solely by seeing the pointer before touching the dial. We compared performance in the visually guided trials with that in the infinite edge condition from the main experiment, which yielded the best accuracy based on tactile information.

Alignment performance was marginally better in the visual than in the tactile condition
(Fig. 4a,b). The smaller absolute alignment in the visual condition $\left(2.1 \pm 0.5^{\circ}\right)$ than in the tactile condition $\left(2.9 \pm 0.5^{\circ} ; \mathrm{F}_{1,9}=12.9, \mathrm{P}=0.006\right)$ mainly stemmed from smaller errors in the visual trials with initial dial orientations closest to the $0^{\circ}$ target (Fig. S3a). The rotation onset time in the visual condition $(0.07 \pm 0.04 \mathrm{~s})$ was shorter than in the in tactile condition ( $0.20 \pm 0.02 \mathrm{~s} ; \mathrm{F}_{1,9}=201.5, \mathrm{P}<10^{-6}$ ) (Fig. S3b), presumably because participants could program the movement based on visual information obtained before touching the dial. The time from touch until contact force reached its plateau was modestly shorter in the visual condition ( $0.25 \pm 0.10 \mathrm{~s}$ as compared to $0.31 \pm 0.10 \mathrm{~s} ; \mathrm{F}_{1,9}=16.8, \mathrm{P}=0.003$; Fig. S3c). Nevertheless, for all participants in the visual condition the onset of the rotation occurred during contact force increase. In fact, the sensory condition did not significantly influence the contact force at rotation onset or the plateau force (Fig. S3d,e) and there were no statistically significant effects related to initial dial orientation on these timing and contact force parameters.

The kinematic structure of the rotation movement was remarkably similar in the visual and tactile pointer-alignment trials. First, we found no statistically significant effect of sensory condition on rotation duration (Fig. S3f). Second, as for the tactile condition, in the visual condition none of the participants showed a significant effect of rotation onset time ( $0.011<\mathrm{F}_{1,100}<3.72 ; 0.06<\mathrm{P}_{\text {uncorrected }}<0.92$ ) or on the duration of the pointer rotation ( $0.002<\mathrm{F}_{1,100}<2.47 ; 0.12<\mathrm{P}_{\text {uncorrected }}<0.96$ ) on alignment error. Third, the frequency distribution of sub-movements did not significantly differ between the visual and tactile conditions (Fig. S3g,h).

Taken together, the comparison of the tactile and the visual pointer-alignment trials revealed similar dial orientation accuracy and kinematics.

## A simple model of edge orientation processing

Here, we propose a straightforward explanation of the tactile acuity we observed based on a generally overlooked feature of the peripheral apparatus - namely, that first order tactile neurons branch in the glabrous skin of the hand and innervate many spatially well segregated mechanoreceptive transduction sites ${ }^{10-12}$. This arrangement yields first-order tactile neurons with heterogeneous cutaneous receptive fields that include many highly sensitive zones or "subfields", apparently randomly distributed within a circular or elliptical area typically covering five to ten papillary ridges ${ }^{13-15}$. At
the neuronal population level, the high degree of receptive field overlap in the fingertips implies that first-order tactile neuron subfields are highly intermingled (Fig. 5a). Thus, for edge orientation processing, an edge contacting the skin at a certain location and orientation will primarily excite that subset of the neurons whose subfields spatially coincide with the edge, while a different subset of neurons will be primarily excited for a slightly different edge orientation (Fig. 5b).

We modelled a virtual patch of skin with known biological constraints to show how, under a coincidence-coding scheme ${ }^{17-20}$, the presence of heterogeneous receptive fields with many subfields influences edge orientation resolution as a function of edge length (see Methods). Briefly, the virtual patch was innervated by synthetic units (i.e., first-order tactile neurons) with innervation density ${ }^{21}$ and receptive field size ${ }^{22}$ based on the known human physiology. Each unit's receptive field was actually composed of receptor elements (i.e. mechanoreceptive transduction sites), the number, size and location of which was parameterized. We simulated the population response to edges that varied in length and orientation. Each unit in the population could be in two discrete states: active if the stimulus intersected any of its subfields or inactive otherwise. We deemed that the population response reliably differentiated between edge orientations when $5 \%$ of the relevant units changed their state between two orientations (see Methods).

Here, we compared two versions of the model. One where units had unique subfields by virtue of being connected to a random ( $2-64$ ) number of receptors each $250 \mu \mathrm{~m}$ in diameter and placed randomly in the units nominally circular receptive field. And, as a comparison, another model where all units had receptive fields with uniform sensitivity by virtue of being connected to one receptor element whose receptive zone corresponded to the unit's receptive field boundary. Figure 5c show the outcome of our modelling effort, which yielded three key insights. First, the model with subfields performed at levels slightly better than our human participants - showing discrimination thresholds $1.3^{\circ}$ for the infinite length edge to $13.1^{\circ}$ for the 1 mm long edge. Second, the model with subfields always outperformed the model with a uniform receptive field. Third, and perhaps most interestingly, the performance gap between the two models grew for shorter edges (infinite edge difference $=6.4^{\circ} ; 1 \mathrm{~mm}=28.4^{\circ}$ ), suggesting that heterogeneous receptive fields are particularly beneficial for demanding tasks that utilize tactile information approaching the limits of the system's spatial resolution.

