24 **Summary:** Over 40 years of research has examined the role of the ventral visual
25 stream in transforming retinal inputs into high-level representations of object identity [1-
26 6]. However, there remains an ongoing debate over the role of the ventral stream in
27 coding abstract semantic content, which relies on stored knowledge, versus perceptual
28 content that relies only on retinal inputs [7-12]. A major difficulty in adjudicating between
29 these mechanisms is that the semantic similarity of objects is often highly confounded
30 with their perceptual similarity (e.g., animate things are more perceptually similar to
31 other animate things than to inanimate things). To address this problem, we developed
32 a paradigm that exploits the statistical regularities of object colors while perfectly
33 controlling for perceptual shape information, allowing us to dissociate lower-level
34 perceptual features (i.e., color perception) from higher-level semantic knowledge (i.e.,
35 color meaning). Using multivoxel-pattern analyses of fMRI data, we observed a striking
36 double dissociation between the processing of color information at a perceptual and at a
37 semantic level along the posterior to anterior axis of the ventral visual pathway.
38 Specifically, we found that the visual association region V4 assigned similar

1 representations to objects with similar colors, regardless of object category. In contrast,
2 perirhinal cortex, at the apex of the ventral visual stream, assigned similar
3 representations to semantically similar objects, even when this was in opposition to their
4 perceptual similarity. These findings suggest that perirhinal cortex untangles the
5 representational space of lower-level perceptual features and organizes visual objects
6 according to their semantic interpretations.

9 **Keywords:** semantic memory; object representation; perirhinal cortex; high-level vision;
10 representational similarity analysis

11

12

13 **Highlights:**

14 -Perirhinal cortex (PRc) contains combinatorial codes of object category and color

15 -These PRc codes reflect semantic knowledge of object colors

16 -V4 encodes color independent of semantic information

17 -These results reveal a transformation from perceptual to conceptual object codes

18

19

20 **In Brief:** Observers of the world know that roses are typically red and violets blue, but
21 neurobiologists know little about how this knowledge is encoded by the brain. Price et
22 al. report a neural mechanism through which humans understand the meaning of object
23 colors, revealing a fundamental biological process that transforms sensory inputs into
24 abstract representations of object meaning.

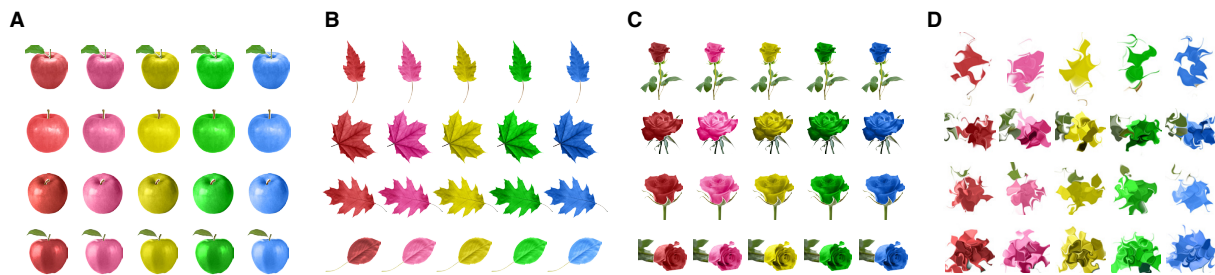

25

26

27 **Results and Discussion:**

28 We designed a novel stimulus set that allowed us to leverage the natural
29 statistics of object-color information in order to investigate the perceptual and semantic
30 coding of visual objects along the ventral stream. Many objects in our natural
31 environment exist in a range of colors and exhibit clear statistical regularities in their

