21 **ACKNOWLEDGEMENTS**

22 We thank Marie Jeschek and Harald Detering from the Berlin Center for Genomics and Biodiversity
23 (BeGenDiv) for assistance in bioinformatics. We further thank Mike Ritchie, Roger Butlin, Daniel
24 Wegmann, and Laurent Excoffier for helpful comments on the analyses and the Biostars and
25 Stackoverflow community for help with scripting. The manuscript strongly benefited from the comments
26 from the associate editor Jeffrey Dudycha and three anonymous reviewers. Sample collection and
27 processing comply with the "Principles of animal care", publication No. 86-23, revised 1985 of the
28 National Institute of Health, and also with the current laws of Germany. The authors declare no conflict of
29 interest. This study is part of the GENART project. The work was supported by the Leibniz Association
30 (SAW-2012-MfN-3). STV was supported by an Alexander von Humboldt Foundation fellowship.

31 **AUTHOR CONTRIBUTIONS**

32 T.B., C.J.M, F.M, and E.L.B designed the study. T.B. and D.A.G collected the samples and I.W. did the
33 lab work. T.B, S.T.V., and E.L.B. analysed the data. T.B and E.L.B. wrote the manuscript with
34 contributions from R.M.H, D.A.G, and S.T.V.

35 **DATA ACCESSIBILITY**

36 Data, including raw reads, sequences used for demographic analyses and SNP data files used in outlier
37 analysis, will be made available on Dryad and the NCBI SRA archive prior to publication.

38 **ABSTRACT**

39 Gene flow, demography, and selection can result in similar patterns of genomic variation and
40 disentangling their effects is key to understanding speciation. Here, we assess transcriptomic variation to
41 unravel the evolutionary history of *Gryllus rubens* and *Gryllus texensis*, cryptic field cricket species with
42 highly divergent mating behavior. We infer their demographic history and screen their transcriptomes for
43 footprints of selection in the context of the inferred demography. We find strong support for a long history
44 of bidirectional gene flow, which ceased during the late Pleistocene, and a bottleneck in *G. rubens*
45 consistent with a peripatric origin of this species. Importantly, the demographic history has likely strongly
46 shaped patterns of neutral genetic differentiation (empirical F_{ST} distribution). Concordantly, F_{ST} based
47 selection detection uncovers a large number of outliers, likely comprising many false positives, echoing
48 recent theoretical insights. Alternative genetic signatures of positive selection, informed by the
49 demographic history of the sibling species, highlighted a smaller set of loci; many of these are candidates
50 for controlling variation in mating behavior. Our results underscore the importance of demography in
51 shaping overall patterns of genetic divergence and highlight that examining both demography and
52 selection facilitates a more complete understanding of genetic divergence during speciation.

53

54

55 INTRODUCTION

56 The study of speciation and the origins of earth's biodiversity are at the core of evolutionary biology. An
57 important first step is understanding the mechanisms that drive genetic divergence between closely related
58 groups of organisms. In the age of next-generation sequencing, our understanding of these mechanisms is
59 rapidly advancing. However, a variety of processes such as gene flow, local variation in recombination
60 and mutation rates, linked or background selection, and divergent selection often simultaneously influence
61 genetic variation between diverging lineages and the different processes may leave similar signatures in
62 the genome (Noor and Bennett 2009; Feder et al. 2012; Nachman and Payseur 2012; Cutter and Payseur
63 2013; Seehausen et al. 2014; Burri et al. 2015). Therefore, to understand how populations diverge, how
64 reproductive isolation evolves, and how this affects the genome, it is essential that we examine both
65 selective and neutral processes.

66 Recently, the role of gene flow in speciation has drawn renewed attention (Smadja and Butlin 2011; Feder
67 et al. 2013; Sousa and Hey 2013; Servedio 2015; Ravinet et al. 2017). It was once thought that
68 reproductive barriers could only evolve in allopatry (Mayr 1963; Bolnick and Fitzpatrick 2007). However,
69 this view has shifted due to accumulating evidence for varying rates of gene flow during early divergence
70 (Bolnick and Fitzpatrick 2007; Nosil 2008; Bird et al. 2012). Although 'true' sympatric speciation is likely
71 rare, there is nowadays a general acceptance that some amount of gene flow occurs during many
72 speciation events, i.e. parapatric speciation (Coyne and Orr 2004; Smadja and Butlin 2011; Arnold 2015).
73 Speciation with gene flow has attracted special attention because strong divergent selection in
74 combination with high migration rates may lead to higher (than background) genomic divergence in the
75 regions harboring loci important for reproductive isolation and local adaptation (Turner et al. 2005; Nosil
76 et al. 2009; Cutter and Payseur 2013; Feder et al. 2013; Ravinet et al. 2017). However, variation in levels
77 of divergence across the genome may also strongly depend on locally reduced intraspecific diversity due
78 to demographic effects or variation in mutation and recombination rates (Nachman and Payseur 2012;
79 Cruickshank and Hahn 2014; Burri et al. 2015). Additionally, the likelihood of detecting the effects of
80 selection above background levels of genomic variation is highly dependent on the genetic architecture of

81 the traits under selection (Jiggins and Martin 2017) and the strength of selection (Ortiz-Barrientos and
82 James 2017). These caveats warrant caution in the interpretation of the results from genomic scans,
83 especially without a detailed understanding of the behavioral ecology and evolutionary history of the
84 study system (Ravinet et al. 2017). Thus, a primary goal of studies aiming to elucidate the effects of
85 selection on genetic variation should be to consider patterns left by neutral or demographic processes that
86 could occlude the genomic signature of selection.

87 Here, we bring this goal into practice by inferring demographic history and characterizing the resulting
88 patterns of genetic variation in the absence of selection. We then use the resulting neutral expectation to
89 inform our inference of putative signatures of selection. For this approach, we use transcriptomic data
90 from two sexually isolated field cricket species, *Gryllus rubens* and *Gryllus texensis*. Given their current
91 distributions (Fig. 1), it is likely that interspecific gene flow has played a dominant role in the evolutionary
92 history of *G. texensis* and *G. rubens*; although, contemporary gene flow is unlikely based on lack of
93 genetic or phenotypic evidence supporting hybridization in nature (Walker 1998; Gray and Cade 2000;
94 Higgins and Waugaman 2004) and reinforcement (Gray and Cade 2000; Izzo and Gray 2004).
95 Additionally, a mitochondrial study found evidence that suggests *G. rubens* has a peripatric origin from *G.*
96 *texensis* (Gray et al. 2008) and thus divergence between *G. texensis* and *G. rubens* may be associated with
97 a strong bottleneck for the latter but not the former species.

98 In addition to demographic processes selection also likely played a role in the divergence of *G. texensis*
99 and *G. rubens*. There is striking variation in acoustic sexual communication behavior in this system,
100 involving multiple traits that compose the wing-generated calling song produced by cricket males and
101 corresponding female preferences. This implies a strong selective pressure on genes related to mating
102 signals. Variation in the cricket mating song depends on (i) the morphology and resonant properties of the
103 wings, (ii) neural networks called central pattern generators that control rhythmic wing movement, and
104 (iii) neuromuscular properties of the muscles that affect the temporal rhythm of the song (reviewed in
105 Gerhardt and Huber 2002). Similarly, song recognition and preference in females are controlled by a
106 complex network of neurons and likely depend on properties of ion channels, in particular potassium

107 channels mediating inhibitory effects (Hennig et al. 2014; Schoneich et al. 2015; Göpfert and Hennig
108 2016). If there is indeed a strong selective pressure on mating behavior in this system, selection signatures
109 are expected to be biased towards gene products that affect the properties of muscles, neuromuscular
110 junctions, and neurotransmitter activity related to rhythmic behaviors and perception, as well as mating
111 behavior variation more broadly. Importantly, combining the inference of putative selection signatures
112 with the demographic analyses allows us to interpret the perceived effects from selection in the
113 appropriate historical context and make predictions about the joint effects from neutral and selective
114 forces during population divergence.

115

116 **MATERIALS & METHODS**

117 *Study system*

118 *Gryllus texensis* and *G. rubens* are widely distributed across the southern Gulf and Mid-Atlantic States in
119 North America, with a broad sympatric region from eastern Texas through western Florida (Fig. 1). Males
120 are morphologically cryptic (Gray et al. 2008) and there is no documented ecological divergence (Gray
121 2011). However, females differ in the length of the ovipositor (Gray et al. 2001), which tentatively reflects
122 ecological adaptation to different soil types (Bradford et al. 1993). In nature, divergence in acoustic
123 signals and preferences is a strong premating barrier acting through both species-specific long-distance
124 mate attraction songs (Walker 1998; Gray and Cade 2000; Blankers et al. 2015a) and close-range
125 courtship songs (Gray 2005; Izzo and Gray 2011). Reproductive isolation is maintained in the zone of
126 overlap, but there is no evidence for reproductive character displacement, indicating that reinforcement is
127 unlikely to affect divergence in these species (Higgins and Waugaman 2004; Izzo and Gray 2004).

