10 **Abstract**

11 The high throughput capacities of the Illumina sequencing platforms and the possibility to label

12 samples with unique identifiers has encouraged a wide use of sample multiplexing. However, this

13 practice results in low rates of read misassignment (<1%) across samples sequenced on the same lane

14 on all Illumina sequencing platforms that rely on the traditional bridge amplification. Alarmingly high

15 rates of read misassignment of up to 10% were recently reported for the newest Illumina machines

16 (HiSeq X and HiSeq 4000). This potentially calls into question previously generated and published

17 results and may make future use of these platforms prohibitive for many applications in biology and

18 medicine. In this study we rely on inline barcodes that are ligated to both ends of the DNA insert, to

19 directly quantify the amount of index hopping in historical museum-preserved samples. As the

20 barcodes become part of the sequencing read, they allow us to reliably infer the read origin even in

21 the presence of index hopping. After sequencing the same pooled library of seven samples on three

22 independent HiSeq X lanes and accounting for multiple possible sources of error, including barcode

23 and index cross-contamination, we identified on average only 0.470% hopped reads. We conclude that

24 index hopping happens on the newest generation of Illumina sequencing platforms, but results in a

29 **Introduction**

30 Multiplexing samples for next-generation sequencing is a common practice in many biological and
31 medical applications (Craig et al. 2008; Meyer and Kircher 2010; Smith et al. 2010; Caporaso et al. 2012;
32 Rohland and Reich 2012). The high throughput capacities of most sequencing platforms clearly
33 encourage multiplexing and optimized sequencing protocols with greater data output are continuously
34 being developed. During multiplexing, samples are individually labelled with unique identifiers
35 (indices) that are frequently embedded within one or both sequencing platform-specific adapters and
36 are separated from the actual template (Meyer and Kircher 2010; Kircher et al. 2012, TruSeq Nano
37 DNA kit (Illumina), NEBNext Ultra DNA kit (New England Biolabs)). The samples are subsequently
38 pooled into a single sequencing library and sequenced on the same lane. Following sequencing,
39 computational demultiplexing based on the sample-specific indices allows for assignment of the
40 sequenced reads to the respective sample of origin. However, ever since multiplexing approaches were
41 introduced, low rates of read misassignment across samples sequenced on the same lane were
42 reported on all Illumina platforms (Kircher et al. 2012; Nelson et al. 2014; D'Amore et al. 2016; Wright
43 and Vetsigian 2016b), the most frequently used next generation sequencing technology (Research &
44 Markets 2017). This process results in reads from one sample carrying a wrong index and
45 consequentially being erroneously attributed to the wrong original sample. The reported rate of read
46 misassignment is low (<1%) on Illumina platforms that rely on the traditional bridge amplification for
47 cluster generation (Illumina Inc. 2017) and therefore this source of error has been readily ignored.

48

49 The use of the exclusion amplification chemistry (ExAmp) in combination with patterned flow cells on
50 the newest generation of the Illumina sequencing platforms (HiSeq X and HiSeq 4000) was an
51 important improvement, as it significantly increased data throughput and lowered sequencing cost
52 (Illumina Inc. 2017). However, recently reported high rates of read misassignment of up to 10%
53 observed for single cell RNA libraries sequenced on the Illumina HiSeq 4000 platform (Griffiths et al.

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. It is made available under aCC-BY-ND 4.0 International license.

54 2017; Sinha et al. 2017) have shaken the scientific community, potentially calling into question many
55 generated and published results. This finding is particularly worrying in light of the recently introduced
56 NovaSeq sequencing platform, which offers even higher throughput while relying on the same
57 technology as HiSeq X and HiSeq 4000. As even more samples can be multiplexed on a single lane, the
58 potential bias from read misassignment would be further increased.