1 color appearance, which have important implications for their meaning (e.g., the color
2 green has a different meaning for leaves than for bananas). The stimuli used in this
3 study were images of objects from three categories (apples, leaves, and roses), which
4 were displayed in five different colors (red, pink, yellow, green, and blue). Example
5 stimuli are shown in Figure 1. The semantic associations of the colors differ in the
6 context of each object category (e.g., green is a common natural color for leaves but not
7 roses). Thus the color-and-object combinations give rise to a unique semantic similarity
8 space for each category, and, importantly, these representational spaces differ from the
9 perceptual similarity space of the colors alone. For example, in the category of apples,
10 green is semantically similar to red (which are both common colors for apples), even
11 though green and red are highly dissimilar in color-perceptual space. We used
12 functional MRI (fMRI) in human participants to measure patterns of neural activity while
13 the subjects viewed images of these objects and performed an unrelated visual-
14 detection task (Supplementary Figure S1).
15

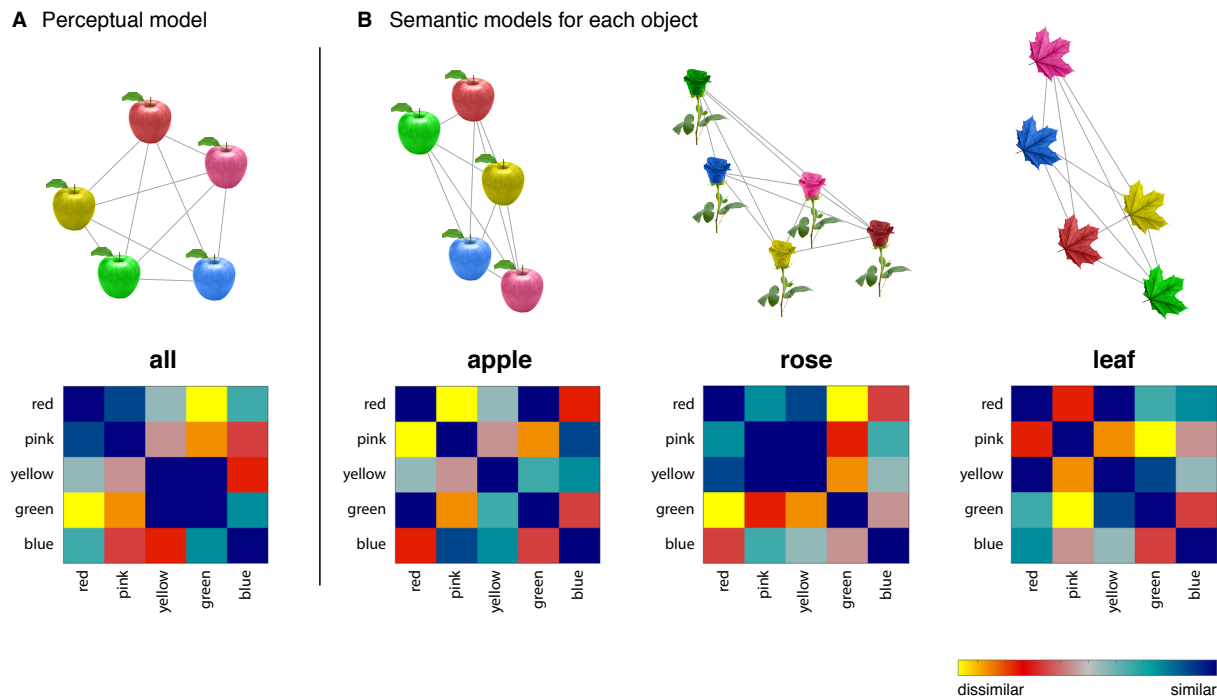

16
17 **Figure 1.** Examples of stimuli from each object category in each color combination. (A)
18 apples (B) leaves (C) roses (D) non-object diffeomorphically warped images.
19
20

21 We examined two theoretically motivated regions of interest along the ventral
22 stream: V4 and perirhinal cortex (PRc). V4 is a mid-level association region that has
23 previously been implicated in color perception [13-15], but whose possible role in color
24 semantics remains unknown. PRc is a subregion of the anterior temporal lobe located at
25 the apex of the ventral visual pathway [6] that has been implicated in object
26 individuation and object semantics [16-24]. However, it is not yet known whether PRc

1 contains a mechanism for untangling the similarity space of lower-level perceptual
2 inputs and organizing objects according to their semantic interpretations, even when
3 this is at odds with their perceptual similarity.