## Discussion

Our study provides the first quantitative account of fine tactile spatial processing during object manipulation. Our findings reveal exquisite sensitivity to edge orientation For edges spanning the entire contact area of the fingertip, accuracy in the tactile pointer-alignment task was on par with that when the participants used vision to orient the pointer (Fig. 4). Performance was impressive even with much shorter edges, Interestingly, the threshold edge-length for $75 \%$ correct rotation direction was $\sim 2 \mathrm{~mm}$ (Fig. 2d), which corresponds to the dimensions of the smallest of manageable objects in everyday tasks. For example, the dimensions of jewellery clasps or buttons

Page 8
designed to be as small as possible for aesthetic reasons, rarely have edge lengths that go below $\sim 2 \mathrm{~mm}$.

## Action versus perception

Tactile edge orientation acuity has previously been examined in perceptual discrimination and identification tasks. The reported orientation acuity is $10-20^{\circ}$ for edges that span a large portion of the fingertip ${ }^{3-5}$ and around $90^{\circ}$ for a 2 mm long edge ${ }^{5}$. This sensitivity to edge orientation is substantially worse than that in our tactile point-er-alignment task ( $3^{\circ}$ and $11^{\circ}$ for the infinite and 2 mm edge lengths, respectively). Several factors may be considered when interpreting this difference.

First, in all of these perceptual tasks, participants report orientation quite a long time (seconds) after the stimuli have been removed from the fingertip and therefore must base their report on a memorized representation of the stimuli, which would decay over time. Of course, memory would have also played role in our tactile pointeralignment task. Although the planning and launching of the rotation movement occurred soon after the dial was initially touched, participants had to maintain the relevant spatial references for planning the movement in working memory since direct sensorimotor information (visual, proprioceptive, efference) about the target position was last available $\sim 3 \mathrm{~s}$ before the touch, i.e., at the end of the previous trial. On the one hand, this is a significant amount of time in view of the decay rate of spatial working memory information reported for planning reaching and grasping movements ${ }^{23-25}$. On the other hand, the working memory load should be tempered because the target position in our experiment was constant across trials.

Second, whereas participants in our pointer-alignment task actively contacted the object, in the perceptual tasks the edge stimuli were applied on an immobilized finger. Therefore, in the pointer-alignment task, participants had the opportunity to configure their entire sensorimotor system to optimize performance by controlling when and how the object was contacted ${ }^{26}$. However, provided that the skin deformations are similar to each other under active and passive conditions, active information seeking seems not to significantly improve spatial discrimination in perceptual tactile tasks ${ }^{27-}$ ${ }^{29}$. Since the edges deformed the skin essentially through perpendicular skin indentation both in our task and in the perceptual tasks, it is unclear whether active touch contributed to the higher edge orientation sensitivity in our study.

A third factor, which in our view may be most important for superior edge orientation sensitivity in object manipulation compared to perceptual tasks, concerns differences in how tactile information is spatially processed to support the behaviour in the two situations. In object manipulation, tactile information about edge orientation is naturally mapped onto the orientation of an object in external space and hence in the same space as the task goal. Moreover, because the object is mechanically coupled to the hand, the spatial transformation required to complete the task (i.e., object rotation) can be directly mapped onto motor commands. In contrast, perceptual discrimination and identification tasks are thought to involve additional processing, including high level cross-modal processing in generation of memorized amodal or multisensory
mental images of stimuli for cognitive comparisons and assessment of similarities and differences ${ }^{30-34}$. It is well established that access to, and processing of, visual information can differ in action and perception ${ }^{35-39}$, and different cortical processing pathways have been associated with vision for action and vision for perception ${ }^{40,41}$. Importantly, a similar scheme is thought to be involved in the processing of tactile/haptic information ${ }^{42}$.

## Processing speed

Our findings also reveal the speed with which fine macro-geometric tactile information can be processed and used by the motor system; something not addressed in previous perceptual studies. The time from touch to rotation onset in the tactile pointeralignment task was ~200 ms. In this time, participants established contact with the dial, acquired and processed edge orientation information, and programmed and initiated the rotation movement. Since the rotation movement could be programmed before touch in the visual trials, it seems reasonable to suggest that the added time between touch and rotation onset in the tactile trials ( $\sim 130 \mathrm{~ms}$ ) represents the time actually required to extract and process tactile edge orientation information. Such fast acquisition and use of tactile information is in agreement with the automaticity by which tactile signals are used in other aspects of object manipulation, including mechanisms supporting grasp stability ${ }^{43}$ and target-directed reaching guided by touch ${ }^{44}$. Likewise, as with other action patterns rapidly triggered by tactile events during unfolding manipulation ${ }^{44,45}$, we found no effect of the fidelity of the sensory information (i.e. edge length) on the latency of the triggering action (i.e., the start of rotation). This contrasts with typical results of perceptual studies where the reaction time measures typically increase when the credibility of the sensory information decreases ${ }^{46}$.

We found that participants did not improve their performance by taking more time to process tactile information during the trial duration or by making sub-movements during the rotation. These results suggest that the important tactile information used in our task was acquired very soon after the edge was initially touched ${ }^{17}$ and thus signalled by the dynamic responses in first order tactile neurons when the edge deformed the skin during the contact force increase. Indeed, tactile afferent information available later during the rotation would have been restricted largely to gradually fading responses in some of the slowly adapting tactile neurons. Interestingly, the dynamic response of first order tactile neurons also seems highly informative for the perception of edge orientation since the duration of stimulation seems to marginally influence performance psychophysical tests - indenting the fingertip with a 10 mm long bar for 400 ms compared to 100 ms only slightly improved average orientation identification threshold (from $26.6^{\circ}$ to $\left.23.4^{\circ}\right)^{4}$.