128 *Sample collection*

129 Animals were collected in the USA in Lancaster and Austin (TX; ca. 80 *G. texensis* females) and in Lake
130 City and Ocala (FL; ca. 40 *G. rubens* females) in autumn 2013 (Fig. 1 black dots). Collected females,
131 which are typically already inseminated in the field, were housed in containers in groups of up to 15

132 individuals with gravel substrate, shelter, and water and food *ad libitum*. Each container also contained a
133 cup with vermiculite for oviposition. During two weeks, eggs were collected and transferred to new
134 containers; hatchlings were then reared to adulthood. We used laboratory-raised offspring of the field-
135 caught females between one and three weeks after their final molt rather than field-caught specimens to
136 standardize rearing conditions across all samples. All animals (males and females) were played back an
137 artificial stimulus resembling the conspecific male song for 10 minutes prior to sacrificing the animal. The
138 rationale here was that one of our primary objectives was to look at genetic divergence in relation to
139 mating behavior polymorphism. In case specific genes involved in female preference behavior were only
140 expressed upon hearing a male song signal, this could potentially be overcome by a brief play back 30 –
141 120 minutes prior to RNA preservation. Stimulus play back occurred for females and males to standardize
142 the RNA sampling method across sexes. Within two hours of stimulus presentation, we sacrificed the
143 cricket, removed the gut and then preserved the body in RNAlater following the manufacturer's
144 instructions; samples were then stored at -80 °C until RNA isolation. A total of five males and five
145 females were used from each of the two populations for each species (40 individuals in total; randomly
146 sampled across containers when there were multiple containers for crickets from the same population).
147 Total RNA extraction and directional, strand-specific Illumina library preparation were done as described
148 in a recently published transcriptomic resource for *Gryllus rubens* (Berdan et al. 2016).

149 *SNP calling*

150 Raw reads were processed using Flexbar (Dodt et al. 2012) to remove sequencing primers, adapters, and
151 low quality bases on the 3' end of the individually barcoded reads. Samples were mapped to the *G. rubens*
152 reference transcriptome (Berdan et al. 2016) using Bowtie2 (Langmead and Salzberg 2012) with default
153 parameters but specifying read groups to mark reads as belonging to a specific individual. Duplicate reads
154 were marked using 'picard' (<http://broadinstitute.github.io/picard>). The Genome Analysis Toolkit (GATK,
155 DePristo et al. 2011; Van der Auwera et al. 2013) was used to call genotypes with the GATK-module
156 'UnifiedGenotyper' (Van der Auwera et al. 2013). The variants were then filtered to only retain high
157 quality SNPs based on the recommendations on the GATK website

158 (<https://gatkforums.broadinstitute.org/gatk/discussion/comment/30641>, accessed on 05/05/2015) and as
159 described in a previous study (Berdan et al. 2015). The minor allele frequency (MAF) cut-off was set at
160 0.025 (a minimum of two copies of the allele).

161 Our sampling design was optimized to standardize the conditions under which we stored RNA samples,
162 but potentially introduced a bias towards collecting related individuals. This may affect both demographic
163 inference and the summary statistics used to identify selective sweeps. To correct for the potential cryptic
164 relatedness, we used the PLINK methods-of-moments approach (Purcell et al. 2007) implemented in the
165 SNPrelate package (Zheng et al. 2012) in R (R Development Core Team 2016) to estimate kinship
166 coefficients for all pairs based on the allele frequencies within each population sample. We excluded eight
167 individuals that showed estimated kinship coefficients above 0.125 (half-sib level) with other individuals
168 from their population, leaving 17 *G. texensis* and 15 *G. rubens* individuals for all downstream analyses.

169 *The demographic history*

170 We first tested whether the sampled populations show geographic genetic structure. We inspected allele
171 frequency variation within and between species and populations using principal component analysis. We
172 also ran STRUCTURE (Falush et al. 2003), once for each species separately and once combining the
173 species, using a single SNP locus per contig (8,835 randomly drawn SNPs). We used the admixture model
174 with sampling location as prior information. We ran STRUCTURE with an MCMC chain length of
175 100,000 and with a burn-in length of 10,000 for K=1 through K=5 (K=4 for the species-specific runs) with
176 three repetitions for each K-value. Results were analyzed using STRUCTURE HARVESTER (Earl and
177 vonHoldt 2012) using the log-likelihood to compare K=1 versus all other values for K and the delta K
178 method (Evanno et al. 2005) to compare K=2 versus all higher values of K.

179 To investigate the demographic history of *G. rubens* and *G. texensis*, we used the approximate Bayesian
180 computation framework (ABC, Beaumont *et al.* 2002). We used ABCsampler from the ABCtoolbox
181 package (Wegmann et al. 2009) to simulate our data under different demographic scenarios in fastsimcoal
182 v2.5.2.3 (Excoffier and Foll 2011; Excoffier et al. 2013) and to calculate summary statistics using
183 arlsumstat v.3.5.1.3 in Arlequin v 3.5 (Excoffier and Lischer 2010). We performed the analysis using the

184 sequences from 1000 randomly drawn contigs (not including contigs with zero SNPs), using fixed
185 recombination and mutation rates (both $1e-8$) and the same minor allele frequency cut-off for the
186 simulated data as for the observed data (0.025). To ensure that a MAF of 0.025 for the observed data was
187 still maintained after removing the potentially related individuals, we removed all singletons that arose
188 *post* subsampling. We initially calculated all between population summary statistics supported by
189 arlsumstat. Then, using partial least squares regression (PLS), we retained the summary statistics with the
190 highest predictive power (i.e. those with high factor loadings on the PLS components that significantly
191 increase the predictive power of parameter estimates) for demographic estimates: the between-species
192 mean and standard deviation of the number of polymorphic sites, the number of private polymorphic sites,
193 Tajima's D , and nucleotide diversity (π) in each species, as well as pairwise (between species) F_{ST} and π .
194 All statistics were calculated as averages across contigs.

195 We compared four possible (groups of) models: a simple divergence model (DIV; 4 parameters for
196 population sizes and the timing/magnitude of demographic events), three models involving gene flow
197 (either continuous, ancient or recent gene flow/secondary contact; CGF, AGF, RGF; 6-7 parameters),
198 three models involving a bottleneck (for either or both species; RB, TB, BB; 6-8 parameters), and a model
199 combining the most likely gene flow and most likely bottleneck model (AGFRB; 9 parameters). We
200 intentionally considered only relatively simple models with few parameters to avoid the risk of
201 overparameterization (Csilléry et al. 2010). For each model, we ran 200,000 iterations to do model
202 selection. Prior ranges for population sizes and time points were chosen on a log-uniform scale spanning
203 across several orders of magnitude and for bottleneck size and migration rates on a uniform scale not
204 overlapping zero (Table 1).

205 After simulating the scenarios, model selection and posterior predictive checks were performed in R.
206 Because of their similarity, the three bottleneck models and the three gene flow models were treated as
207 two groups of models that were first tested inter-se; the best model of each group was then tested against
208 the DIV and best combined models. We first retained the 1% of the samples that had the smallest
209 Euclidean distance between the summary statistics of the simulated data and the observed data (1%

210 nearest posterior samples' from hereon) for each scenario separately. We then obtained a set of linear
211 discriminants that maximized the distance among models within the nested categories (gene flow and
212 presence of bottleneck). Next, posterior model probabilities were calculated based on these linear
213 combinations of summary statistics using the 'postpr' function in the 'abc' package (Csilléry et al. 2012).
214 The first two model selection steps were used to retain one gene flow and one bottleneck model with the
215 highest posterior probability ('best model' from hereon). A third round of model selection was used to
216 select among a simple divergence scenario (DIV), the best gene flow and bottleneck scenarios (AGF and
217 RB, respectively; see Results), and a scenario combining the best gene flow and the best bottleneck
218 scenario (AGFRB). Model selection was validated by performing leave-one-out cross validation with
219 logistic regression using the 'cv4postpr' function. Here, one simulated sample, chosen at random from the
220 posterior distribution, is left out and considered to be the "true" model while repeating the model selection
221 step (with the remaining posterior samples) to evaluate the robustness of the model selection (Csilléry et
222 al. 2012).

223 To estimate demographic parameters, we then ran 1,000,000 new simulations under the model(s) with the
224 highest posterior probability. Posterior predictive checks were performed by calculating the predicted R^2
225 and root mean squared error prediction (RMSEP) using the 'pls' package (Mevik and Wehrens 2007). We
226 also used the 'cv4abc' function from the 'abc' package to evaluate prediction error. We estimated the
227 demographic parameters with the 'abc' function using non-linear regression and a tolerance rate of 0.05.

228 An important goal of this study was to assess the effects of demography, in particular the timing of gene
229 flow, on the *patterns* of transcriptome-wide genetic variation (*e.g.* the F_{ST} distribution), rather than only on
230 summary statistics. This will provide important insight into the extent to which loci that have evolved in
231 the absence of selection are expected to confound the signatures of selection. We thus estimated a null
232 distribution of the allele frequency spectrum (*i.e.* Tajima's D, Tajima 1989) under the best fitting
233 demographic model (see below). In addition, for the 1% nearest posterior samples of the models
234 simulating continuous, recent, and ancestral gene flow and the AGFRB model we obtained the simulated

235 F_{ST} distribution for each posterior sample. The median and variation of these distributions were then
236 visually contrasted with the observed F_{ST} distribution.