4

5 **Figure 2.** Representational dissimilarity models for the perceptual color model and the
6 category-specific semantic models. Each plot shows a dissimilarity matrix on the bottom
7 and a two-dimensional embedding of stimuli for that model on the top. (A) Perceptual-
8 color model. This model is based on the perceptual similarity of the colors alone and is
9 thus the same for all object categories. The apple category is shown as an example. (B)
10 Semantic color models reflected category-specific co-occurrence statistics and thus are
11 unique for each object category.
12
13

14

15 We used representational similarity analysis (RSA) to probe the information
16 encoded in the multivariate activity patterns in our regions of interest. We specifically
17 examined the fit of two models that capture the perceptual and semantic similarity of the
18 colors within each category (Figure 2). A key aspect of this design is that we specifically
19 modeled representational dissimilarities within each object category (e.g., roses). This
20 approach perfectly controls for shape information, allowing us to examine the coding of

1 object semantics in a manner that is completely independent of perceptual confounds
2 related to shape.

3 This analysis revealed a strong double dissociation between the perceptual
4 representation of object colors in V4 and the semantic representation of object colors in
5 PRc (Figure 3; 2×2 repeated-measures ANOVA interaction of region by model, $F(1,15)$
6 $= 14.9$, $p = 0.001$). As hypothesized, the semantic similarity model fit significantly in PRc
7 but not V4 (V4: $t(15) = 0.87$, $p = 0.40$, Cohen's $d = 0.22$; PRc: $t(15) = 5.41$, $p < 0.001$,
8 Cohen's $d = 1.35$), whereas the perceptual color model fit significantly in V4 but not PRc
9 (V4: $t(15) = 2.22$, $p = 0.04$, Cohen's $d = 0.56$; PRc: $t(15) = 0.54$, $p = 0.60$, Cohen's $d =$
10 0.13). Furthermore, direct comparisons showed that the semantic similarity model fit
11 significantly better in PRc than in V4 ($t(15) = 3.87$, $p = 0.002$; Cohen's $d = 1.31$) and the
12 perceptual similarity model fit significantly better in V4 than in PRc ($t(15) = 2.13$, $p =$
13 0.05 ; Cohen's $d = 0.67$).

14

19

20

21 These findings indicate that PRc integrates the shape and color features of visual
22 objects and links these perceptual inputs with knowledge representations of object
23 colors. In doing so, PRc appears to embed visual object representations in a semantic
24 space that is orthogonal to the lower-level perceptual similarity space of object features.
25 These results are remarkably consistent with a previous neuropsychological report of a

1 patient with a lesion encompassing PRc who had a profound deficit in object-color
2 knowledge but a relative sparing of color perception [25]. These findings are also
3 broadly consistent with previous studies of the semantic variant of primary progressive
4 aphasia (also known as semantic dementia), a neurodegenerative disease that
5 encompasses PRc and results in a profound impairment in object meaning with a
6 relative sparing of visual-perceptual abilities [26, 27]. Furthermore, the results of our
7 color-perceptual model align well with recent work implicating V4 in the coding of a fine-
8 grained perceptual color space [13, 28].

9 To test for possible effects in other regions of the ventral stream, we performed
10 the same analyses in a series of regions along ventral occipital-temporal cortex
11 (including early visual cortex, lateral occipital complex, inferior temporal gyrus, and
12 fusiform gyrus). We found no significant effects in any other ventral visual regions for
13 either the perceptual color model or the semantic model (Supplementary Figure S2B-C).
14 We also performed an analysis to test for possible univariate effects related to the
15 typicality of color-and-category combinations, which might reflect a coarse familiarity
16 signal in PRc. We found no reliable correlation between color frequency and the mean
17 univariate signal in either PRc or V4 (Supplementary Figure 3S).