59

60 Several different processes can lead to read misassigment, i.e. presence of reads with a switched index.
61 The effect of sequencing errors that can convert one index sequence into another is well known and
62 has led to series of recommendations for designing highly distinct indices (e.g. Meyer and Kircher
63 2010). Jumping PCR during bulk amplification of library molecules that carry different indices can
64 generate chimeric sequences and should be avoided (Meyerhans et al. 1990; Odelberg et al. 1995; Lahr
65 and Katz 2009; Holcomb et al. 2014; McDevitt et al. 2016). Similarly, cross-contamination of indexing
66 adapters during oligonucleotide synthesis or laboratory work can lead to reads being attributed to the
67 wrong sample of origin. Mixed clusters that can form on the flow cell if colonies from different
68 template molecules grow into each other during cluster generation were identified as source of
69 misassigned reads on older Illumina platforms (Kircher et al. 2012). For the Illumina platforms with
70 patterned flow cells and ExAmp chemistry, read misassigment has been suggested to be caused by the
71 presence of free-floating indexing primers in the final sequencing library. These primers can anneal to
72 the pooled library molecules and get extended by DNA polymerase before the rapid exclusion
73 amplification on the flow cell, creating a new library molecule with a wrong index (Illumina Inc. 2017;
74 Sinha et al. 2017). We refer to this particular process of generating misassigned reads as index hopping.

75

76 The preprint by Sinha and colleagues (2017) has started an active discussion about the prevalence of
77 index hopping on the Illumina platforms with ExAmp chemistry. Illumina acknowledged a higher rate
78 of index hopping on platforms with ExAmp chemistry compared to platforms that rely on bridge

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-ND 4.0 International license.

79 amplification for cluster generation, reporting up to 2% compared to ≤1% read misassignment
80 (Illumina Inc. 2017). However, another study found no evidence for index hopping neither on HiSeq X
81 nor on HiSeq 2500 platforms (Owens et al. 2017). Rigorously removing free-floating primers and
82 adapters during library preparation by means of size-specific library clean-up was suggested to be the
83 most efficient way to avoid index hopping (Illumina Inc. 2017; Griffiths et al. 2017; Sinha et al. 2017).
84

85 Due to the conflicting reports, the prevalence and severity of index hopping on Illumina HiSeq X and
86 HiSeq 4000 platforms remain unclear. This is partly due to the difficulties to reliably identify
87 missassigned reads in sequencing experiments, particularly if pooling similar samples types (e.g.
88 multiple individuals from the same population that have high sequence similarity). However, some
89 research questions clearly require high confidence in read identity, as presence of rare sequence
90 variants can influence biological and medical conclusions. For instance, detection of low abundance
91 transcripts or rare mutations can influence diagnostic inferences (Greenman et al. 2007; Schmitt et al.
92 2012; Flaherty et al. 2012; Trapnell et al. 2013). Studies with low input DNA quantities are particularly
93 susceptible to such errors. Besides single cell RNA sequencing, these include ancient and historical
94 samples (Kircher et al. 2012). Similarly, population genomics studies frequently rely on low-coverage
95 genomic data, and presence of shared rare alleles across several populations or species can be
96 interpreted as evidence for gene flow (Green et al. 2010; Nielsen et al. 2012; Fumagalli et al. 2013;
97 Allentoft et al. 2015; Wall et al. 2016; Therkildsen and Palumbi 2017).
98

99 In this study we make use of inline barcodes, short unique 7-bp sequences ligated to both ends of the
100 DNA fragments (Rohland and Reich 2012), in combination with indexed primers that subsequently
101 were used to amplify the libraries. This enabled us to directly quantify the amount of index hopping in
102 historical museum-preserved samples. These barcodes become part of the sequencing read and thus
103 allow for identification of the read origin, even in the presence of index hopping. Historical samples

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. 104 are characterized by low DNA quantity and quality (the DNA is degraded, chemically modified and
105 shows single-strand overhangs (Mulligan 2005; Sawyer et al. 2012)). We purposefully use this low-
106 quality sample source, as it has been suggested that libraries constructed from difficult samples may
107 be more prone to index hopping than libraries constructed from high-quality and high-quantity
108 samples (Froenicke, 2017). Following sequencing on the HiSeq X platform, we identified a small
109 fraction of reads (<1%) with a wrong combination of barcodes and indices. After excluding several
110 possible explanations, we conclude that index hopping likely happens in this system, but results in a
111 similar rate of read misassignment as reported for older versions of Illumina sequencing platforms.
112 After demonstrating how the use of inline barcode-containing sequencing adapters enables detection
113 and removal of falsely indexed reads, we recommend using this approach independent of the
114 sequencing platform in studies that rely on low-coverage data, require absolute certainty and/or aim
115 to characterize rare variants.

