14

15 **Abstract**

16 ATP11C, a member of P4-ATPase flippase, exclusively translocates phosphatidylserine
17 from the outer to the inner leaflets of the plasma membrane, and maintains the
18 asymmetric distribution of phosphatidylserine in the living cell. However, the
19 mechanisms by which ATP11C translocates phosphatidylserine remain elusive. Here we
20 show the crystal structures of a human plasma membrane flippase, ATP11C-CDC50A
21 complex, in an outward-open E2P conformation. Two phosphatidylserine molecules are
22 in a conduit that continues from the cell surface to the occlusion site in the middle of the
23 membrane. Mutations in either of the phosphatidylserine binding sites or along the
24 pathway between significantly impairs specific ATPase and transport activities. We
25 propose a model for phosphatidylserine translocation from the outer to the inner leaflet
26 of the plasma membrane.

27

28 **Introduction**

29 Phospholipids are asymmetrically distributed between the outer and inner
30 leaflets in the plasma membrane of eukaryotic cells. Aminophospholipids such as
31 phosphatidylserine (PtdSer) and phosphatidylethanolamine (PtdEtn) are confined to the
32 inner leaflet, while phosphatidylcholine and sphingomyelin are enriched in the outer
33 leaflet¹. The asymmetric distribution of phospholipids is widely conserved in eukaryotes,
34 being tuned for barrier functions and various signal transductions on the plasma
35 membrane². On occasion, this phospholipid asymmetry in the plasma membrane is
36 disrupted, exposing PtdSer on the cell surface. Cells undergoing apoptosis expose
37 PtdSer as an “eat me” signal to phagocytes^{3,4}. Activated platelets also display PtdSer as
38 a scaffold for clotting enzyme reactions⁵. The amphipathic nature of phospholipids
39 prevents their spontaneous flip-flop movement across the lipid bilayer in most cases,
40 and the translocation of phospholipids therefore needs membrane proteins to overcome
41 the energetic barrier required for the phospholipid translocation².

42 While scramblases mediate non-specific and bi-directional movement of
43 phospholipids between inner and outer leaflets⁶, flippases exhibit ATP-driven,
44 directional and up-hill translocation of phospholipids from the outer to inner leaflets
45 against their concentration gradient across the membrane bilayer^{7,8,9}. Different from
46 other members of cation-transporting P-type ATPases¹⁰⁻¹³, Type IV P-type ATPase
47 (P4-ATPase) comprises a subfamily of P-type ATPases that transports phospholipid¹⁴.
48 Among all 14 members of P4-ATPase in humans, ATP11A and ATP11C work as
49 aminophospholipid-specific flippases at the plasma membrane^{3,4}. They require an
50 accessory subunit, CDC50A, for their correct localization and the functional expression
51 on the plasma membrane¹⁵⁻¹⁷. In fact, cells lacking ATP11A and ATP11C, or CDC50A
52 almost completely lose flippase activity for PtdSer and PtdEtn at the plasma membrane,
53 resulting in failure to maintain the asymmetric accumulation of PtdSer in the inner
54 leaflet. Their inactivation causes PtdSer exposure on the cell surface. In apoptotic cells,
55 ATP11A and ATP11C are subjected to a caspase-mediated proteolysis and irreversible
56 inactivation. It is proposed that calcium ions likely also inhibit the flippase activity for
57 calcium-dependent PtdSer exposure in activated platelets or lymphocytes¹⁸. Regulation
58 of aminophospholipid asymmetry by flippases is physiologically important;
59 ATP11A-deficient mice are embryonic lethal¹⁹, and ATP11C-deficient mice display
60 pleiotropic phenotypes such as B-cell lymphopenia^{20,21}, cholestasis²², mild anemia²³,
61 and dystocia. Recently, mutations in the ATP11C gene were identified in patients
62 suffered from anemia²⁴.