18 Much of the work examining high-level semantic coding in the ventral visual
19 stream has focused on the representation of broad categories of objects (e.g., animate
20 versus inanimate; fruit versus vegetables). However, category membership is often
21 highly correlated with basic shape information [9, 11, 12]. Furthermore, semantic
22 representations of objects encompass much more than their broad category labels. An
23 essential aspect of the semantic memory system is information about individual objects
24 *within* a category. Here we were able examine the coding of fine-grained object
25 semantics in a manner that completely controls for the contribution of perceptual shape
26 information. Interestingly, we did not observe evidence for the coding of fine-grained
27 object semantics in inferior temporal cortex, a region that is strongly associated with the
28 representation of object categories but whose contribution to high-level object
29 semantics has long been debated [7-12]. Rather this more fine-grained semantic
30 information appears to be encoded in PRc—a higher-level region of the ventral stream
31 that has previously been implicated in the detailed analysis that underlies object

1 individuation [17, 19-21, 29, 30]. Our findings are consistent with the proposed role of
2 PRc in object individuation, but they suggest that the mechanism for object
3 representation in PRc is more complex than a perceptual analysis of feature
4 conjunctions. Specifically, these findings suggest that PRc not only disambiguates
5 perceptually confusable objects (e.g., green apple and blue apple) but also assigns
6 similar representations to perceptually distinct objects with similar meanings (e.g., green
7 apple and red apple). Thus, PRc appears to untangle the similarity space of lower-level
8 perceptual inputs and organize individual objects according to their semantic
9 interpretations.

10

11

12 **Author contributions:** A.R.P, M.F.B, J.E.P, and M.G. designed the experiment,
13 reviewed the analyses, and discussed the results. A.R.P. and M.F.B. collected the data
14 and performed the analyses. A.R.P, M.F.B, J.E.P, and M.G. wrote the paper.

18 Wyncote Foundation, and the Jameson-Hurvich fund. The authors thank B. Stojanoski
19 for sharing code for diffeomorphic transformations, and R. Epstein for helpful comments
20 on this project.

1 **Experimental Procedures:**

2 Participants. Sixteen healthy participants (7 female; mean age = 24.6, SD = 2.6) with
3 normal or corrected-to-normal vision were recruited from the University of Pennsylvania
4 community. Participants provided written informed consent in compliance with
5 procedures approved by the University of Pennsylvania Institutional Review Board.

6
7 MRI acquisition. Participants were scanned on a Siemens 3.0 T Trio scanner. We
8 acquired high-resolution T1-weighted structural images using an MPRAGE protocol (TR
9 = 1620 ms, TE = 3.9 ms, flip angle = 15°, 1 mm slice thickness, 192 x 256 matrix, 160
10 slices, resolution = 0.9766 x 0.9766 x 1 mm). There were 3 functional scanning runs
11 using gradient echo EPI sequences (32 slices in descending order of 3 mm thickness, a
12 between slice gap of 0.75 mm, a resolution of 3 x 3 x 3 mm, a matrix size of 64 x 64, a
13 flip angle of 78°, a TR of 2 s, and a TE of 30 ms). Each functional run lasted
14 approximately 15 minutes.