116 **Methods**

117 **Library preparation and sequencing**

118 DNA extracts from seven historical eastern gorilla samples that previously yielded good sequencing
119 results on the Illumina HiSeq 2500 platform and showed high endogenous content were turned into
120 sequencing libraries following the strategy outlined in Rohland and Reich (2012) and Rohland et al.
121 (2015), as detailed below. All library preparation steps except indexing PCR were performed in a
122 dedicated ancient DNA facility to minimize contamination. Briefly, 20 µl DNA extract was used in a 50
123 µl blunting reaction together with USER enzyme treatment to remove uracil bases resulting from aDNA
124 damage (final concentrations: 1× buffer Tango, 100 µM each dNTP, 1 mM ATP, 25 U T4 polynucleotide
125 kinase (Thermo Scientific) 3U USER enzyme (NEB)). Samples were incubated for 3 h at 37°C, followed
126 by the addition of 1 µl T4 DNA polymerase (Thermo Scientific) and incubation at 25°C for 15 min and
127 12°C for 5 min (Fig. 1). DNA fragment within each sample were then ligated to a unique combination
128 of incomplete, partially double-stranded P5- and P7-adapters (10 µM each), each containing a unique
129 seven base pair sequence. We refer to these as the P5 and P7 barcodes from here on. All barcode
130 sequences were at least three nucleotides apart from each other to ensure high certainty during
131 demultiplexing and avoid converting one barcode into another through sequencing error (Rohland et
132 al. 2015, Table S1). To increase the complexity of the pooled sequencing library, one sample received
133 two different barcode combinations (Table 1). Adapter ligation was performed in 40 µl volume using
134 20 µl of blunted DNA and 1 µl of unique P5 and P7 barcodes per sample (final concentrations: 1× T4
135 DNA ligase buffer, 5% PEG-4000, 5 U T4 DNA ligase (Thermo Scientific), Fig. 1). Samples were incubated
136 for 30 minutes at room temperature and cleaned using MinElute spin columns following the
137 manufacturer's protocol. Adapter fill-in was performed in 40 µl final volume using 20 µl adapter ligated
138 DNA (final concentrations: 1× T4 DNA ligase buffer, 5% PEG-4000, 5 U T4 DNA ligase (Thermo
139 Scientific), Fig. 1), incubated at 37°C for 20 minutes, heat-inactivated at 80°C for 20 minutes, and
140 cleaned using MinElute spin columns as above.

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-ND 4.0 International license.

141 Indexing PCR was performed for 10 cycles in 125 µl volume using a unique P7 indexing primer for each
142 sample, as in Meyer & Kircher (2010) (final concentrations: 1x AccuPrime reaction mix, 0.3µM IS4
143 primer, 0.3µM P7 indexing primer, 7 U AccuPrime Pfx (Thermo Scientific), cycling protocol: 95°C for 2
144 min, 30 cycles at 95°C for 30 s, 55°C for 30 s and 72°C for 1 min and a final extension at 72°C for 5
145 minutes, Fig. 1). Note that indexing PCR for sample 7 that received two different barcode pairs was
146 performed in a single reaction combining both fractions of this sample. All index sequences differed
147 by at least three base pairs from each other (Table S1). Following the indexing PCR, each DNA fragment
148 contained three unique identifiers: the P5 and P7 barcodes directly ligated to the ends of the DNA
149 fragments, and the P7 index which is part of the Illumina sequencing adapter (Fig. 1). Sample libraries
150 were cleaned using MinElute spin columns, fragment length distribution and concentrations were
151 measured on the Bioanalyzer. We then pooled all seven sample libraries in a ratio of 2:1:2:1:1:1:2 for
152 samples 1 to 7 and performed two rounds of AMPure XP bead clean-up using 0.5X and 1.8X bead:DNA
153 ratio, respectively. We confirmed that indexing primers were successfully removed during clean-up by
154 running the final library on a Bioanalyzer (Fig. S1). The pooled library with final concentration of 18mM
155 was sequenced on three HiSeq X lanes (150 bp paired-end, 1% PhiX) that were part of independent
156 runs, at the SciLife sequencing facility in Stockholm.