## Tactile versus visual acuity

Our comparison of the tactile and the visual pointer-alignment trials revealed similar dial orientation accuracy. We justify our comparison by the fact that both tasks primarily gauged the accuracy of movement planning before rotation onset, where touch
specified the initial orientation of the dial in the tactile task and vision in the visual task. Since there was no visual feedback during the rotational movement in any of the tasks, in both tasks the information available for possible online control of the pointer's state (position, velocity) was restricted to proprioceptive and/or efference information about the movement of the hand ${ }^{47}$. The fact that the edge was touched during the rotation in the tactile trial did not mean that tactile afferent signals from the fingertip conveyed information about the pointer's state during the rotation. Tactile signals related to the orientation of the edge would provide information about the pointer's orientation relative to the fingertip rather than information about the pointer's orientation in external space. Because of its very low rotational friction and moment of inertia (see Methods), the dial offered negligible resistance to rotation, limiting skin deformation changes related to rotation of the dial (i.e., no rotational slips and virtually no twist forces impeding the movement occurred in the digit-dial interface during the rotation). However, we cannot fully exclude that signals mainly in slowly adaptive tactile neurons could have helped in the tactile task by facilitating possible proprioceptively based online control by gradually improving the assessment of the orientation of the edge relative to the fingertip during the ongoing movement. On the other hand, a disadvantage for the tactile task in this comparison was the decay of working memory, which provided information necessary for maintaining spatial references for motion planning (see Action versus Perception section above). Such decay could have deteriorated tactile performance in a manner that did not affect the visual task, in which the target, hand and pointer all were visible during movement planning.

## Neural mechanisms

The actual sensitivity of the tactile apparatus to edge orientation must be better than indicated by our experiment, since our approach, though naturalistic, introduces several sources of information loss in this regard. This would include noise related to arm-hand coordination and postural actions in our standing participants, as well as information loss associated with memory decay as discussed above. Yet, the edge orientation sensitivity as revealed in our tactile pointer-alignment task substantially exceeds that predicted by the Shannon-Nyquist sampling theorem if assuming a pixel-like mosaic of tactile innervation determined by the density of relevant first-order tactile neurons in the human fingertips. For example, with the 4 mm edge the average alignment error $\left(5.9^{\circ}\right)$ corresponds to a position change of just 0.21 mm at the end of the edge if rotated around its center, which is very small in relation to the $\sim 1 \mathrm{~mm}$ average spacing between receptive field centers in human fingertips ${ }^{21}$ (Fig. 2c). The ability of humans to perform spatial discrimination finer than that predicted by the average spacing between receptive field centers, termed hyperacuity, has been examined extensively in vision ${ }^{48}$, but has also been reported for touch ${ }^{7,8,49}$. The currently accepted model supporting tactile hyperacuity, built largely on neural recordings in monkeys, is based on first-order tactile neurons that have simple Gaussian-like sensitivity profiles and implies that spatial tactile details are resolved based on the relative discharge rates of neurons with neighbouring receptive fields via an unknown neural interpolation scheme ${ }^{6-9,50}$.

We propose an alternative explanation for tactile hyperacuity. We are motivated by
the fact that first order tactile neurons branch in the skin and innervate many spatially segregated mechanoreceptive transduction sites ${ }^{10-12,51-57}$, a feature of the peripheral apparatus not incorporated into previous models of tactile acuity. For the human fingertips, this arrangement yields first-order tactile neurons with heterogeneous cutaneous receptive fields that include many highly sensitive zones distributed within a circular or elliptical area typically covering five to ten papillary ridges ${ }^{13-15}$. Critically, at the population level, these receptive fields are highly intermingled (Fig. 5a) meaning an edge contacting the skin at a certain location and orientation will excite one subset of the neurons while contacting the skin at a different location or orientation will excite a slightly different subset of neurons (Fig. 5b). Under our proposed scheme, the degree to which different edge orientations synchronously engage different subsets of neurons determines edge orientation resolution, which would be higher than predicted by the center-to-center spacing of the receptive fields because the average spacing between subfields is substantially less than the average spacing between receptive field centers. This coincidence code is attractive because established neural mechanisms for central sensory processing provide rich possibilities for moment-tomoment segregation and representation of edge orientation (and other spatial features) at a speed suitable for rapid integration in the control of manipulation. That is, the massive divergence and convergence of first-order neurons in the periphery onto second and higher order neurons in the central nervous system ${ }^{58}$, together with these neurons functioning as efficient coincidence detectors ${ }^{59,60}$, allows fast feedforward processing of spatially correlated spiking activity in ensembles of first-order neurons ${ }^{15,17,43,61}$.

A fundamental question is why the nervous system evolved to sample tactile inputs via neurons that have small and heterogeneous receptive fields. We believe that the convergence of inputs from multiple mechanoreceptive transduction sites on individual first-order neurons (yielding subfields) represents an optimal scheme for preserving behaviourally relevant spatial tactile information given the relatively tight space constraints for neurons in the peripheral nerve (axons) and dorsal root ganglion (cell bodies) as compared to mechanoreceptors in the skin ${ }^{62}$. For example, recent work from the field of compressed sensing shows that randomly sampling a sparse input signal often allows it to be fully reconstructed with fewer measurements than predicted by the Shannon-Nyquist theorem ${ }^{63,64}$, suggesting that heterogeneous connections in the tactile periphery may help overcome sensory processing bottlenecks related to pathway convergence ${ }^{63,64}$.

## Methods

## Participants

Twenty healthy people ( 9 female, age range: 20-38) volunteered for these experiments. Participants provided written informed consent in accordance with the Declaration of Helsinki. The ethics committee at Umea University approved the study.