237 *The role of selection*

238 To assess the role of selection in driving genetic divergence, we employ three approaches that differ in
239 their sensitivity to distinguish signals of selection from the confounding effects from past demographic
240 events. All else being equal, variation in allele frequencies between populations is expected to increase
241 more rapidly in the presence of selection. However, the most common measure of the variance in allele
242 frequencies among populations, F_{ST} , which is also a common test statistic to distinguish selected loci from
243 the genomic background, has been criticized as a reliable indicator from various angles (e.g. Narum and
244 Hess 2011; Cruickshank and Hahn 2014; Lotterhos and Whitlock 2014). Other methods may be better
245 suited for detection of selected loci given strong demographic effects. For instance given sufficiently long
246 divergence times and high levels primary or secondary gene flow, elevated sequence divergence (d_{xy}) may
247 be expected to better contrast the regions harboring loci involved in reproductive isolation from the rest of
248 the genome (Nachman and Payseur 2012; Cruickshank and Hahn 2014). Additionally, a recent selective
249 sweep may increase between population differentiation and decrease within population diversity and shift
250 allele frequency spectrum (AFS) towards a higher frequency of rare alleles. Although demographic effects
251 may also shift the AFS, these effects can be modeled and taken into account. Here, we contrast an F_{ST}
252 outlier scan (the “ F_{ST} approach” from hereon) with two alternative methods that should be better suited to
253 withstand demographic effects (hereafter “ d_{xy} approach” and the “selective sweep approach”,
254 respectively).

255 We considered loci to be potentially under positive or divergent selection if they exceeded genomic
256 background levels of (1) F_{ST} , (2) absolute sequence divergence (d_{xy}), or (3) frequencies of rare alleles
257 (Tajima’s D), low diversity (π), and high differentiation (F_{ST}). For the F_{ST} approach, we used the
258 hierarchical island model (Slatkin and Voelm 1991) implemented in Arlequin (Excoffier et al. 2009;
259 Excoffier and Lischer 2010). To accommodate the data to Arlequin’s input file restrictions, we only
260 considered SNPs with MAF > 5% (81,125 SNPs). We pooled the two *G. rubens* populations in one group

261 and two *G. texensis* populations in another group and performed 100,000 simulations to establish the
262 neutral expectations for the relationship between among population heterozygosity and F_{ST} . We
263 considered all loci with F_{ST} higher than the 99th quantile for a given level of heterozygosity to be selection
264 outliers.

265 For the d_{xy} approach and the selective sweep approach, we used VCFtools (Danecek et al. 2011) to
266 calculate the following summary statistics: Tajima's D (Tajima 1989), nucleotide diversity π (Nei and Li
267 1979), and weighted F_{ST} (Weir and Cockerham 1984) in 1000 bp windows, and the absolute difference
268 between the frequency of the major allele in the two species. We also calculated the average interspecific
269 pairwise distance d_{xy} for each window as $d_{xy} = \pi / (1 - F_{ST})$, where π is the mean of the nucleotide diversity
270 across species and F_{ST} is the weighted mean F_{ST} (Hudson et al. 1992; note that this method is similar to the
271 often used $d_{xy} = p_i(1-p_j) + p_j(1-p_i)$, with p_i and p_j are the major or minor allele frequencies in species i and
272 j , averaged across windows, weighed by the number of SNPs). For the d_{xy} approach, we retained the top
273 1% contigs with respect to d_{xy} predicting that these loci have diverged relatively early in the evolutionary
274 history and remained shielded from gene flow throughout. For the selective sweep approach, we retained
275 all loci that had Tajima's D below the 5% lowest simulated Tajima's D values under the inferred
276 demographic scenario and with values for π and F_{ST} in the lowest and highest 10%, respectively. As this
277 approach uses intraspecific population genetic data, we retained sets of outlier loci for both species
278 separately

279 For all sets of outliers we checked for enriched Gene Ontology terms using 'topGO' (Alexa and
280 Rahnenfuhrer 2016), part of the Bioconductor toolkit in R. The GO annotation was obtained from the *G.*
281 *rubens* reference transcriptome (Berdan et al. 2016), which used the GO mapping module in Blast2Go
282 (Conesa et al. 2005). We limited our gene set enrichment to biological process terms only and used the
283 parent-child algorithm (Grossmann et al. 2007) to correct the P values for the 'inheritance problem' (i.e.,
284 the problem that higher GO terms inherit annotations from more specific descendant terms leading to false
285 positives). We considered any GO term significantly enriched if the false discovery rate (Benjamini and
286 Hochberg 1995) associated with the corrected P-value was below 10%. To get a more detailed picture of

287 the putative functions of a given outlier locus, we looked up the functional annotation for the
288 corresponding predicted gene product (*i.e.* the homolog with the highest similarity) on Flybase (Gramates
289 et al. 2017) if that locus had been annotated using the *Drosophila melanogaster* proteome (see Berdan et
290 al 2016 for details regarding transcriptome annotation).

291 **RESULTS**

292 *Transcriptomic divergence*

293 We sequenced RNA from 40 individuals (20 *G. rubens* and 20 *G. texensis*) on a HiSeq 2000 (Illumina,
294 San Diego, CA, USA) obtaining on average 51,046,578 100-bp reads per individual (range 37,887,468-
295 72,304,968) at a sequencing depth of eight libraries per lane. Reads mapped to the *G. rubens*
296 transcriptome at an average rate of 83.2% (Table S1). Mapping rates were not higher in *G. rubens* despite
297 the use of the *G. rubens* transcriptome (*G. rubens*: 83.0%; *G. texensis*: 83.0%; $P = 0.9968$), but females
298 mapped at a significantly higher rate than males (86.0% versus 79.6%; $P < 0.0001$). At a MAF cut-off of
299 0.025 we found a total of 175,244 SNPs across 8835 contigs. The average transition-transversion ratio was
300 1.6:1. Nucleotide diversity (π) was similar among *G. rubens* ($\pi = 0.11$, $\sigma_\pi = 0.14$) and *G. texensis* ($\pi =$
301 0.13, $\sigma_\pi = 0.15$). Median D was 0.07 (first quantile: 0.05, third quantile 0.20) and 2.7% of the SNPs
302 (4,828) were fixed between the species (Fig. 2A). Average Tajima's D was negative for both species, but
303 the distribution across loci showed substantial variation (Fig. 2B, C).

304 *The demographic history*

305 We found no substantial evidence for genetic structure in the two populations considered within either
306 species. The species axis was the predominant axis of variation among individuals in the Principal
307 Component Analysis (23.93% of total SNP variation, Fig. S1A), followed by axes separating *G. texensis*
308 (PC2, 6.13% and PC3, 4.60%) and *G. rubens* (PC4, 4.35%) individuals. Variation within species was not
309 related to geographic locations from which the individuals were collected (Fig. S1B, C). STRUCTURE
310 further supported the finding that neither of the species was strongly differentiated geographically. The
311 optimal K equaled 2 when we ran STRUCTURE with both species included (Fig. S2). Examining

312 population structure within species revealed weak evidence for population substructure in both species at
313 $K=2$, but $K = 1$ was the most parsimonious given the spread in log-likelihoods across K -values (Fig. S2).
314 These results are robust across different subsets of SNPs and sample sizes (Fig. S3).
315 To infer the role of gene flow and bottlenecks during the evolutionary history of *G. texensis* and *G.*
316 *rubens*, we used a nested rejection procedure to select the best model out of eight different models varying
317 in the presence and timing of bottlenecks and gene flow (Fig. 3). First, we compared the gene flow models
318 with each other. The gene flow model with the highest posterior probability was the ‘ancestral gene flow’
319 model (AGF $P_{\text{posterior}} = 0.99$ versus continuous gene flow, CGF: $P_{\text{posterior}} < 0.01$, and recent gene flow, RGF:
320 $P_{\text{posterior}} = 0.01$). Then we compared the bottleneck models with each other and found that the ‘*G. rubens*
321 bottleneck’ model had the highest posterior probability (RB $P_{\text{posterior}} = 0.67$ versus *G. texensis* bottleneck,
322 TB: $P_{\text{posterior}} = 0.43$ and both bottleneck, BB: $P_{\text{posterior}} < 0.01$). We then combined these best models into a
323 model with both ancestral gene flow and a bottleneck for *G. rubens* (AGFRB) and compared that model
324 against a simple divergence model (DIV), the best gene flow model (AGF), and the best bottleneck model
325 (RB). In this final model comparison, the combined model had the highest posterior probability (AGFRB:
326 $P_{\text{posterior}} = 0.68$; AGF: $P_{\text{posterior}} = 0.22$; DIV: $P_{\text{posterior}} = 0.02$; RB: $P_{\text{posterior}} = 0.08$; Fig. 3, Fig. 4). Similar
327 results were obtained using the full sample, including additional, but potentially related individuals:
328 AGFRB: $P_{\text{posterior}} = 0.75$; AGF: $P_{\text{posterior}} = 0.21$; DIV: $P_{\text{posterior}} = 0.03$; RB: $P_{\text{posterior}} = 0.01$.
329 As posterior probabilities may differ even among very similar models, it is critical to evaluate statistical
330 support for model choice. Overall, model choice was well supported. For each selection step, we used
331 cross validation to verify that models can be distinguished by assuming one of the models is the ‘true’
332 model and then performing 1,000 independent model selection steps under that assumption. The accuracy
333 with which the assumed ‘true’ model was chosen was high for the gene flow models (98%, 96%, and 52%
334 for AGF, CGF, and RGF, respectively), bottleneck models (76%, 66%, and 71% of the time for RB, TB,
335 and BB respectively), and the final model selection step (75%, 82%, 82%, 84% for DIV, AGF, RB,
336 AGFRB, respectively). It is important to note that the AGFRB model had the highest support overall and

337 final model selection was well supported, but there is overlap of the posterior distribution of the summary
338 statistics in multivariate space between the AGF and AGFRB models (Fig. 4).