15
16 Stimuli. Stimuli were colored objects presented on a phase-scrambled background.
17 Three categories of objects (apples, leaves, and roses) were presented in five colors
18 (red, pink, yellow, blue, and green). There was also a warped, non-object condition that
19 was presented in the same five colors. Examples of stimuli from each condition are
20 displayed in Figure 1. To create the stimuli, high-resolution images of natural objects
21 were edited in Adobe Photoshop. The background was removed, leaving an object in
22 isolation. The portion of the object containing the relevant color property was manually
23 segmented and placed into a separate layer, where we were able to modify its color
24 independent of the other object features (e.g., for an apple image, the body of the apple
25 was segmented and its color was modified without altering the stem or the leaves). This
26 segmented portion of the object was first set to grayscale. We then created colored
27 versions of each object by modifying the RGB color settings for this grayscale
28 segmentation to red (RGB: 121 18 21), pink (RGB: 222 103 147), yellow (RGB: 187 174
29 30), blue (RGB: 0 67 166), and green (RGB: 0 171 0). Each object appeared in all five
30 colors, ensuring that shape information was the same across all color conditions for a
31 given object category. We repeated this procedure for 27 unique images within each

1 object category (i.e., 27 apples, 27 leaves, and 27 roses). The same procedure and
2 color settings were used for all objects. We also created mirror-flipped versions of the
3 colored objects, resulting in 54 unique stimuli for each color-object condition (producing
4 a total of 810 unique object stimuli). We created non-object images by applying a
5 diffeomorphic warping procedure to the object stimuli described above. This procedure
6 involves a smooth and continuous image transformation applied iteratively (40 iterations
7 were used), and preserves low-level perceptual properties of the stimuli while making
8 them unrecognizable as real-world objects [31]. All objects and non-object stimuli were
9 centrally placed over a grayscale phase-scrambled background (the same background
10 was used for all images).

11
12 Stimulus presentation. We presented 810 unique object images to participants while
13 collecting fMRI data from 15 categories of color-and-object combinations (Figure 1).
14 Stimuli were presented in an event-related design using a continuous carry-over
15 sequence within each run [32]. In each of the three runs, subjects viewed 270 unique
16 object images (18 unique examples x 15 color-object conditions), as well as 36 unique
17 non-object images. There were also 18 null events (5 s) in each run (null events were
18 treated as an additional condition in the continuous carryover design) [32]. Each
19 stimulus was presented on the screen for 1 s with an inter-stimulus interval of 1.5 s. On
20 each trial subjects indicated by button press whether the image was an object or a non-
21 object foil (Supplementary Figure S1). Therefore, subjects responded yes to all object
22 images, regardless of typicality or category, and no to the non-object foils. Task
23 accuracy was high. For object images the mean accuracy was 99.9% (SD = 0.1%), and
24 for non-object images the mean accuracy was 96.4% (SD = 3.7%).

25
26 Regions of interest. We defined a series of bilateral regions of interest (ROI) along the
27 ventral visual pathway. These included ROIs for early visual cortex (EVC), V4, lateral
28 occipital complex (LOC), inferior temporal gyrus (ITG), fusiform gyrus (FG), and
29 perirhinal cortex (PRc). The ITG and FG ROIs were taken from the AAL atlas [33]. The
30 EVC and LOC ROIs were taken from probabilistically defined parcels of functional
31 localizer contrasts from a large number of subjects in a separate experiment (shared by

1 the Epstein lab and described here [34]). These parcels were created through an
2 automated procedure that identifies clusters of common activation across individuals for
3 a series of functional ROI contrasts [35]. The LOC parcel was created from a contrast of
4 objects > scrambled images, and the EVC parcel was created from a contrast of
5 scrambled images > objects. We used the entire parcels for both EVC and LOC, and we
6 did not apply any further voxel-selection procedures to these ROIs. Our V4 ROI was
7 created by placing spheres with a 6-mm radius around MNI coordinates that were
8 reported in a classic study of color-perceptual processing [15], and which have
9 previously been used to define ROIs for color processing [36]. The perirhinal cortex ROI
10 was taken from a probabilistic map of anatomic segmentations [37] and was threshold
11 to include voxels with at least 30% overlap across subjects.