## General Procedure

Study participants stood at a table ( 90 cm high) and rested their left hand on the tabletop. The tip of their right index finger was held at a home position located above a horizontally oriented dial located on the tabletop (Fig. 1a-1). Participants were instructed to move their right index finger down from the home position to contact the dial at its center of rotation (Fig. 1a-2) and rotate the dial such that the pointer, extending from the horizontally oriented contact surface, pointed at the center position of the dial, labeled $0^{\circ}$ (Fig. 1a-3), which corresponded to orienting the pointer straight ahead. The task was considered completed when the pointer was positioned within $\pm 2^{\circ}$ of the $0^{\circ}$ target (Fig. 1a-4). A black clip attached to the dial indicated this target zone. Oriented in the direction of the pointer, a 1 mm thick raised edge on the otherwise flat contact surface of the dial provided tactile information about the initial orientation. The length of this edge and the initial orientation of the dial when initially contacted constituted experimental variables. Participants wore shutter glasses, which could prevent the participant from seeing the apparatus before and during the rotation.

## Apparatus

The pointer ( 11.5 cm long) was attached to the periphery of a horizontally oriented exchangeable circular contact surface (diameter $=44 \mathrm{~mm}$ ). The center of the contact surface was mounted on a vertical shaft of a practically frictionless potentiometer (Model 3486, Bourns Inc., Toronto, Canada) that measured the orientation of the dial (resolution $<0.1^{\circ}$ ) (Fig. 1b). Both the pointer and the contact surface were made of plastic and the entire assembly had a very low moment of inertia ( $337 \mathrm{~g}^{\star} \mathrm{cm}^{2}$ ). Due to the very low rotational friction and moment of inertia of the dial, the device exhibited virtually no mechanical resistance to rotation. A force transducer (FT-Nano 17, Assurance Technologies, Garner, NC, USA) mounted in series with the potentiometer measured the normal force applied to the contact surface. A model aircraft servo with a fork-like assembly attached to the rotation axis could set the pointer to any position within $\pm 38^{\circ}$ relative to the target position (i.e. straight ahead, $0^{\circ}$ ). When the servo had moved the dial to the set orientation, it returned to a home position so that it did not affect the range of pointer rotation, which was $\pm 38^{\circ}$. All servo actions took place between trials and, to avoid auditory cues from the motor about the initial dial orientation, the servo was programmed to always carry out a similar pattern of movements prior to each trial. Shutter glasses (PLATO, Translucent Tech., Toronto, Canada) occluded the participant's vision at specific times during the pointer-alignment trials. A loudspeaker provided auditory commands and trial feedback.

The raised edge of the contact surface was 1 mm high and 1 mm wide. It had a hemi-cylindrical top in cross section (radius $=0.5 \mathrm{~mm}$ ) and curved ends (radius $=0.5$ $\mathrm{mm})($ Fig. 1d). The length of the straight portion of the edge was varied between conditions and could be 0, 1, 2, 4, 8 or 44 mm (Fig. 1c). Since the 44 mm edge spanned the entire area of contact with the fingertip, we refer the length of this edge as being infinite. The 0 mm edge was actually a 1 mm diameter raised dot with hemispherical top. All edges $>0 \mathrm{~mm}$ were aligned with the long-axis of the pointer and

## Orientation processing during manipulation

were centered on its rotational axis, thus providing veridical information about the orientation of the pointer.

When the index finger was at its home position, it rested on the upper surface of a horizontally oriented rectangular plate ( $20 \mathrm{~mm} \times 32 \mathrm{~mm}$ ) mounted above the distal segment of the circular contact surface (Fig 1b). A raised edge, centered on the plate and spanning its entire length, was pointing towards the target position (i.e., $0^{\circ}$ ). The cross section profile of this edge was the same as the edges on circular contact surface. The function of this edge was to offer the participants a tactile reference for the finger's home position.

## Main experiment

Tactile pointer-alignment
Ten study participants volunteered in this main experiment (5 female). In periods between trials, with the shutter glasses closed, the pointer was rotated to one of six angular positions relative to the target position ( $-30^{\circ},-20^{\circ},-10^{\circ}, 10^{\circ}, 20^{\circ}$ and $30^{\circ}$ ). Therefore, reaching the target position $\left(0^{\circ}\right)$ from these initial dial orientations, required rotation of the dial clockwise by $30^{\circ}, 20^{\circ}, 10^{\circ}$ and counter-clockwise by $10^{\circ}, 20^{\circ}$ and $30^{\circ}$, respectively.

An auditory signal consisting of three short beeps ( $1.2 \mathrm{kHz}, 300 \mathrm{~ms}$ ), instructed the participant to perform a trial, which entailed moving their finger from the home position to the contact surface and turning the pointer to the target position. Participants were free to choose the speed with which to move their finger and rotate the pointer, but were told to turn the dial when contacted.

The shutter glasses opened when the rotation movement ended, defined as the time when the speed of the rotation fell below $10 \% \mathrm{~s}$ for a period $\geq 200 \mathrm{~ms}$. The rotation speed, computed online by numerical differentiation, was filtered by a first-order low pass filter with a 10 ms time constant (cut-off frequency $=16 \mathrm{~Hz}$ ). If a movement ended outside the $\pm 2^{\circ}$ target zone, the participant made final adjustments under visual guidance. When the pointer had been kept within the target zone for 300 ms , the shutter glasses closed again and the participant received auditory feedback indicating goal completion (beep @ 240 Hz for 50 ms ). If the initial movement ended within the $\pm 2^{\circ}$ target zone, the shutter glasses opened for 300 ms and when the shutters closed again, the participant received auditory feedback indicating goal completion (beep @ 240 Hz during 50 ms ). Thus, in either case, the participant obtained visual feedback about the outcome of the rotation.