339 Because there was some overlap between the posteriors of AGF and AGFRB (Fig. 4), and AGFRB only
340 differs from AGF in the addition of a bottleneck, both models were used for demographic parameter
341 estimates. Divergence times were distributed rather widely in both the AGF and AGFRB scenario and
342 posterior density distributions were widely overlapping. The median divergence time varied between
343 350,000 years ago (700,000 generations ago) for AGF and double that for AGFRB. The ancestral effective
344 population size was estimated around 200,000, almost an order of magnitude higher than the model
345 estimates for current effective population sizes in *G. rubens* (~31,000 for AGFRB and ~18,000 for AGF)
346 and *G. texensis* (~60,000 and ~28,000; Table 1, Table S2, Fig. 6A). A bottleneck for *G. rubens* was
347 estimated at 15% of the current effective population size (Table 1, Fig. 6C) and recovery to current
348 population sizes was achieved around 50,000 years ago (Table 1, Fig. 6B). Ancestral gene flow was
349 bidirectional (median $m = 0.18$ and $m = 0.27$ for gene flow from *G. texensis* into *G. rubens* and vice versa,
350 respectively; Table 1, Fig. 6C) and ceased around 18,000 years ago (Table 1, Table S2, Fig. 6B). The
351 parameter estimates for the main model, AGFRB, were robust to the inclusion of additional, but
352 potentially related, individuals; the estimates for times and population sizes were slightly higher and the
353 inclusion of more samples gave similar results but at slightly higher accuracy (narrower HPD interval,
354 Table S3, Fig. S4).

355 Statistical support for parameter inference varied across demographic events. Overall, the observed
356 summary statistics fell well within the range of the simulated multivariate summary statistics under the
357 AGF and AGFRB models (Fig. 4) and 95% HPD intervals of the distributions were generally narrow (Fig.
358 6, Table 1). For some demographic parameters (current population sizes for *G. rubens* [N_{RUB}] and *G.*
359 *texensis* [N_{TEX}], and time since cessation of gene flow [T_{ISO}] support was high ($R^2 > 0.81$; $RMSEP < 0.44$);
360 for other parameters estimated error rates were appreciably higher (Table 1, Table S2).

361 We compared F_{ST} distributions simulated under the AGF, CGF, RGF, and AGFRB models with the
362 observed F_{ST} distribution as a measure of the effect of demography on the patterns of transcriptome-wide

363 genetic variation. We found that the observed distribution (red line in Fig. 5) closely matched the
364 simulated distribution of the two models with ancestral gene flow for most parts, including the secondary
365 peak at the highest F_{ST} bin ($0.95 < F_{ST} \leq 1.00$, Fig. 5C, D). In contrast, the observed F_{ST} distribution
366 showed substantial mismatch with the recent and continuous gene flow models.

367 *The role of selection*

368 The F_{ST} approach gave by far the highest number of outlier contigs. There were 514 contigs (5.8% of
369 contigs) that had at least one SNP designated as a selection outlier (99th quantile) in Arlequin's F_{ST} based
370 hierarchical island method. There were no significantly (FDR < 10%) enriched Gene Ontology categories
371 among the predicted gene products of these contigs and the most strongly enriched categories included
372 mitochondrial processes, GTPase activity and cellular metabolism (Table S4, Table S5, Fig S5).

373 There were 80 contigs with d_{xy} values in the 99th percentile. The putative gene products corresponding to
374 these 80 contigs were significantly (FDR < 10%) enriched for pheromone biosynthesis, hormone
375 biosynthesis, mating behavior, and protein maturation (Table S4). Several of the most divergent loci
376 match genes involved in *Drosophila melanogaster* sex pheromone pathways, such as *α -esterase* and
377 *Desaturase1*, mushroom body development and neuromuscular synaptic targets, such as *S-lap1*, *tartan*,
378 including those involved in flight muscle activity (*Stretchin-Mlck*), and acoustic mating behavior, such as
379 *Juvenile hormone esterase* and *calmodulin* (Table S6).

380 We retained 55 and 92 contigs that showed possible signatures of recent selective sweeps (Tajima's D
381 below 5% of the simulated sequences under the AGFRB scenario and π and F_{ST} in the 90th percentile) in
382 *G. texensis* and *G. rubens*, respectively. The combined set of outlier loci was not significantly enriched for
383 any biological processes after FDR correction. The most strongly enriched GO terms were predominantly
384 higher order GO terms such as 'organelle organization', 'primary metabolic process', and 'regulation of
385 biological process', but also contained more specific terms: 'sperm mitochondrion organization', 'oocyte
386 fate determination', and 'regulation of female receptivity' (Table S4). Six contigs were shared between the
387 species-specific sets of loci that showed potential signatures of a recent selective sweep signature. Three
388 of these have no functionally characterized gene products. The other three are *neuroglian* (*nrg*), which is

389 involved in various aspects of nervous system development and associated with male and female courtship
390 behavior in *D. melanogaster*; *discs large 1* (*dlg1*), which affects neuromuscular junctions and changes
391 fruit fly behavior across several domains including circadian activity and courtship; and *secretory 23*
392 (*sec23*), which is an important component in differentiation of extra-cellular membranes in neurons and
393 epithelial cells (Table S7). Several other gene products associated with contigs in the species- specific sets
394 have functional roles in calcium or potassium channel activity (e.g., *nervana2*, expressed in the
395 *Drosophila* auditory organs), nervous system development (e.g. *muscleblind*, which also alters female
396 receptivity during courtship), veined-wing song generation (e.g. *period*), as well as many genes related to
397 metabolic and cellular processes.

398 There was one (unannotated) contig shared between the d_{xy} approach and the selective sweep approach.
399 Additionally, among the 514 outlier loci detected in Arlequin encompassed 11 contigs also found with the
400 d_{xy} approach, and 25 and 9 contigs respectively that were shared with the *G. rubens* and *G. texensis*
401 specific selective sweep approach. These included the genes described above that are potentially related to
402 sex pheromones biosynthesis (*Desat1*), flight muscle activity (*Mlc-k*), sensory neuron development (*nrg*),
403 and auditory pathway ion channel activity (*nrv2*).

404 **DISCUSSION**

405 Here, we illuminate the role of demographic and selective processes in shaping genetic variation during
406 speciation. Combined insight in putative neutral (neutral divergence given the demographic history) and
407 selective effects allowed us to infer the evolutionary history of *Gryllus rubens* and *G. texensis*, sibling
408 species with large, overlapping distributions and strong phenotypic divergence in sexual traits with limited
409 divergence in other phenotypes. We find strong support for a long history of ancestral gene flow and a
410 bottleneck in *G. rubens*. Importantly, our data lend support to the hypothesis that loci showing high
411 relative genetic differentiation compared to the genomic background may have evolved in response to
412 demographic events and drift rather than in response to selection. Interestingly, several of the loci with
413 show signatures of positive or divergent selection after taking into account the effects from demography
414 are potential orthologs of *D. melanogaster* genes involved in premating isolation, a major source of

415 reproductive isolation between *G. rubens* and *G. texensis*. This work represents an important first step in
416 assessing the contribution of neutral and selective forces to genetic divergence in a model system for
417 sexual selection research.

418 *Neutral divergence and demography*

419 We sequenced the transcriptomes of 40 individuals across four populations. Our observed
420 transition:transversion ratio of 1.6:1 compares well with the estimate (1.55) from another cricket species
421 pair, *G. firmus* and *G. pennsylvanicus* (Andrés et al. 2013), and suggests that sequencing errors did not
422 contribute unduly to SNP discovery. Divergence across ~175K SNPs showed a bimodal and slightly right-
423 skewed distribution of absolute (allele frequency) divergence, D (Fig. 2), and genetic differentiation, F_{ST}
424 (Fig. 5). The F_{ST} distributions simulated under our top two scenarios were also right-skewed and strongly
425 resembled the observed distribution of genetic differentiation, in strong contrast to F_{ST} distributions
426 corresponding to other models. Most importantly the simulated distributions under the most likely
427 demographic scenarios, AGF and AGFRB, showed secondary peaks at $F_{ST} > 0.95$. This indicates that a
428 significant proportion of our fixed loci may have risen to fixation stochastically due to neutral processes (a
429 combination of drift, population size variation, and gene flow) while gene flow homogenizes other
430 (random) parts of the genome. Concordantly, the F_{ST} based approach uncovered substantially more loci
431 with putative signatures of positive selection than methods based on allele frequency spectra (with
432 thresholds informed by inferred demographic history) or absolute sequence divergence (514 contigs in the
433 F_{ST} approach versus ~50-90 contigs in the other approaches). Our findings emphasizes the shortcomings
434 of traditional F_{ST} outlier approaches to discern selection effects from genomic background variation
435 (Narum and Hess 2011; Lotterhos and Whitlock 2014).