63 The directional translocation of specific phospholipids mediated by

64 P4-ATPases is achieved by the cyclic conversion of enzyme conformations, E1, E2 and
65 their auto-phosphorylated forms E1P and E2P, similar to the Post-Albers type reaction
66 scheme^{14,25} for cation-transporting P-type ATPases. However, despite the huge size of
67 phospholipids relative to inorganic cations, the mechanism by which P4-flippases
68 translocate phospholipids across the membrane, the so-called “giant substrate problem”
69 ^{26,27}, has remained elusive and yet is of considerable interest. Here, we describe a crystal
70 structure of a *bona fide* human plasma membrane flippase ATP11C-CDC50A complex
71 in the outward-open E2P conformation, analyzed to 3.9 Å resolution. Our structure has
72 two PtdSer molecules simultaneously bound in the putative lipid translocating conduit.
73 The structure, together with functional analyses, enable us to propose a molecular
74 mechanism for the phospholipid translocation across the plasma membrane by ATP11C.

75

76 **Results and Discussion**

77

78 **Overall structure of the outward-open conformation**

79 Human ATP11C and CDC50A were expressed using the BacMam system (Fig.
80 S1, Methods)²⁸. Purified and deglycosylated proteins were mixed with
81 dioleoylphosphatidylcholine (DOPC)²⁹, and crystallized in the presence of phosphate
82 analogue³⁰ beryllium fluoride (BeF_x) and dioleoylphosphatidylserine (DOPS). Crystals
83 were harvested in the presence of excess DOPS, which was key to preservation of
84 crystal quality. X-ray diffraction data from more than 1,500 individual crystals were
85 merged, and the structure was determined by molecular replacement using the atomic
86 model of the E2BeF state of ATP8A1³¹ as a search model, at a resolution of 3.9Å with
87 acceptable statistics of $R_{\text{work}}/R_{\text{free}} = 27.9/34.7$ (Fig. S1, Table S1). As is seen in most of
88 the other crystallized P-type ATPases, molecular packing occurs as type I crystals in
89 which complexes are embedded in the lipid bilayer³². The asymmetric unit of the crystal
90 consists of four protomers of ATP11C-CDC50A. Due to different crystal contacts, the
91 appearance of the electron density map differs significantly for each protomer (Fig. S2).
92 Despite limited resolution, however, well-ordered regions, especially the
93 transmembrane (TM) region of protomer A and B were visible at side chain level (Fig.
94 S3). The overall molecular conformations of the four protomers are essentially the same,
95 although structural variations in some of the loop structures exist (Fig. S2). We therefore
96 focus on the well-ordered protomer A in what follows.

97 Like other members of the well-characterized, cation-transporting P-type
98 ATPases¹¹⁻¹³, the up-hill translocation of aminophospholipids by ATP11C is achieved
99 according to the Post-Albers type reaction scheme^{14,25} (Fig. 1A). The outward-open E2P

100 conformation captures PtdSer or PtdEtn on the outer leaflet and induces
101 dephosphorylation of E2P, thus PtdSer- or PtdEtn-dependent ATP hydrolysis can be
102 detected (Fig. 1B), similar to the inward transport of K^+ by Na^+,K^+ -ATPase and
103 H^+,K^+ -ATPase. As we included BeF_x and PtdSer for the crystallization, the molecular
104 conformation³³ was expected to be the outward-open E2P state in which PtdSer is bound
105 to the conduit facing to the exoplasmic side (Fig. 1A). In fact, the overall structure of
106 the ATP11C-CDC50A complex (Fig. 1C) is very close to the corresponding E2P
107 structures of recently reported flippases yeast Drs2p-Cdc50p³⁴ and human
108 ATP8A1-CDC50A³¹ complexes. The sequence identities of each catalytic subunit are
109 35.3% and 36.2%, respectively (Fig. S4 for sequence alignment)³⁵. The molecular
110 conformation is also defined by the relative orientations of the cytoplasmic domains³⁶
111 (actuator (A), phosphorylation (P) and nucleotide-binding (N) domains), and the
112 arrangement of the ten transmembrane (TM) helices of the catalytic subunit ATP11C.
113 The phosphate analogue BeF_x likely forms a covalent bond to the invariant aspartate in
114 the ⁴⁰⁹DKTG signature sequence, which is covered by the ¹⁷⁹DGES/T motif located on
115 the surface of the A domain to prevent spontaneous dephosphorylation by the bulk water
116 (Fig. S5). In this conformation, the N domain is segregated from the P domain, and is
117 expected to be relatively flexible compared to the other two domains due to the lack of
118 intimate inter-domain interactions, and this is consistent with its poor electron density
119 (Fig. S2,3). The relative orientation of the A and P domains in ATP11C is close to those
120 observed in Drs2p and ATP8A1 E2P states, and clearly different from that in the
121 ATP8A1 E2-P_i transition state (Fig. S5), indicating that the present ATP11C structure
122 adopts an E2P state.