The auditory feedback about goal completion indicated to the participant to return their finger to the home position. During this inter-trial period, the shutter glasses were closed and the servo rotated the dial to the initial dial orientation of the forthcoming trial. The servo started 0.8 s after the contact with the dial was broken (assessed online based on the force transducer signal) and operated for 1.8 s irrespective of the programmed dial orientation.

To engage participants and encourage good performance, after each block they received verbal feedback on the number of trials in which the rotation ended within the target zone. Furthermore, to keep the participants alert and to maintain a good pace in the experiment, the rotation had to be initiated less than 350 ms after the contact surface was touched. In trials where participants did not meet this timing requirement (< $10 \%$ ), they received auditory feedback and the trial was aborted. Aborted trials were re-inserted at a randomly selected point in the experiment. In this on-line control of the trial progression the time of touch and onset of rotation were defined by the time the normal force exceeded 0.2 N and the time rotation speed exceeded $10 \%$, respectively.

In the main experiment, each participant performed 648 pointer-alignment trials (6 edge lengths x 6 initial orientations $\times 18$ repeats), which were broken down into blocks of trials where the edge length was held constant. For each edge length, participants performed three consecutive blocks of 36 trials per block (6 initial orientations $\times 6$ repeats). Within each block, the various initial orientations were randomly interleaved preventing the participants from predicting the direction and magnitude of the rotation required to reach the target. The blocks with the various edge lengths were presented in the following order for all participants: Infinite, 8, 4, 2, 1 and 0 mm length. To familiarize subjects with the task, the participants ran one practicing block of pointer-alignment trials with the infinite edge prior to beginning the main experiment
(Fig. S1). Participants could rest between blocks as desired.

## Visual pointer-alignment

For comparison with the tactile pointer-alignment task, we also studied the performance of the same ten individuals who participated in the main experiment when they could see the dial, including the position of the pointer, and the target position before initiating the rotation. The trials were identical to the trials of the main experiment with two exceptions. First, the shutter glasses opened at the beginning of the auditory cue telling the participant to perform a trial and were open until the contact surface was touched. Second, only the raised dot was used (edge length $=0 \mathrm{~mm}$ ), meaning that 108 visual pointer-alignment trials were performed (6 initial dial orientations $\times 6$ repeats $\times 3$ blocks). As with the tactile pointer-alignment trials, participants were familiarized with the visual trials by performing one block of trials under the visual condition before first formal block was executed. The order by which the blocks of tactile and visual pointer-alignment trials were presented was counterbalanced across participants.

## Follow-up experiment

In our main experiment, the dial was initially oriented at one of six orientations. Thus, it is possible that participants may have learned 6 rote responses and then selected one of these responses based on coarse discrimination among the 6 edge initial orientations ( $10^{\circ}$ apart). Although the results of the main experiment indicate that this is unlikely (see Results), we carried out a follow-up experiment with 50 initial dial orientations to rule out this possibility.

## Orientation processing during manipulation

Ten additional participants performed the same tactile pointer alignment task used in the main experiment with the following differences. Only two edges were used: the infinite edge and the raised dot ( 0 mm edge); the inclusion of the raised dot allowed us to verify that the experiment did not include cues about the dial orientation in addition to those provided by the edge when present. For each edge, two consecutive blocks of trials were run, including 100 trials in total. The initial orientation of the edge was randomized, without replacement, between $-32^{\circ}$ to $-8^{\circ}$ and $+8^{\circ}$ to $+32^{\circ}$ in $1^{\circ}$ increments ( $0^{\circ}$ is straight ahead), resulting in 50 different initial orientations. As in the main experiment, the participants were familiarized with the task by performing one block of 50 trials with the infinite edge before the first formal block was executed. This experiment was carried out in conjunction with an experiment on perceptual edge orientation acuity not presented here.

## Data analysis

The signals representing the orientation of the dial, the orientation of the "reporting line", and the normal force applied to the contact surface were digitized and stored with 16-bit resolution at a rate of 1000 Hz (S/C Zoom, Umeå, Sweden). Using parameters that we defined during a preliminary analysis of the data, we extracted the following variables for data analysis.

The time of initial contact with the dial (initial touch) represented the event when the right index finger first contacted the contact surface. This was measured as the first instance the normal contact force exceeded 0.01 N of the median force value during a 500 ms period ending immediately before the time of the go signal. To prevent triggering on possible noise in the force signal occurring when the participant moved the finger from the home position, we first searched for a contact force exceeding 0.2 N and then searched backwards to the criterion force level.

The duration of contact force increase in the pointer-alignment trials was the period between time of touch of and the time when the contact force reached a plateau-like state. To calculate the latter time, we first calculated the force rate (i.e. derivative of force) with cut-off frequency of 8.7 Hz . We searched forward for the maximum local peak of force rate increase during the period $50-350 \mathrm{~ms}$ after touch. We then searched further forward and defined the end of force increase as the instance that the force rate first decreased below $10 \%$ of the maximum local peak force rate. At this instant, we also recorded the plateau contact force. The selected time window for peak detection avoided capturing the end of a transient, generally small, impact force that could occur when the finger initially touched the dial. It also avoided triggering on transient contact force changes that occasionally occurred late during the trials.