436 We find strong evidence for a long history of bidirectional gene flow before *G. rubens* and *G. texensis*
437 became fully reproductively isolated around 18,000 years ago, sometime during the last Pleistocene
438 glacial cycles. This finding adds to a growing body of work that suggest divergence can occur in the face
439 of gene flow (Bolnick and Fitzpatrick 2007; Nosil 2008; Bird et al. 2012; Feder et al. 2013). A large
440 amount of recent work has focused on the role of gene flow in speciation, especially in combination with

441 divergent or positive selection. In the genic view of speciation (Wu 2001) most areas of the genome are
442 homogenized among populations during divergence with gene flow, and regions showing excess
443 differentiation are thus likely protected by selection. This idea has been tested in many model systems
444 with mixed results (Turner et al. 2005; Ellegren et al. 2012; Nosil et al. 2012; Cruickshank and Hahn
445 2014; Burri et al. 2015; Marques et al. 2016). Recent work suggests that genomic mosaics may in fact be
446 mostly a consequence of linked selection caused by differences in recombination rates and density of
447 selected loci and are thus expected to be conserved in pairwise comparisons even among distantly related
448 taxa (Nachman and Payseur 2012; Burri et al. 2015; Van Doren et al. 2017). Our results support this idea
449 as our demographic simulations recreated heterogeneous patterns similar to our observed data. Although
450 selection certainly contributed to transcriptome divergence in *G. rubens* and *G. texensis* our results
451 suggest a larger role for neutral divergence shaped by the effects of migration and population size
452 variation and echo recent insights into the importance of considering neutral divergence when interpreting
453 potential selection effects (e.g. reviewed in Ravinet et al. 2017).

454 In addition to bi-directional gene flow, the early stages of divergence between *G. texensis* and *G. rubens*
455 were also influenced by a substantial bottleneck in *G. rubens*. There is some overlap between the AGF (no
456 bottleneck) and AGFRB (with a *G. rubens* bottleneck) scenarios in the simulated summary statistic
457 distribution, but the latter has a substantially higher posterior probability and corroborates the peripatric
458 origin for *G. rubens* hypothesized in a previous study (Gray et al. 2008). Although that study used a single
459 mitochondrial locus, it was done with extensive geographic sampling, and both studies suggest a
460 bottleneck for *G. rubens*. Furthermore, estimates of strong admixture between populations within species
461 and divergence time estimates are overlapping (this study: median ~ 0.35 - 0.70 million years ago; Gray *et*
462 *al.* study: 0.25 – 2.0 mya). Estimates for current effective population sizes (roughly between 30 and 60
463 thousand for the AGFRB model and between 20 and 30 thousand for the AGF model) are surprisingly low
464 given the potential census population size for *G. texensis* is in the millions (Gray et al. 2008). Potentially,
465 the discrepancy is due to recent population expansion (Ptak and Przeworski 2002; Nadachowska-brzyska

466 et al. 2013) or variation in individual mating success (Lande and Barrowclough 1987), as is observed in
467 wild populations of closely related species (Ritz and Köhler 2010; Rodriguez-Munoz et al. 2010).

468 *The role of selection*

469 A central aim of this study was to elucidate the role of selection during divergence within the context of
470 the inferred demographic history. The species have strongly divergent mating behaviors with no evidence
471 for reinforcement (Gray and Cade 2000; Higgins and Waugaman 2004; Izzo and Gray 2004; Blankers et
472 al. 2015a). Many other cricket species show similarly strong divergence in various aspects of their mating
473 behavior and several lines of evidence from various taxa indicate that this is at least in part driven by
474 selection (Gray and Cade 2000; Bentsen et al. 2006; Shaw et al. 2007; Bailey 2008; Thomas and Simmons
475 2009; Oh and Shaw 2013; Blankers et al. 2017; Pascoal et al. 2017). Here, we show that the striking
476 behavioral divergence is to some extent reflected in elevated sequence divergence of loci with putative
477 functions in acoustic and chemical mating behavior. We find evidence that the set of loci showing the
478 highest levels of sequence divergence are enriched for contigs bearing significant similarity to genes with
479 known function in mating behavior in *D. melanogaster*. In addition, among the six contigs that showed
480 evidence for a selective sweep in both species, three are potential orthologs of genes that affect
481 neuromuscular properties in fruit flies and have effects on the flies' mating behavior. Several other
482 species-specific outliers are potential orthologs of genes that can be tied to mating behavior variation in
483 *Drosophila spp.*

484 Given the substantial time since divergence and the long history of gene flow, high sequence divergence is
485 expected for loci that have experienced limited homogenizing effects from gene flow relative to the rest of
486 the genome. The theoretical support for speciation with gene flow driven by divergence in secondary
487 sexual characters is very thin at best (van Doorn et al. 2004; Weissing et al. 2011; Servedio 2015). Here
488 we provide exciting and rare evidence for speciation with primary gene flow while both phenotypic (Gray
489 and Cade 2000), quantitative genetic (Blankers et al. 2015b, 2017), and genomic analyses (this study)
490 highlight a role for selection on (acoustic) mating behavior in driving reproductive isolation. A compelling
491 alternative interpretation of the findings here is that the peripatric origin of *G. rubens* has allowed for an

492 initial phase of reduced gene flow; during this phase mating signals and preferences may have diverged
493 sufficiently (aided by a founder effect following a population bottleneck) to maintain reproductive
494 isolation during a subsequent phase of range expansion culminating into the contemporary, widespread,
495 and largely overlapping species' distributions. More empirical studies examining the role of gene flow and
496 selection in systems characterized by strong sexual isolation are needed to test the theoretical predictions
497 for speciation by sexual selection. However, this study along with other recent findings in finches
498 (Campagna et al. 2017), fresh water stickleback (Marques et al. 2017), and cichlids (Malinsky et al. 2015)
499 provide exciting first genomic insights into the joint effects from mating behavior divergence, sexual
500 selection, and gene flow in the earliest phases of speciation.

501 We acknowledge that there are likely to be false positives among the detected outliers, as both linked
502 (background) selection and demographic effects are expected to confound the signatures of positive or
503 divergent selection (Cruickshank and Hahn 2014; Ravinet et al. 2017) and *a priori* expectations also
504 increase the risk of “storytelling” (Pavlidis et al. 2012). By using coalescent simulations under the inferred
505 evolutionary history, we have accounted for some confounding effects from demography. However, there
506 is still potential neutral genetic variation that is unaccounted for, most notably the potentially confounding
507 effects of recent population expansion and variation in recombination rates. We therefore caution that
508 there is the uncertainty associated with the results obtained here and with genomic scans on quantitative
509 traits in general (Jiggins and Martin 2017). Nevertheless, our findings provide exciting incentive for
510 validation using alternative methods (e.g., QTL mapping) and follow-up functional genomic analyses.

511 Unsurprisingly, not all “outlier” contigs could be linked to mating behavior. The rest of these outliers are
512 likely comprised of three groups: (1) Loci that are physically linked to loci under selection: In the earliest
513 phases of speciation, only loci directly under strong divergent selection will differ. However, gene
514 frequencies at tightly linked loci will also change and, given sufficient time as well as low to moderate
515 migration and recombination rates, these loci will be swept to fixation along with selected sites (Smith and
516 Haigh 1974) in a process called divergence hitchhiking (Feder et al. 2012; Via 2012); (2) Loci that are
517 under selective forces that we have not yet elucidated: It is unlikely that divergent selection only targets

518 loci involved in mating behavior and other traits may be differentiated between *G. rubens* and *G. texensis*.
519 For example, females differ in the length of the ovipositor (Gray et al. 2001), a trait which reflects
520 potential ecological adaptation to different soil types (Bradford et al. 1993); (3) Loci that are not under
521 selection: Genetic drift can cause loci to drift to fixation and demographic effects such as bottlenecks and
522 migration patterns (Holsinger and Weir 2009) can aid this process. Our simulations predict a significant
523 number of fixed loci (1.90% on average for the AGFRB scenario) solely due to neutral processes (Fig. 5).
524 Additionally, practical limitations of discovering low-frequency SNPs causing ascertainment bias (Clark
525 et al. 2005) can contribute to misinterpretation of the patterns of genetic diversity (Vitti et al. 2013). A
526 genomic map of *Gryllus* and further analyses would make strong headway into determining which of these
527 categories the other potential outliers fall into.

528 Finally, there may be loci that are under selection but that were not detected by our scan because they
529 simply were not being expressed. We sequenced samples from first generation laboratory offspring rather
530 than animals directly from the field. Despite the fact that there are no differences between *G. texensis* and
531 *G. rubens* in ecology, microhabitat use, or feeding behavior have been described (but note there is
532 variation in the ovipositor length which is a potential adaptation to soil properties), the laboratory
533 conditions have potentially limited our potential to detect genetic differences related to local adaptation.

534 In summary, this study underlines the importance of considering the joint effects from neutral divergence
535 and selection in understanding the speciation process. Our results also offer unprecedented insight into the
536 evolutionary history and the role of demography and selection in driving transcriptomic divergence in two
537 sexually isolated field cricket sister species. We inferred that a long period of bidirectional, ancestral gene
538 flow and a bottleneck in *G. rubens* preceded completion of reproductive isolation (Fig. 3,6). Importantly,
539 the timing of gene flow appears to have significantly influenced the pattern of divergence (i.e. the F_{ST}
540 distribution) that we observe (Fig. 5). We also uncovered several loci that show signatures of positive or
541 divergent selection and show that these contigs are potentially associated with courtship behavior,
542 neuromuscular development, and chemical mating behavior. Future work will place these data on a
543 genomic map allowing us to determine how genetic divergence is distributed relative to loci under

544 selection. These findings provide important steps towards understanding the role of selective and neutral
545 processes in shaping patterns of divergence and the role of sexual selection during speciation-with-gene
546 flow. They also highlight the strength of combining information on (i) the phenotypes that contribute to
547 reproductive isolation, (ii) demographic inference, and (iii) scans for loci under selection.