123 The CDC50A subunit consists of two TM helices with a long N-terminal tail
124 and a short C-terminus on the cytoplasmic side, and a large exoplasmic domain in
125 which four *N*-linked (Asn107, Asn180, Asn190 and Asn294) and one *O*-linked (Ser292)
126 glycosylation sites are located. We extensively investigated various combinations of
127 glycosylation site mutants to improve protein expression and crystal quality, and found
128 that the Asn190Gln/Ser292Trp double mutant produced the best crystals. Because the
129 samples were treated with endoglycosidase to remove excess glycans during
130 purification, an acetylglucosamine (GlcNAc) moiety is retained on each three remaining
131 *N*-linked glycosylation sites. Interestingly, PNGase treatment, which truncates all
132 glycans including core GlcNAc, produced tiny crystals, suggesting that these GlcNAcs
133 contribute to rather stable crystal packing. We modeled one GlcNAc moiety for each of
134 the two sites (Asn107, Asn294), and three glycans at a position close to Asn180
135 (Asn180-GlcNAc-GlcNAc-Man). The three glycans at Asn180 fit into a groove formed

136 between two lobes (lobe A and B) of CDC50A and Trp323 (in the connecting loop
137 between TM3 and TM4 of ATP11C and conserved in mammalian flippases that requires
138 CDC50A), like a wedge, thereby keeping them together and sterically protecting them
139 from the endoglycosidase during purification (Fig. 1D).

140 The electron density map of the N domain allowed visualization of its overall
141 folding at C α level, and made it possible to assign the location of the three caspase
142 recognition sites (Fig. 1E,F). Inactivation of ATP11A or ATP11C by effector caspases
143 requires cleavage of multiple caspase sites located on the N domain, and a single site
144 cleavage is not enough for full inactivation of the flippase^{4,18}. There are three
145 caspase-recognition sites in ATP11C (site I – III, Fig. 1, Fig. S4), and these are located
146 on loops at both ends of an α -helix-containing region. Site I and site II are very close to
147 each other at the N-terminal side of the helix, and site III is at the C-terminal side. This
148 region, especially the α -helical part in between caspase recognition sites, is located at
149 the center of the N domain scaffold, and seems like a bolt that holds together the
150 surrounding α -helix and several β -sheets, and thus obviously important for N domain
151 folding. Interaction between this helix and surrounding N domain segments may be
152 sufficient to keep its fold even if one of the caspase sites is cleaved. Cleavage at both
153 ends of the helix must lead to irreversible unfolding of the N domain which is required
154 for the ATP binding. Note, all three sites are exposed on the same side of the N domain
155 with a distance of around 35~40Å in between two regions (site I,II and site III). Such
156 geometry of cleavage sites suggests that instantaneous two-site cleavage may occur by a
157 caspase-3 dimer³⁷ upon apoptotic signal transduction, rather than single, independent
158 cleavages, given that the distance between the catalytic center of the caspase-3 dimer is
159 around 40Å.