The rotation velocity of the dial and of the reporting line was calculated by symmetric numerical time differentiation of the dial orientation signals ( $\pm 1$ samples) after being low-pass filtered with a cut-off frequency of 17 Hz (symmetrical triangular filter). Inspection of the velocity profiles during dial rotation revealed that the rotation could possess sub-movements, i.e., it could contain multiple distinct velocity peaks (see Fig. S2a-b). We defined peaks (positive and negative) in the velocity profile by

## Orientation processing during manipulation

searching for zero-crossings (with negative slope) in the first time differential of the dial rotation speed computed as the absolute value of the rotation velocity and low-pass filtered with cut-off frequency of 8.7 Hz . For each defined peak, we recorded its time and the pointer velocity. By identifying minima in a symmetrical high-pass filtered version of the pointer speed signal (triangular filter, cut-off frequency of 2.1 Hz ) we could accurately estimate the time of rotation onset, durations of sub-movements if present, and the time of the end of the rotation. That is, the rotation onset was measured as the point when the high-pass filtered pointer speed had its first minimum found by searching backwards from the time of the first peak in the time differentiated pointer speed signal. At this time, we also recorded the contact force. In pointer-alignment trials that contained sub-movements, subsequent minima defined times that separated successive sub-movement and the last minimum encountered $>$ 200 ms before the time that the shutter opened defined the end of the rotation movement. Likewise, in trials without sub-movements (single velocity peak) the second (and last) minimum defined the time of the end of the rotation movement.

The duration of dial rotation was the time between of rotation onset and end of rotation and the resultant dial orientation, providing the alignment error in the pointeralignment tasks, was defined as the orientation at the time of rotation ended. The displacement of the pointer was calculated as the difference between resultant dial orientation and the initial orientation referenced to the direction towards the target, i.e., positive and negative values indicated rotation towards and from the target, respectively. Peak contact force was the maximum contact force recorded during the period of contact.

## Statistical analysis

Effects of the experimental factors on behavioral variables were assessed using re-peated-measures analyses of variance (ANOVAs). Unless otherwise indicated, edge length and initial dial orientation constituted the categorical predictors (factors) in the analysis pertaining to the main experiment whereas sensory condition (tactile, visual) and initial orientation were categorical predictors in comparisons between the tactile and visual pointer-alignment tasks. In analyses of covariance (ANCOVAs) performed at the level of individual participants (see Results), we used Holm-Bonferroni correction for multiple comparisons. In statistical analyses that involved the absolute alignment error as a dependent variable, the data were logarithmically transformed to approach a normal distribution. Data were Fisher and arcsine transformed when performing parametric statistics on correlation coefficients and proportions, respectively. Throughout, we defined a statistically significant outcome if $P<0.01$ and for post-hoc comparisons, we used the Tukey HSD test. Unless otherwise stated, reported point estimates based on sample data refer to mean $\pm 1$ standard deviation of participant's medians computed across all edge orientations and relevant edges.

## Model

We modelled a virtual patch of skin $(2 \times 2 \mathrm{~cm})$ constrained by known biological features of the human tactile periphery. The patch was connected to synthetic units
meant to represent first-order tactile neurons. The center of each unit's receptive field was randomly placed on the patch. Units were placed until the average distance between the center of each receptive field and the center of its six nearest neighbours was, on average, $\sim 1 \mathrm{~mm}$ as previously described ${ }^{21,65}$. Each unit had a nominally circular receptive field drawn from a log normal distribution as previously described ${ }^{22}$ (in $\log _{10}$ units: mean $=1, S D=0.45$ ). The receptive field was composed of receptor elements meant to represent a neuron's mechanoreceptive transduction sites. Although a unit could have many transduction sites, its output could be in only two discrete states: active when the stimulus intersects with any of its receptor elements or inactive when the stimulus does not intersect with any of its receptor elements.

We compared two versions of the model that differed at the level of the receptor elements. The first version (with subfields) had units with receptive fields composed of many receptor elements. The presence of many receptor elements was meant to represent the fact that first-order tactile neurons branch and innervate many mechanoreceptive end organs, and have complex receptive fields with many highly-sensitive zones (or subfields) ${ }^{13-15}$. In this version of the model, the number, size and location of receptor elements were parameters chosen as follows. The location of the elements was randomized except for the first two elements, which were placed opposite to one another on the receptive field boundary. The diameter of the circular receptor elements was fixed to 250 microns (that is, they were considered active if the stimulus was within 125 microns of the element's center). The number of receptor elements was randomized between 2 and 64 (uniform distribution). Such complex receptive fields correspond to the known sensitivity profiles of human first order tactile neurons
(Fig. 5a). The second version of the model (without subfields) had units with a single receptor element. In this version of the model, the size and location of each unit's receptor element corresponded precisely to its receptive field boundary. Such platelike receptive fields, which consider only the boundary of first-order tactile neuron receptive fields and ignore their internal topography rendering uniform sensitivity throughout the field, have previously been used to describe the sensitivity profile of first-order tactile neuron receptive fields ${ }^{65,66}$.

Our main interest was testing how well these two versions of the model could signal edge orientation as a function of edge length. We did this by generating the same virtual fingertip for both versions of the model. That is, runs were paired such that the receptive field sizes and locations, along with the location of stimulus, were identical for both versions of the model. Moreover, our stimuli for different edge lengths always rotated the edge about its center at the same location and in the same direction. At the beginning of each simulation, for each model, we determined which units were active at the initial edge placement (termed $0^{\circ}$ ). We also determined the number of units that could be potentially activated by the edge - that is those that could be contacted if the edge rotated completely about is center. We then rotated the edge about its center in $0.5^{\circ}$ increments and recalculated which units were active at each step. We deemed that the edge was discriminated when $5 \%$ of the potentially active units changed their state from the initial stimulation. We repeated this process with 100 virtual fingertips for each model.