775

776 DATA ACCESSIBILITY

777 Data, including raw reads, sequences used for demographic analyses and SNP data files used in outlier
778 analysis, will be made available on Dryad and the NCBI SRA archive prior to publication.

779

780 FIGURE LEGENDS

781 Fig. 1. Geographic distributions for *G. texensis* (red) and *G. rubens* (blue). The sympatric zone is marked
782 with turquoise. The distributions are approximate and based on the Singing Insects of North America data
783 base (<http://entnemdept.ufl.edu/Walker/buzz/>). The black dots in Texas and Florida represent the sampling
784 locations for *G. texensis* and *G. rubens*, respectively.

785

786 Fig. 2. Genomic divergence. The distribution of the interspecific allele frequency difference, D , across
787 SNPs (A), of the absolute divergence, d_{xy} , in 1000 bp windows (B), and of Tajima's D in 1000 bp
788 windows for *G. rubens* (C) and *G. texensis* (D), respectively

789

790 Fig. 3. Demographic scenarios for Approximate Bayesian Computation. Eight scenarios were simulated
791 under the ABC framework. (A) A simple divergence scenario (DIV) with a log uniform prior on the
792 divergence time (T_{SPLIT}), the ancestral population size (N_{ANC}) and the current effective population sizes for
793 *G. rubens* and *G. texensis* (N_{RUB} , N_{TEX}). (B) Three different gene flow models with either continuous gene
794 flow (CGF), ancestral gene flow (AGF), or recent gene flow (secondary contact; RGF) were additionally
795 defined by parameters describing migration rates ($M_{\text{TEX} \gg \text{RUB}}$, $M_{\text{RUB} \gg \text{TEX}}$; uniform priors not overlapping
796 zero) and the time point since cessation of gene flow (T_{ISO}) or of secondary contact (T_{CONT}), both with log
797 uniform priors. (C) Three bottleneck models defined by the time since recovery to current population sizes
798 (T_{BOT} ; log uniform prior) and the relative population size reduction (BOTSIZ; uniform prior not
799 overlapping zero) for *G. rubens* (RB), *G. texensis* (TB), or both (BB). (D) An additional model (AGFRB)
800 combining the best gene flow (AGF) and best bottleneck (RB) model, marked by the black, dashed
801 rectangles. The posterior probabilities for model selection are given left of the square (opening) brackets
802 for the three gene flow and the three bottleneck models, and right of the square (closing) brackets for the
803 final model selection step.

804

805 Fig. 4. Distribution of observed and simulated data sets in multivariate summary statistic space. For each
806 of the four models used in the final model selection step (see also Fig. 3) the distribution of the 1%
807 posterior samples with the smallest Euclidean distance to the observed data is shown relative to the
808 coordinates of the observed data. The multivariate summary statistic space is constrained by the first two
809 linear discriminants representing linear combinations of the summary statistics used in model selection
810 (see text for details).

811

812 Fig. 5. F_{ST} distributions of simulated and observed data. The distribution of Weir and Cockerham's F_{ST} as
813 calculated by the program arlsumstat are shown for 2,000 simulated data sets for different demographic
814 model: recent gene flow (secondary contact; RGF), continuous gene flow (CGF), ancestral gene flow
815 (AGF), and the AGFRB model. Observed data (1,000 1kbp sequences) are represented by the red solid

816 line. The histograms show the density (y-axis) to enhance comparison between simulated and observed
 817 data.

818
 819 Fig. 6. Demographic parameter estimation. For the AGFRB (A-C) and the AGF (D-F) models, the density
 820 distribution of the ancestral and current population sizes (A, D), the time since divergence, cessation of
 821 gene flow, and recovery to current population sizes after the bottleneck (B, E), and the migration rates and
 822 bottleneck size (C, F) are shown. The density lines have been trimmed to the existent parameter
 823 distribution (i.e., no density extrapolation) and have been smoothed by adjusting the bandwidth. For lines
 824 within one panel the same smoothing bandwidth has been used.

871

872

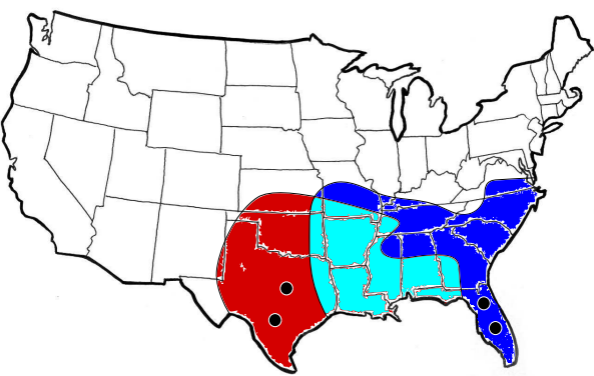

873 Table S4. GO enrichment results. The top ten terms of the Gene Ontology enrichment is shown for the d_{xy}
 874 outliers and the Allele Frequency Spectrum (AFS) outliers. For each Biological Process, the number of
 875 annotated transcripts and the number of observed and expected transcripts in the sample with a given
 876 annotation are shown. The Fisher's exact test P-value is corrected using the parent-child algorithm
 877 (Grossmann *et al.* 2007). The FDR is the false discovery rate based on the corrected P-values.

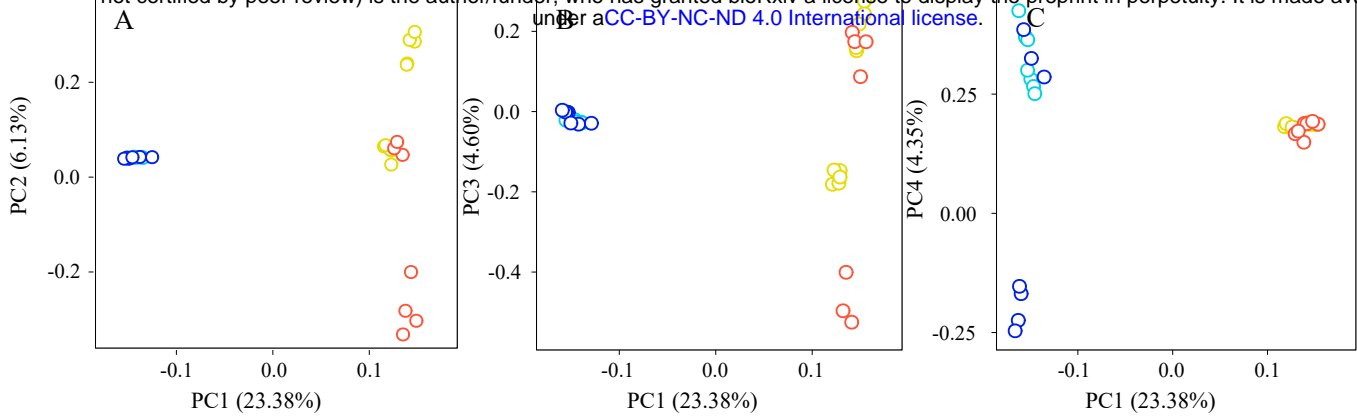

Fig S1. Population substructure in *G. rubens* and *G. texensis*. Variation in allele frequencies between species and between populations within species (Lake City and Ocala for *G. rubens*; Lancaster and Austin for *G. texensis*) is shown. The allele frequency variation in all 175,244 SNPs is summarized in the first four principal components teasing apart the species (PC1), and the populations in *G. texensis* (PC 2) and *G. rubens* (PC 4). Note that clustering along the PCs explaining within species variation among populations is much weaker compared to clustering of the species along PC1.