12
13 *fMRI preprocessing and modeling.* The fMRI data were processed and modeled using
14 SPM8 (Wellcome Trust Centre for Neuroimaging, London, UK) and MATLAB (R2014a
15 Mathworks; The MathWorks, Natick, MA). For each participant, all functional images
16 were realigned to the first image [38] and co-registered to the structural image [39]. The
17 images were spatially smoothed using a 3 mm FWHM isotropic Gaussian kernel. We
18 modeled voxel responses to all conditions in each run in a single general linear model.
19 Low-frequency drifts were removed using a high-pass filter with a cutoff period of 128
20 sec, and auto-correlations were modeled with a first-order autoregressive model. The
21 parameter estimates for each condition were then averaged across runs. The resulting
22 images were whole-brain maps of the voxel responses to each condition, which we then
23 normalized to standard Montreal Neurological Institute space using a unified
24 segmentation approach [40]. We used these maps to characterize the multivoxel
25 information content in a series of ROIs through representational similarity analysis [41].

26
27 *Representational similarity analysis.* We used representational similarity analysis (RSA)
28 [41] to characterize the information encoded in the population responses of ROIs
29 throughout the ventral visual pathway. For each ROI we constructed neural
30 representational dissimilarity matrices (RDM) that represented all pairwise comparisons
31 of conditions within each object category. The responses within each voxel were first z-

1 scored across conditions, and we then computed neural dissimilarity as one minus the
2 Pearson correlation coefficient between the multivoxel activation patterns for each
3 condition. We also constructed dissimilarity matrices that represented the distances
4 between conditions based on two models of representational content. The specifics of
5 these two models are discussed below. We tested how well each model accounted for
6 the representational structure in an ROI by calculating the Spearman correlation
7 between the model and the neural dissimilarity matrices. The significance of each model
8 was assessed using random-effects t-tests of the RSA correlations across subjects.

9 We examined two key models to test for the coding of a perceptual color space
10 and a semantic color space. The perceptual model was created from subjective
11 evaluations of color similarity collected in a norming study (described below). This
12 model reflects the perceptual similarity of the colors independent of the object
13 categories, and it was thus the same for each object category (e.g., red is more similar
14 to pink than to green; Figure 2A). We converted these data into a dissimilarity matrix by
15 taking the negative of the pairwise similarity values. The semantic model represents the
16 dissimilarities between colors within each object category (e.g., red apple is more
17 similar to green apple than to pink apple). Because the semantic statistics were unique
18 to each object category, these models differed across categories (Figure 2B). Model fits
19 were computed for each category separately, and we calculated the mean fit across
20 categories. An important strength of this design is that all dissimilarity measurements
21 reflect comparisons within an object category (i.e., apples, leaves, and roses), which
22 means that the stimuli in each comparison contain the same shape information and only
23 differ on color. This completely controls for shape information in both the perceptual and
24 the semantic color models.

25

26 *Perceptual color model.* We constructed a model of perceptual color similarity using
27 subjective evaluations collected in a separate norming survey (N=18). This model
28 captures color similarity independent of object categories. We presented the subjects
29 with colored squares using the same RGB values used for the colored object images.
30 Subjects judged the color similarity of the color swatches in a forced-choice two-
31 alternative task with a reference swatch shown at the top and two choice swatches

1 shown below. In an example trial, a subject might be shown a pink square at the top of
2 the screen and asked to judge which of the two squares on the bottom, a red square or
3 a blue square, is more similar. We constructed all possible pairings of reference and
4 choice swatches (30 triads total), resulting in an equal number of judgments for all
5 pairwise comparisons of colors. We used these data to construct a similarity matrix. For
6 each pairwise comparison in this matrix, we counted the number of times that subjects
7 reported those two colors as similar across all trials of the similarity judgment task. In
8 other words, we filled the cells of this matrix with frequency counts of similarity pairings.
9 We then converted this into a dissimilarity matrix by taking the negative of the similarity
10 values. The resulting matrix captures color relationships that are closely matched to the
11 perceptual space of a color wheel, as can be seen in the two-dimensional embedding in
12 Figure 2A (all visualizations of two-dimensional embeddings were generated using t-
13 distributed stochastic neighbor embedding [42]).