Figure 1. Experimental approach. (a) Four principle phases of the pointer-alignment trials. (b) Photograph of the apparatus. (c) The left panel shows a top-down schematic view of the dial and pointer along with an exemplar fingerprint superimposed on the contact surface for scale purposes. The six panels on the right show the six edge lengths. The edge that spanned the entire area contacted by fingertip was termed the infinite edge and the 0 mm edge refers to raised dot stimulus. (d) Cross-sectional and side views of the edges. (e) Normal force, pointer position and rotation velocity shown for six superimposed exemplar trials with the six initial dial orientations. Data aligned on initial touch (vertical line). Dashed horizontal lines represents the target $\pm 2^{\circ}$ zone. The resultant pointer position was measured when the rotation velocity fell below $10 \%$ (red dots). Gray segments of the traces represent final adjustments of the orientation with the shutter glasses opened to allow visual guidance of the movement during the final adjustment of the pointer into the target zone when required.

Figure 2. Alignment accuracy during tactile pointer-alignment trials. (a) Distribution of the alignment error for the various edge lengths for all trials by all ten participants (108 trials/participant and edge length). Gray segments of the distributions refer to trials with rotation in the wrong direction. The accumulation of data at the $\pm 38^{\circ}$ represents trials in which the pointer reached the end of its movement range (see Methods). (b) Absolute alignment error (deviation from the $0^{\circ}$ target position) as a function of edge length based on median values for individual subjects (gray lines) and the corresponding data averaged across participants (black line; means $\pm 1$ sem). (c) Contours superimposed on a fingerprint - photographed through a flat glass plate - show the 8,4 and 2 mm edges twice with an orientation difference that corresponds to the average alignment errors with these edges. For reference, superimpose of the fingertip is an array of black dots, laid out in a hexagonal array with a center-to center spacing of 1 mm , which approximately correspond to the spacing of receptive field centers of relevant tactile neurons if uniformly spaced across the fingertip. (d) Proportion of trials with rotations in the correct direction as function of edge length for each participant for all initial dial orientations pooled (gray lines) and the corresponding data averaged across participants (black line). Under the criterion that $75 \%$ correct responses define the threshold level, the vertical dashed lines indicates an estimation of the range across participants of threshold of edge length for correct rotation direction. (e) Cumulative frequency distribution of the pointer displacement referenced to movement in the direction of the target for trials performed by all participants with each edge length and initial dial orientation. The vertical dashed lines indicate the displacement required to reach the target position. The dashed segments of the distributions refer to trials with rotation in incorrect direction (i.e., negative displacement values) and are curtailed by the pointer reaching the end of its movement range. (f) Pointer displacement in the correct direction as a function of initial dial orientation and edge length shown as mean values across subjects ( $\pm 1$ sem; $N=10$ ) based on participants' medians. The dashed horizontal lines indicate the displacement required reaching the target for the $\pm 10^{\circ}, \pm 20^{\circ}$ and $\pm 30^{\circ}$ initial dial orientations. Data are pooled across the $\pm 10^{\circ}, \pm 20^{\circ}$ and $\pm 30^{\circ}$ orientations since there was no significant effect of sign of the orientation on the pointer displacements these initial orientations.

Figure 3. Contact behavior and temporal parameters in tactile pointer-alignment trials. (a,b) Time of onset of the orienting of the dial ('Rotation onset time') and the time when the contact force reached its plateau-like state ('Time of contact force increase') as a function of edge length referenced to the time of initial touch of dial. ( $\mathbf{c}, \mathbf{d}$ ) Contact force at the time of the start of dial rotation and during the plateau-like state of the force, respectively. (a-d) Gray lines indicate median values for individual subjects and black line represents their mean values averaged across participants. Error bars indicate the standard error of the mean. (e) The duration of the dial rotation as a function of the dial's initial orientation for each of the edges that were 2 mm and longer. Lines indicate means across participants' medians. Error bars indicate the standard error of the mean.

Figure 4. Comparing performance in the visual and the tactile pointer-alignment tasks. (a) Distribution of the alignment error during the visual (gray) and tactile (black) pointer-alignment tasks for all trials by all ten participants (108 trials/participant and task). (b) Absolute alignment error in the two tasks. Height of black and white bars indicates mean values across participants' medians in the tactile and visual condition, respectively, and gray lines indicate median values for each participant and condition.

Figure 5. Neural mechanisms for edge orientation processing. (a) Schematic of a $5 \times 5 \mathrm{~mm}$ square area on the skin surface. The gray lines and circles represent papillary ridges and mechanoreceptive end organs, respectively. Three colors of filled dots represent the mechanoreceptors (e.g. Meissner corpuscles) innervated by one of three first-order tactile neurons, the shaded area behind subsets of these mechanoreceptors represent subfields and the color-matched contour represents that neuron's receptive field boundary. (b) Top: Same format as (a) but showing color-coded subfields for 10 first-order tactile neurons. Note the high amount of receptive field overlap and subfield intermingling and that, in practice, even this representation is simplified as any point on the fingertip skin would activate $\sim 36$ of the relevant first-order tactile neurons ${ }^{22}$ (20 fast-adapting type 1: FA-1; 16 slow-adapting type 1: SA-1). The two edges ( 2 mm long) are superimposed on the layout are centered at the same location but differ in orientation by $20^{\circ}$. Bottom: Activation pattern of the population of neurons in the cartoon above. Neurons are filled if the edge touches any of its subfields and unfilled otherwise. Arrows point to two neurons that change their state for the two edge orientations. (c) Output of our toy model relating subfields to the neuronal populations' ability to signal edge orientation (ordinate) as a function of edge length (abscissa). Here we directly contrast two synthetic populations where: (1) each unit has a uniform receptive field by virtue of being connected to one receptive element the same size as its receptive field and (2) each unit has subfields by virtue of being connected to a random number (2-64) of receptor elements (each $250 \mu \mathrm{~m}$ in diameter). Each simulation was repeated 100 times for each edge length. The lines indicate the mean and the shaded areas represent the $95 \%$ confidence interval.