165 **Data processing**

166 All reads were demultiplexed based on their unique indices using Illumina's bcl2fastq (v2.17.1)
167 software with defaults settings, allowing for one mismatch per index and only retaining "pass filter"
168 reads (Illumina Inc.). All unidentified reads, i.e. reads with indices that were not used in our
169 experiment, were subjected to the same filtering steps, as described below. We removed adapter
170 sequences using AdapterRemoval V2.1.7 using standard parameters and subsequently merged the
171 reads, requiring a minimal overlap of 11bp and allowing for a 10% sequencing error rate (Schubert et
172 al. 2016). Unmerged reads and reads below 29 bp were removed leaving only merged reads with an
173 original insert size of at least 15 bp (7 bp barcodeP7 + 7 bp barcodeP5 + 15 bp DNA fragment = 29 bp).
174 To increase certainty, we only retained reads with intact and error-free P5 and P7 barcodes (assessed
175 using an in-house python script) and an average quality score of at least 30 using prinseq V0.20.4
176 (Schmieder and Edwards 2011).

177

178 **Estimating barcode and index cross-contamination and index hopping across sequencing runs**

179 To estimate the rate of barcode cross-contamination, we identified reads with wrong barcode pairs for
180 each sample within each run. We also included unidentified reads with wrong barcode pair
181 combinations into this calculation. The proportion of cross-contaminated reads within a given
182 sequencing run was determined as the ratio between the sum of all reads with wrong barcode pairs
183 and the sum of all sequenced reads that passed the filtering criteria. Given that we used a total of eight
184 different barcodes, we calculated the probability that barcode cross-contamination results in a valid
185 barcode pair (i.e. barcode pair that is actually used in the experiment) as 7*(x/7 * x/7), where x
186 corresponds to the estimated percentage of wrong barcode pairs present in our experiment.

187

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-ND 4.0 International license.

188 Reads with a correct barcode combination but wrong index can result from index cross-contamination
189 and/or index hopping. To distinguish between these two possibilities, we relied on the fact that only
190 seven different indices were used in our experiment, whereas 40 different indices are routinely used
191 in the ancient DNA laboratory. Therefore, we quantified index cross-contamination as the fraction of
192 reads containing indices that were not included in our experiment. These reads are present within the
193 unidentified reads and carry a valid barcode combination but an unused index.

194

195 To determine the proportion of hopped reads, for each sequencing run we calculated the ratio
196 between the sum of all reads showing a wrong index-barcode combination and the sum of all
197 sequenced reads that passed the filtering criteria. To account for the possibility of barcode cross-
198 contamination that produces valid barcode combinations and index cross-contamination, we
199 subtracted these two estimates from the proportion of reads with wrong barcode-index combination.

200

201 **Statistical analyses**

202 Statistical analyses were performed in R 2.15.3 (Team R Core 2016). Significant global chi-square tests
203 were followed by a post hoc procedure as implemented in the R package polytomous
204 (https://artax.karlin.mff.cuni.cz/r-help/ library/polytomous/html/00Index.html). The minimum value
205 of the chi-squared test statistic for the given degrees of freedom was used to assess if individual
206 observed values differ significantly from an overall hypothetical homogeneous distribution. The test
207 also identified the direction of these differences.

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. It is made available under aCC-BY-ND 4.0 International license.

208 **Results**

209 Our sequencing libraries were made from degraded historical samples containing a large proportion
210 of short DNA fragments (Fig. 2A), the majority of which could be confidently merged (95.3% SE ± 1.0%).
211 After filtering (see Methods), the final dataset contained 89.3% ±1.9% of the original sequence reads.