14
15 *Semantic color model.* We constructed a model of semantic color similarity based on
16 the feature co-occurrence frequencies for the colors and object categories. This model
17 reflects color similarity relationships that are unique to each object category (e.g., green
18 apples are more similar to red apples than to blue apples based on how frequently
19 apples occur in these colors). We used a metric of co-occurrence frequency that
20 captures the statistics of how people talk about object colors in written text [43]. This
21 metric is derived from billions of words of text, and we reasoned that it would be strongly
22 tied to how people think about and interpret these objects in the natural environment.
23 We measured co-occurrence frequencies using Google ngram, a large corpus of
24 English-language books [44]. Specifically, we quantified the directional co-occurrence
25 frequencies of the color and object terms using both the singular and plural forms of the
26 object terms (e.g., “red apple” and “red apples”) from 2008 (the most recent available
27 data). We used log-transformed values of the co-occurrence statistics. To verify that
28 these co-occurrence statistics related to the semantic interpretation of the objects, we
29 asked the participants from the fMRI experiment to complete a series of subjective
30 typicality ratings for the object images at the end of the study. The ratings were made
31 on a 1-to-7 scale of highly atypical to highly typical. We were specifically interested in

1 assessing whether subjects' intuitions about color typicality related to the co-occurrence
2 statistics of the object and color terms (e.g., that the high co-occurrence of "red apple" in
3 text corresponded to subjective ratings that this color and object combination was highly
4 typical). Indeed, there was a strong correlation between the co-occurrence statistics and
5 mean subjective ratings of typicality across all objects ($r = 0.71$, $p = 0.001$). These co-
6 occurrence statistics were then used to construct a model dissimilarity matrix of the
7 semantic color space for each object category. We calculated the relative difference in
8 co-occurrence for all pairwise comparisons of objects within a category (i.e., the
9 absolute difference divided by the sum of the co-occurrence statistics). These
10 dissimilarity matrices capture a model in which highly typical colors for an object
11 category are close together in representational space, as can be seen in the two-
12 dimensional embedding in Figure 2B [42].

29

Figure 2. Representational dissimilarity models for the perceptual color model and the category-specific semantic models. Each plot shows a dissimilarity matrix on the bottom and a two-dimensional embedding of stimuli for that model on the top. (A) Perceptual-color model. This model is based on the perceptual similarity of the colors alone and is thus the same for all object categories. The apple category is shown as an example. (B) Semantic color models reflected category-specific co-occurrence statistics and thus are unique for each object category.

30
31
32
33

Figure 3. Double dissociation between the processing of color at a perceptual level in V4 and the processing of color at a semantic level in perirhinal cortex. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. Plots depict correlation means \pm SE

1 **Supplemental Information:**

2

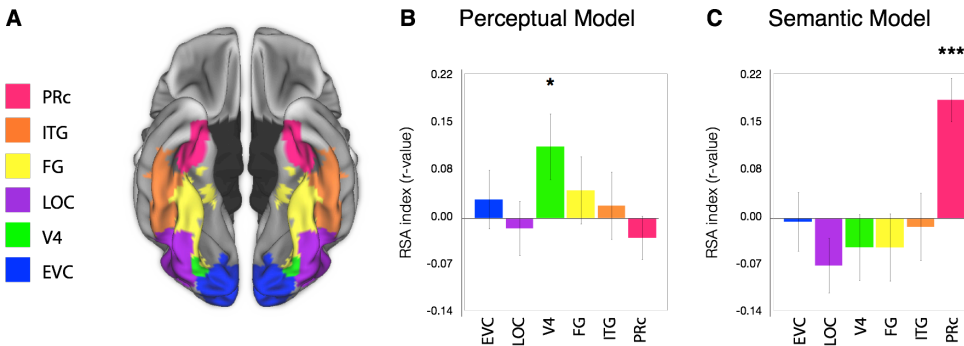

3

4 **Supplementary Figure S1.** Visual-object behavioral task. Related to Figures 1 and 2.
5 On each trial, participants viewed a single image on a phase-scrambled background
6 and had to decide whether it was an object image or a warped non-object image.