Supplemental Figure 1. Participants quickly learned the tactile pointer-alignment task. The horizontal axis shows the actual sequence of tactile pointer-alignment trials performed by each participant, starting with the infinite edge practice block (Pr), followed by three experimental blocks for each of the infinite, $8 \mathrm{~mm}, 4 \mathrm{~mm}$, and 2 mm edge length. Note that data from the 1 mm edge length and the raised dot are not shown for clarity. The vertical axis represents the absolute alignment error. The black line was obtained by averaging the absolute alignment error trial by trial across participants after first filtering each participant's data with a symmetrical moving median filter comprising three consecutive trials. The shaded area represents the standard error of the mean. Most of the performance improvement took place in the first 10 trials of the practice block. A repeated measures ANOVA restricted to the infinite edge length, including the practice and three experimental blocks shows a significant effect of block on absolute alignment accuracy ( $\mathrm{F}_{3.27}=3.14, \mathrm{P}=0.04$ ). Post hoc examinations indicated that the alignment accuracy during the practice block differed from the three test blocks ( $\mathrm{P}<0.002$ for all three comparisons; Tukey HSD test) but that there were no significant differences between the test-blocks ( $P>0.75$ for all three comparisons). A repeated measures ANOVA with edge length ( 0 - Infinite) and experimental block (1, 2, 3) as factors failed to indicate an effect of block on the absolute alignment accuracy (median value during the block) and there was no significant interaction between block and edge length.

Supplemental Figure 2. Presence of sub-movements did not influence alignment accuracy or direction errors in the tactile pointer-alignment task. (a) Identification of movement components in the dial rotation. Top panel: Pointer position and dial rotation velocity shown for an exemplar trial ( $30^{\circ}$ initial dial orientation) that we found to contain two movement components. Middle panel: We identified a movement component by a reliable peak (positive and negative) in the velocity profile defined as a zero-crossing with negative slope of a low-pass filtered version of the first time derivative of rotation speed computed as the absolute value of the rotation velocity. Bottom panel: We defined the beginning and end of identified movement components by identifying minima in a high-pass filtered version of the pointer speed signal. Vertical dashed line indicates time of initial contact with the dial. For further details, see Methods. (b) Pointer position and rotation velocity shown for exemplar trials with the six initial dial orientations conducted by one of the participants with the 4 mm long edge. Left, middle and right panels show trials with one major movement, and with two and with three or four movement components, respectively. Data aligned on initial touch (vertical dashed line). (c) Frequency of trials with 1, 2, 3 and 4 movement components as a function of edge length. Note that the frequency distribution of trials with and without sub-movements was similar for all edge lengths. (d) Frequency distribution of number of movement components for each participant for all trials with all edge-lengths $>1 \mathrm{~mm}$ and all initial dial orientations (gray lines), and the corresponding data averaged across participants (black line). (e-f) Absolute alignment error and proportion of rotations in the correct direction for trials with (solid lines) and without (dashed lines) sub-movements as a function of edge length. Data pooled across all initial dial orientations and edge-lengths of 2 mm and longer. (c, e, f) Lines indicate means across participants' medians $(\mathrm{N}=10)$. Error bars indicate the standard error of the mean.

Supplemental Figure 3. Comparing performance in the visual and tactile pointer-alignment tasks. (a) Absolute alignment error as a function of initial dial orientation in the tactile (black) and visual (gray) pointer-alignment task, which involved the infinite edge and raised dot, respectively. Lines indicate means across participants' medians $(\mathrm{N}=10)$. Error bars indicate the standard error of the mean. The greater average alignment error in the tactile than in the visual condition ( $\mathrm{F}_{1,9}=12.9, \mathrm{P}=0.006$ ) mainly stemmed from smaller errors in the visual trials with initial dial orientations closest to the $0^{\circ}$ target. That is, there was a significant interaction effect of the initial orientation and sensory condition on the alignment error ( $F_{5,45}=6.5 ; P=0.0001$ ) besides a main effect of initial orientation ( $F_{5,45}=10.6 ; P<10^{-6}$ ). A post-hoc examination revealed that the initial orientation did not significantly influence the performance in the tactile condition but that it did significantly influence performance in the visual condition. It also revealed that alignment error was significantly different only for the $-20^{\circ},-10^{\circ}$ and $10^{\circ}$ initial orientations between the tactile and visual conditions ( $\mathrm{P}<0.01$ for all comparisons). (b-e) Time from initial touch to rotation onset, time from initial touch until contact force reached its plateau-like stage, contact force at rotation onset, and plateau contact force during the tactile and visual pointer-alignment tasks. Height of black and white bars indicates mean values across participants' medians in the tactile and visual condition, respectively, and gray lines indicate median values for each participant and condition. (f) Rotation duration as a function of initial dial orientation for both visual and tactile conditions. Lines indicate means across participants' medians and error bars indicate the standard error of the mean. (g-h) Frequency distribution of number of movement components and mean number of movement components as a function of initial orientation. Lines indicate means across participants' means and error bars indicate the standard error of the group mean.