212

213 **Barcode cross-contamination**

214 We observed low levels of barcode cross-contamination (0.0276% SE ± 0.0026 across all three runs,
215 Table 1, Table S2). The rate of barcode cross-contamination differed significantly by sample (global chi-
216 square test, $P<10^{-15}$). The implemented posthoc procedure suggested that samples 5 and 7 had
217 significantly more reads with wrong barcode combinations than expected, whereas all the other
218 samples had significantly fewer such reads. Among reads with barcode cross contamination we found
219 an overrepresentation of incorrectly paired barcodes #9 and #14 (Figure 3, Table S2), both of which
220 were used for sample 7 in the following combinations: P5-#9 with P7-#9 and P5-#14 with P7-#14 (Table
221 1). Elevated cross-contamination between these two barcodes during laboratory procedures could
222 explain the results. However, the observed high rate of wrong barcode pairs (P5-#9 with P7-#14, P5-
223 #14 with P7-#9, Figure 3) is more likely the result of jumping PCR during the 10 rounds of indexing PCR,
224 as both fraction of sample 7 were indexed in a pooled reaction. Equal frequency of wrong barcode
225 pairs is further supporting this notion (Table S2) and can be explained by jumping PCR happening
226 randomly among the reads. In contrast, it is rather unlikely that all four barcodes would have received
227 equal amounts of cross-contamination during laboratory procedures. Assuming that adapter ligation
228 of barcodes is unbiased with respect to the barcode sequence (Rohland et al. 2015), the detected low
229 average percentage of cross-contamination will lead to $1.55x10^{-5}$ % of reads (7*(0.00276/7 *
230 0.00276/7)) * 100% = 0.0000155%) with a valid barcode pair, but wrongly appear as having undergone
231 index hopping.

232

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-ND 4.0 International license.

233 **Index cross-contamination**

234 The Illumina HiSeq X platform does not support a double-indexing design. Therefore, in contrast to
235 barcode cross-contamination, index cross-contamination cannot be directly quantified from the
236 sequencing data. Instead, we focused on the fraction of unidentified reads, which contain indices that
237 were not used in our experiment (Methods, Table S3). The fraction of such reads was nearly identical
238 among the three sequencing runs, ranging from 0.12% to 0.13% (mean = 0.124% SE ± 0.0023).

239

240 **Index hopping**

241 Index hopping will not affect the barcodes that are directly attached to the DNA fragments. Therefore,
242 it can be readily distinguished from barcode cross-contamination by the presence of reads containing
243 a wrong combination between an index and a barcode pair. Across all three sequencing runs, we
244 detected a low proportion of reads with wrong index-barcode combinations (mean=0.594%, SE ±
245 0.0434%, Table 1). As detailed in Methods, to obtain the proportion of reads that result from index
246 hopping, but not from barcode or index cross-contamination, we subtracted our estimates of barcode
247 cross-contamination and index cross-contamination from this value. The estimated rate of index
248 hopping in our experiment across all three sequencing runs is therefore 0.470% SE ± 0.044 (0.594% -
249 1.55×10^{-5} % - 0.124 %). The proportion of hopped reads differed significantly by sample (chi-square
250 test, $P<10^{-15}$). We observed a significant positive correlation between the number of sequenced reads
251 per sample and the number of reads that hopped from this sample to other samples (Pearson's r =
252 0.96, P = 0.0005), suggesting that samples with higher number of sequenced reads will serve as a
253 dominant source of hopped reads (Fig. 3). Therefore, even though the overall rate of index hopping is
254 low, samples with low number of sequenced reads are more affected by index hopping, leading to
255 1.47% SE ± 0.11% and 2.49% SE ± 0.29% of index hopped reads within these samples in our experiment
256 (e.g. samples 2 and 4 in Table 1, Table S4, Fig. 3).