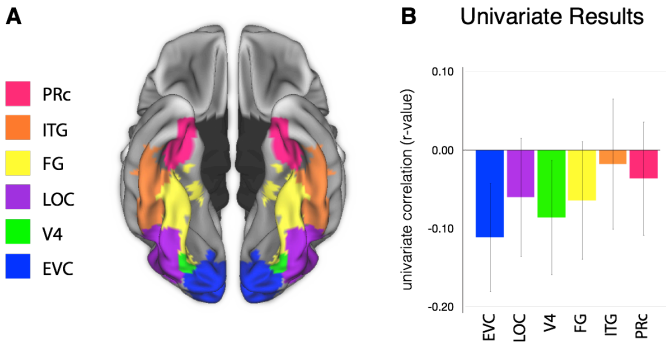

7

8

9

10 **Supplementary Figure S2.** Representations of perceptual-color similarity and
11 semantic-color similarity along the ventral visual stream. Related to Figure 3. To test for
12 possible effects in other regions of the ventral stream, we performed the same analyses
13 in a series of regions along ventral occipital-temporal cortex. (A) Color-coded regions of
14 interest (B) Results for the perceptual-color model. The only region to show an effect for
15 this model was V4 ($p = 0.02$). EVC: $t(15) = 0.69$, $p = 0.50$; LOC: $t(15) = 0.33$, $p = 0.75$;
16 ITG: $t(15) = 0.46$, $p = 0.65$; FG: $t(15) = 1.14$, $p = 0.27$. (C) Results for the semantic
17 model. The only region to show an effect for the semantic model was perirhinal cortex
18 ($p < 0.001$). EVC: $t(15) = 0.11$, $p = 0.91$; LOC: $t(15) = 1.71$, $p = 0.11$; ITG: $t(15) = 0.25$, p
19 $= 0.81$; FG: $t(15) = 0.86$, $p = 0.40$). Bar plots depict means \pm SE. EVC = early visual
20 cortex, LOC = lateral occipital complex, FG = fusiform gyrus, ITG = inferior temporal
21 gyrus, PRC = perirhinal cortex. * $p < 0.05$, *** $p < 0.001$

1
2 **Supplementary Figure S3.** Summary of results from univariate analysis in all regions.
3 Related to Figure 3. This analysis examined possible correlations between the typicality
4 of color-and-category combinations and univariate activation, which might reflect a
5 coarse familiarity signal within each object category. We calculated the correlation
6 between the mean activity of each ROI and the log n-gram frequency of the color and
7 object combinations. The correlation was calculated across all conditions after mean-
8 centering the data within each object category (in order partial out overall differences
9 across object categories and specifically examine the within-category effects of color
10 typicality). Significance was assessed using random-effects t-tests of the univariate
11 correlations across subjects. (A) Color-coded regions of interest. (B) We found no
12 reliable correlation between color frequency and univariate signal in either PRc or V4 or
13 in any of the other ventral visual regions of interest. (EVC ($t(15) = 1.61$, $p = 0.13$); LOC
14 ($t(15) = 0.80$, $p = 0.44$); V4: $t(15) = 1.18$, $p = 0.26$; ITG ($t(15) = 0.22$, $p = 0.83$); FG ($t(15)$
15 $= 0.86$, $p = 0.40$) PRc: $t(15) = 0.50$, $p = 0.62$). Bar plots depict means \pm SE. EVC = early
16 visual cortex, LOC = lateral occipital complex, FG = fusiform gyrus, ITG = inferior
17 temporal gyrus, PRc = perirhinal cortex.