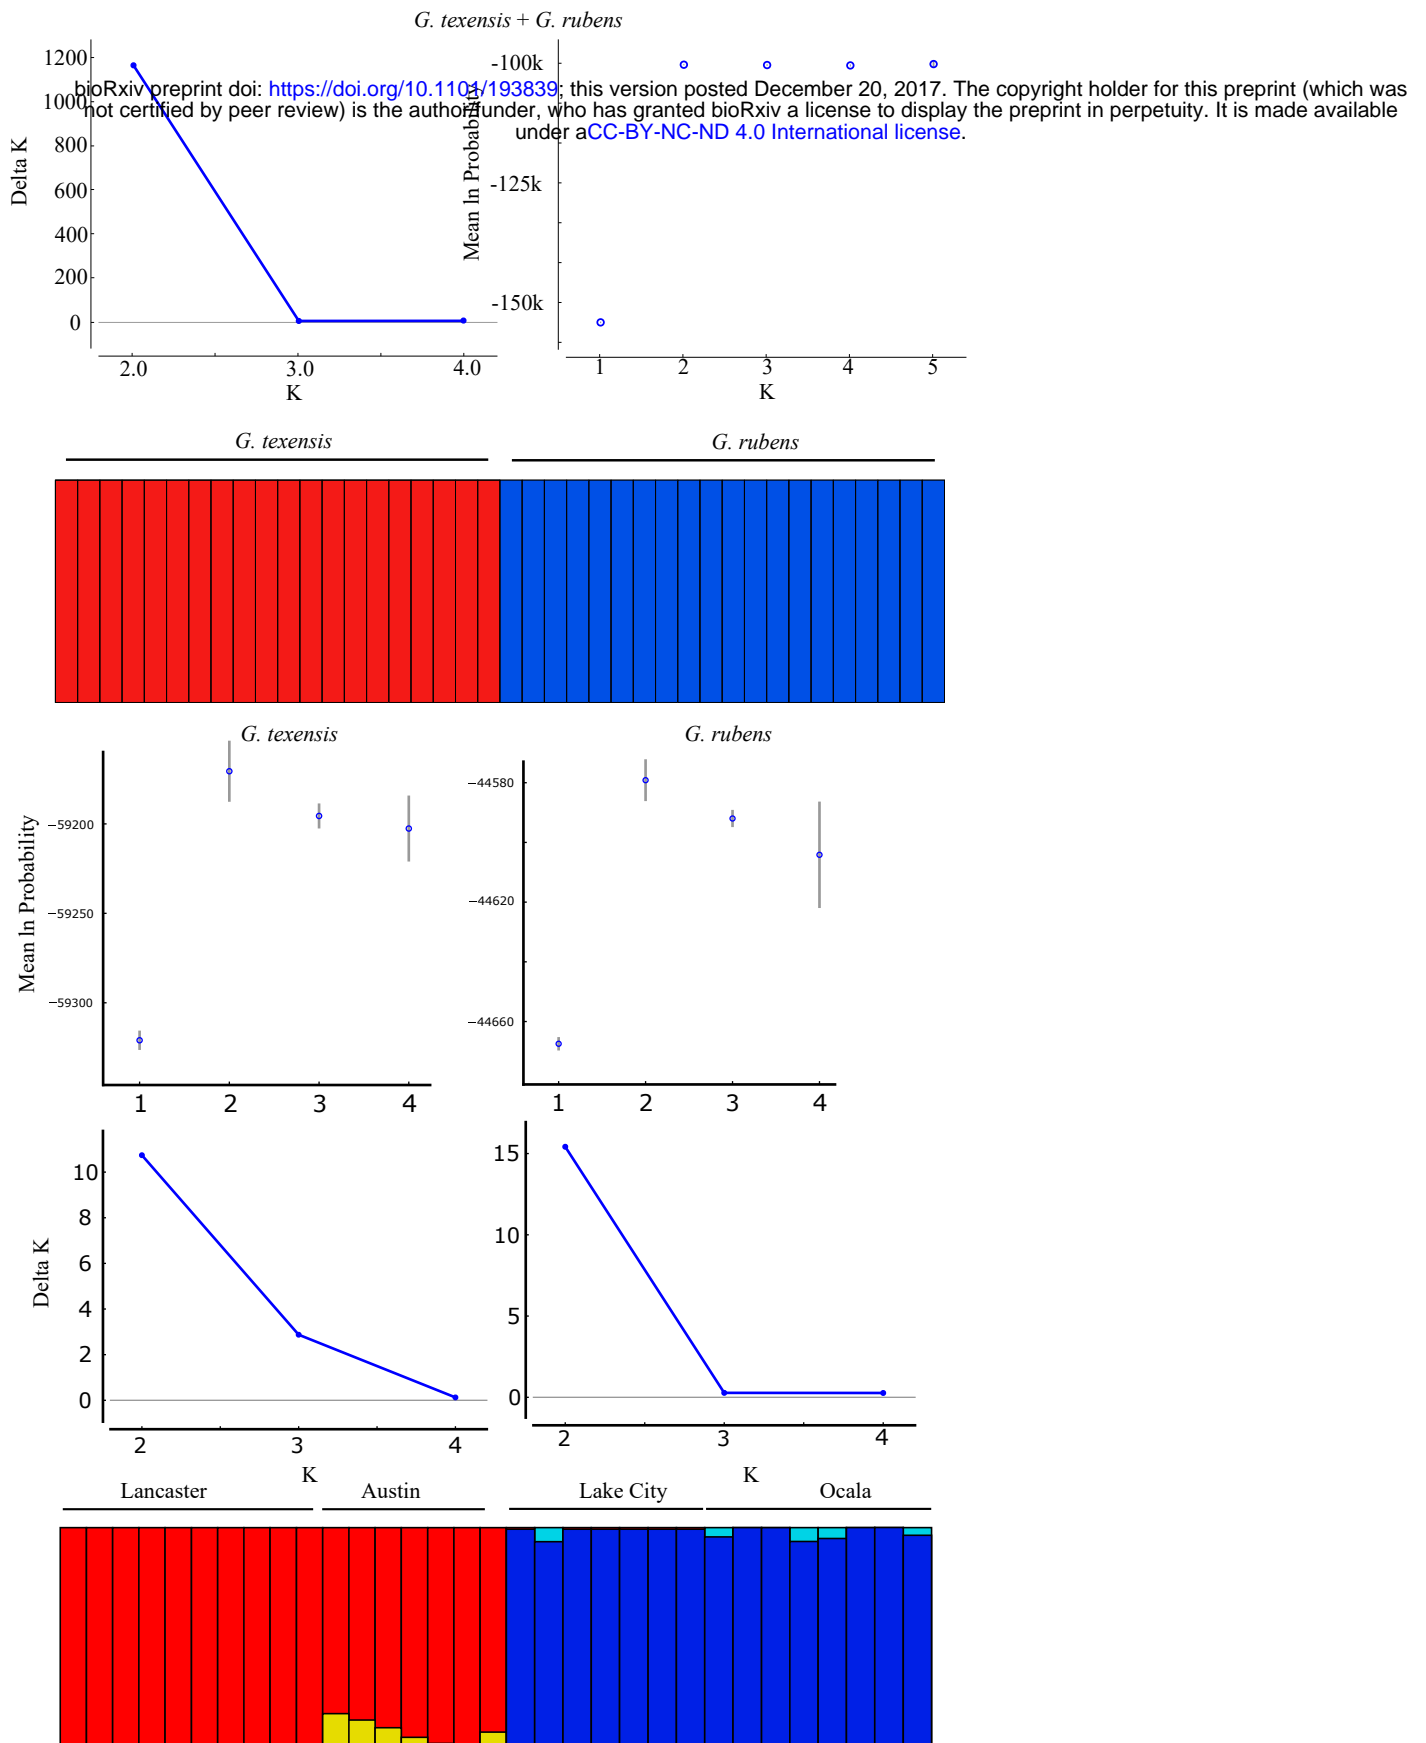

Fig S2.STRUCTURE results. For each of the species, STRUCTURE was run for 100,000 iterations at values for K=1 through K=4 (K=5 for the species combined). The mean natural logarithm of the probability and the delta K (increase or decrease in likelihood between consecutive runs for different values of K) were inspected to determine the most likely predicted number of populations. A run of *G. rubens* and *G. texensis* separately showed in both cases that, although the highest likelihood was for K=2, differences with K=1 were only marginal and a defined pattern in population substructure was absent (see also the bar plots at the bottom). The run for the species combined (K=2) shows no introgression of *G. texensis* genes into the *G. rubens* or vice versa.