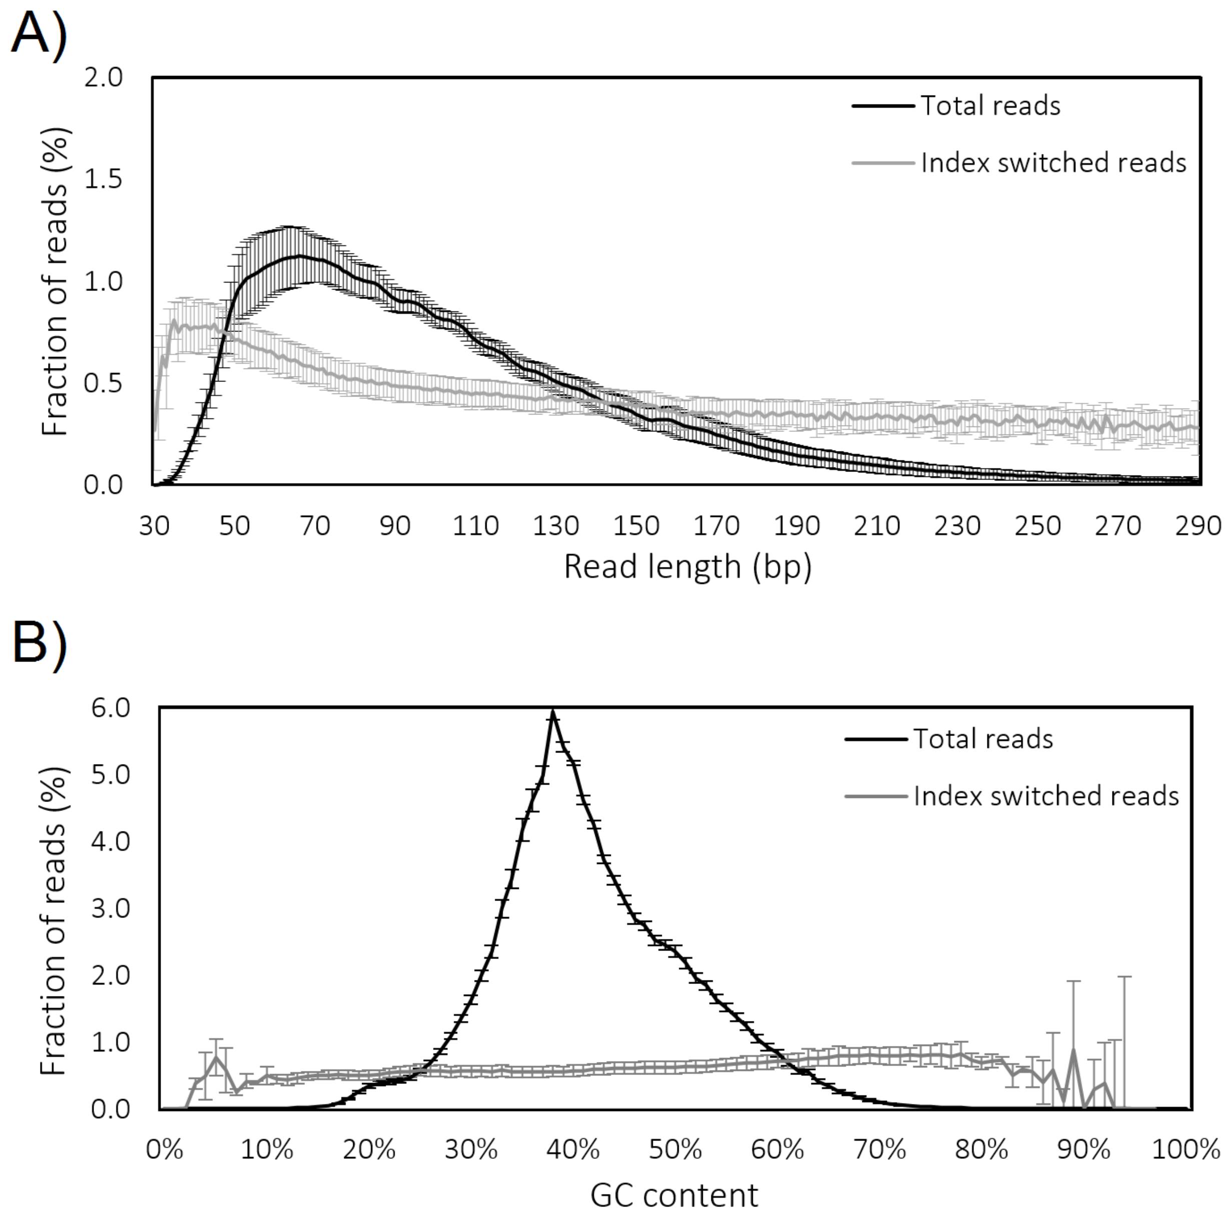
257 The rate of index hopping differed significantly by read length and GC content (chi-square test, $P<10^{-}$
258 ^{15}, Figure 2). Reads shorter than 90 bp and reads with GC content above 40% showed significantly
259 higher proportion of hopped reads than expected.



260

276 **Discussion**

277 We show that index hopping is a real phenomenon occurring on the Illumina HiSeq X platform, but its
278 rate is below 1% in our study. Multiple sources of error can result in read misassignment on the HiSeq
279 X platform, including barcode and index cross-contamination, jumping PCR, sequencing errors, and
280 index hopping. However, through a careful experimental design, we can exclude these error sources
281 and reliably quantify the rate of index hopping. First, we show that the rate of cross-contamination of
282 barcodes is very low (on average, only 0.0027%). A slightly higher level of observed barcode cross-
283 contamination in sample 7 is likely due to jumping-PCR. However, jumping PCR can be eliminated as
284 explanation for wrong index-barcode combinations, as we prepared all libraries individually and
285 avoided amplification of pooled libraries from different samples. Library pooling only occurred directly
286 prior to sequencing. Second, we detect low levels of index cross-contamination by quantifying the
287 presence of indices that are routinely used in the lab among our sequenced reads (0.124%). This
288 further suggests that the presence of wrong index-barcode pairs cannot be explained by index cross-
289 contamination. Third, we employed a very stringent procedure to control for sequencing error: we did
290 not allow for mismatches in the 7-bp P5 and P7 barcodes, required high average read quality and only
291 retained merged reads. By using the library preparation protocol as described in Rohland et al. 2015,
292 we can thus accurately identify and quantify reads containing wrong index-barcode combinations that
293 are the result of index hopping and not the effect of other sources of error.

294 Read misassignment is not a novel phenomenon for the Illumina sequencing platforms. Reported error
295 rates range from 0.1% to 0.582% for HiSeq 2500 (Kircher et al. 2012; Wright and Vetsigian 2016a,
296 Wright and Vetsigian 2016b) and from 0.06% to 0.21% for the MiSeq platforms (Nelson et al. 2014;
297 D'Amore et al. 2016). It is therefore noteworthy that the fraction of hopped reads as estimated in our
298 study (0.470%) is similar to that reported for other platforms. However, it markedly differs from the
299 recent estimates for the Illumina HiSeq X/4000 platforms (Griffiths et al. 2017; Owens et al. 2017; Sinha
300 et al. 2017). While (Owens et al. 2017) failed to detect any index hopping in libraries sequenced both

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. 301 on Illumina HiSeq X and HiSeq 2500, (Griffiths et al. 2017) and (Sinha et al. 2017) reported >1% and up
302 to 10% of misassigned reads for single-cell RNA libraries on the HiSeq 4000 platform. Our low observed
303 rate of index hopping might be explained by the low amounts of free-floating adapters during library
304 preparation, since these had been rigorously removed through size selection and cleaning (Figure S1).

305

306 The number of reads with hopped indices is proportional to the total number of reads contributed by
307 a given sample to the pooled sequencing library. Pooling samples in unequal amounts leads to a
308 greater proportion of hopped reads into samples with fewer sequenced reads. In this study, libraries
309 with the lowest number of sequenced reads displayed up to 3.2% of misassigned reads (Table 1). When
310 working with low-quality samples, the effect of unequal amounts of index hopping can become even
311 more severe if the endogenous content is markedly different between samples, as is often observed
312 in aDNA studies (Damgaard et al. 2015; Pinhasi et al. 2015; van der Valk et al. 2017). In this case,
313 hopping of endogenous reads will occur from samples with high endogenous content into samples
314 with low endogenous content, potentially leading to pronounced biases. The interplay between
315 endogenous content and the number of sequenced reads may result in libraries, in which the
316 proportion of false assigned endogenous reads is considerably higher than reported here (Fig. S2).

317

318 Our study shows that while index hopping occurs on the Illumina HiSeq X platform, it results in low
319 proportion of erroneous reads. Importantly, these reads can be readily identified using a library
320 preparation protocol that combines two separate inline-barcodes and a unique index (or index pair on
321 the HiSeq 4000). For studies generating high coverage data, the low detected rate of read
322 misassignment, which is similar to that of the older sequence platforms, might be insignificant.
323 However, in cases where low coverage data is generated or absolutely certainty is required, even low-
324 rate index hopping might represent a major problem. Using short barcode adapters allows for the
325 filtering of misassigned reads, and in the case of short read lengths (such as in aDNA studies) will lead

bioRxiv preprint doi: https://doi.org/10.1101/179028; this version posted August 22, 2017. 326 to only a minimal loss of sequencing data. We therefore recommend the use the 7-bp barcode
327 adapters when preparing pooled ancient DNA libraries or in studies were absolute certainty is required.