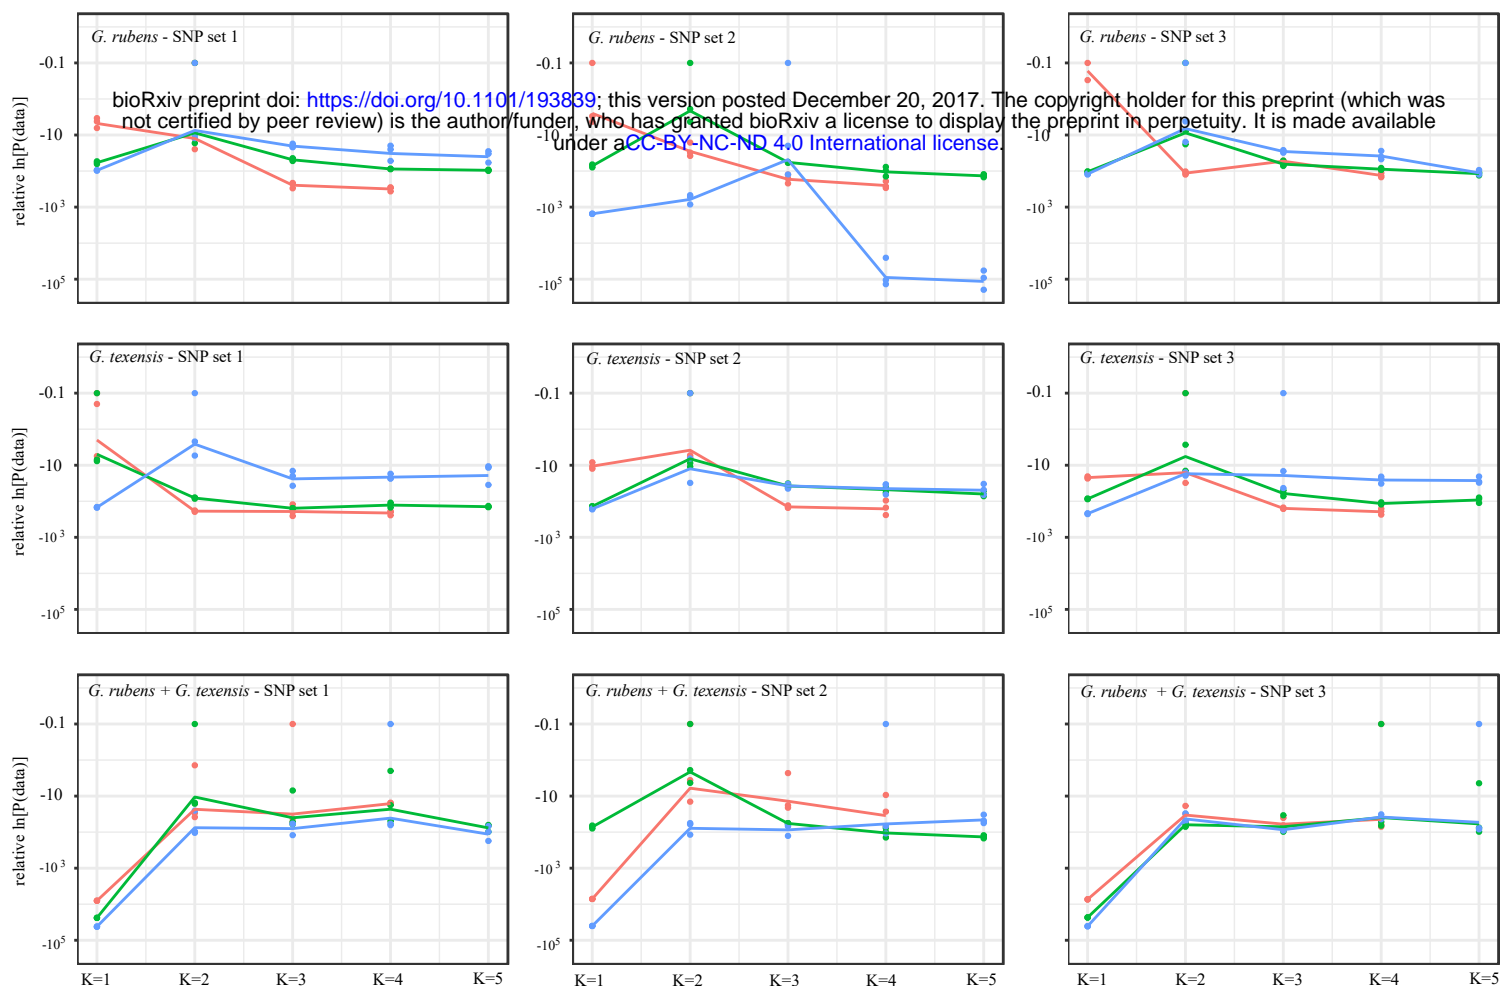

Figure S3. Relative natural log transformed probability of the data under different values for K. The raw probabilities from STRUCTURE relative to the maximum probability is shown for each K, for three random sets of 8835 SNPs (one per contig), and for *G. rubens*, *G. texensis*, and for the species combined (excluding eight individuals to correct for cryptic relatedness). Within each panel, the dots show each of the three iterations and the lines show the trend in the average difference in probability with the maximum probability for three different sample sizes: two random individuals per population (red), five random individuals per population (green), and all the individuals sampled from the populations.

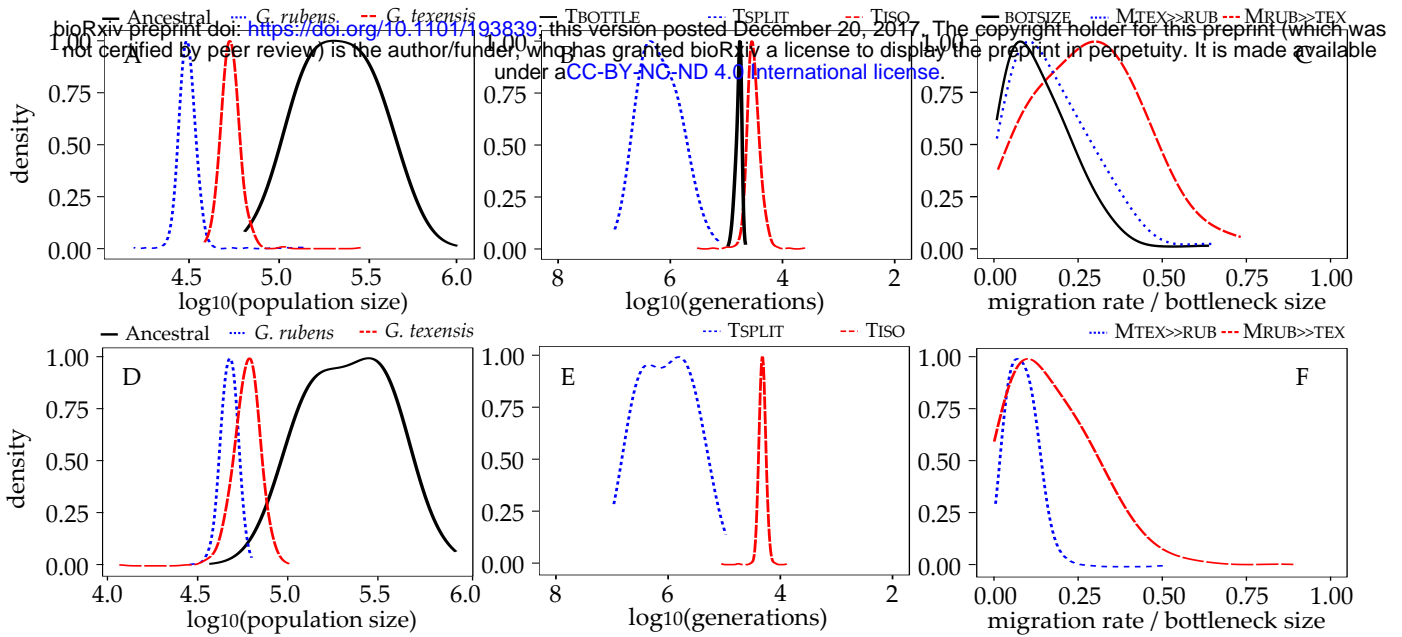

Fig S4. Demographic parameter estimation for the model with all 40 individuals. For the AGFRB (A-C) and the AGF models (D-F) the density distributions of the the ancestral and current population sizes (A,D), the time since divergence, cessation of gene flow, and recovery to current population sizes after the bottleneck (B,E), and the migration rates and bottleneck size (C,F) are shown. The density lines have been trimmed to the existent parameter distribution (i.e., no density extrapolation) and have been smoothed by adjusting the bandwidth. For lines within one panel the same smoothing bandwidth has been used.

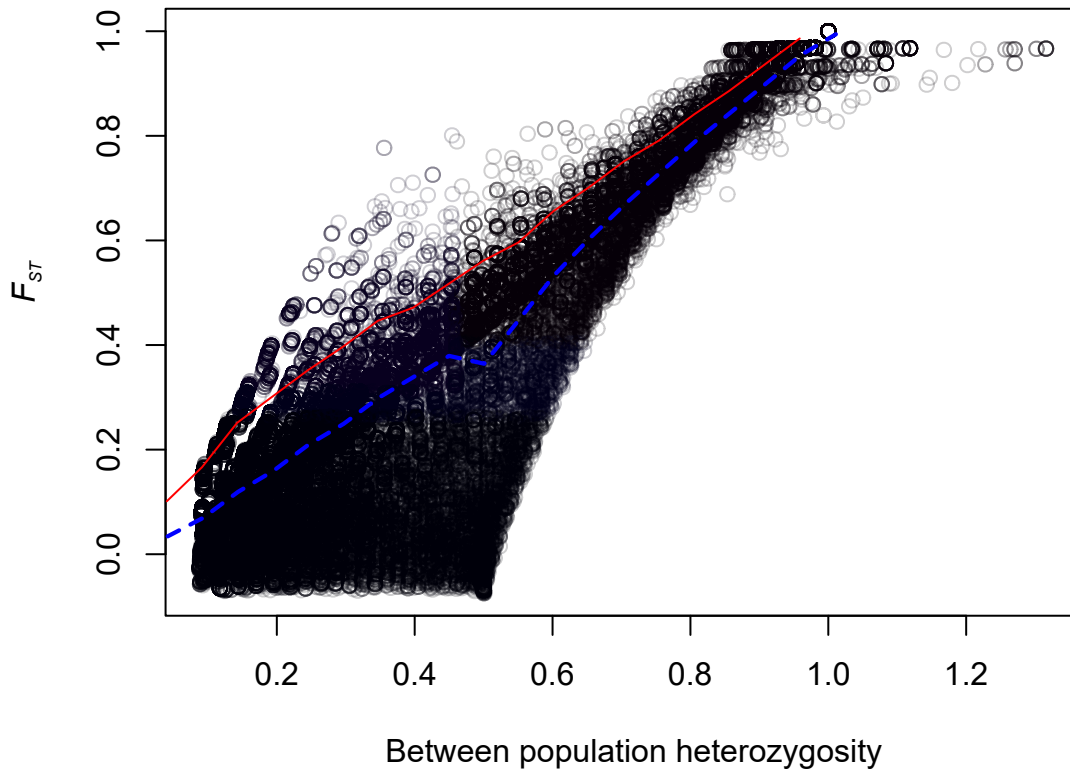

Fig. S5. Arlequin F_{ST} based selection scan. The circles represent estimates for the F_{ST} and between population heterozygosity for all SNPs with $MAF > 0.05$ (81,125 SNPs). The blue dashed and red solid line are the median and 99th quantile, respectively, of the simulated null distribution for this relationship under a hierarchical island model. Any SNPs above the red solid lines were considered outliers.