160

161 **Outward-open conformation**

162 According to the reaction scheme of P4-flippase (Fig. 1A), the outward-open
163 E2P state, mimicked by the BeF $_x$ -binding, is a reaction state responsible for the
164 incorporation of PtdSer from the outer leaflet to the transport occlusion site. A structural
165 requirement for the outward-open conformation is therefore the transient formation of a
166 conduit that physically allows the translocation of the phospholipid head group from the
167 outer leaflet to the occlusion site in the middle of the membrane. We found a
168 longitudinal crevice in the peripheral region of TM in ATP11C (Fig. 2A, Fig. S6). The
169 crevice is composed of TM2, TM4 and TM6 helices and runs along TM4, and is
170 continuous from the exoplasmic surface of the lipid bilayer to the middle of the
171 membrane (Fig. 4B). Thus, the unwound part of TM4 (³⁵⁶PVSM motif), which has been

172 implicated in the lipid transport²⁷, is exposed to the hydrophobic bulk lipid. Comparison
173 with other flippase structures in the corresponding reaction state reveals that the crevice
174 in ATP11C is wider than that in Drs2p activated form³⁴ (Fig. S6). In the ATP8A1 E2P
175 state, a membrane crevice is not formed at all³¹, probably due to its longer C-terminal
176 regulatory domain compared with that in ATP11C (~38 amino acids)³⁸ (Fig. S4). The
177 exoplasmic side of the crevice is closed in the PtdSer-occluded E2-P_i transition state of
178 ATP8A1, and clearly different from that in the ATP11C E2P state (Fig. S6). In ATP11C,
179 TM2 is kinked at Pro94, an amino acid residue conserved in all mammalian P4-ATPases
180 (Fig. 2B, Fig. S6), so that the exoplasmic side of TM2 departs from the central axis of
181 the crevice in this region. This structural feature enables the formation of the wide and
182 continuous crevice from the exoplasmic side to the PtdSer occlusion site near the
183 unwound part of TM4. Substitution of Pro94 for alanine significantly reduces apparent
184 affinities for both PtdSer and PtdEtn (Fig. 2C), indicating that the TM2 kink is key for
185 developing a crevice structure that is wide enough for passage of a phospholipid head
186 group. We conclude that the observed longitudinal crevice is in fact the outward facing
187 conduit that enables the phospholipid translocation.

188 Well-ordered crystals were generated in the presence of both BeF_x and DOPS.
189 The thermal stability³⁹ of the purified ATP11C-CDC50A complex in the presence of
190 both BeF_x and PtdSer ($T_m = 53.5^\circ\text{C}$) is markedly higher than those in the absence ($T_m =$
191 33.6°C), or presence of either BeF_x ($T_m = 41.3^\circ\text{C}$) or PtdSer alone ($T_m = 46.4^\circ\text{C}$) (Fig.
192 2D), indicating that the BeF_x-bound form binds PtdSer, and the enzyme is likely
193 accumulates in a distinct PtdSer-bound, but not occluded, E2P form in the crystal. This
194 conclusion is supported by the fact that an excess of PtdSer is required for preservation
195 of the crystals when harvested for X-ray diffraction studies (Methods), indicating that
196 PtdSer dissociates from the binding site at low to zero concentration. In fact, the
197 electron densities found in the crystal structure (Fig. 1C, Fig. 3) led us to model two
198 PtdSer molecules in the structure.

199

200 **PtdSer binding at the exoplasmic cavity**

201 There is a cavity at the exoplasmic side of the conduit (Fig. 3), which is formed
202 by the TM3-4 loop of ATP11C and the exoplasmic domain of CDC50A around the
203 surface of the membrane outer leaflet. This cavity is connected to the crevice observed
204 in the TM region (Fig. 3, Fig. S6). Unexpectedly, the omit map showed an extra density
205 at this position, and one PtdSer can be modeled here (Fig. 3C). The head group of the
206 PtdSer is accommodated deep in the cavity, the surface of which is highly hydrophilic
207 and electro-positive because of the many basic amino acids from both ATP11C and

208 CDC50A arranged here (Fig. 3AB, Fig. S4). A cluster of basic amino acids is also
209 observed in the cryo-EM structure of ATP8A1³¹. This positively-charged, and
210 hydrophilic binding cavity would be favorable for attracting the negatively-charged
211 phosphate group of a phospholipids. The hydrocarbon tails of the bound PtdSer lie
212 along the membrane plane, projecting towards the membrane lipid phase. Single
213 replacements of the positively-charged amino acids located at the entrance of the cavity
214 produced only moderate effects on PtdSer- or PtdEtn-dependent ATPase activities,
215 probably due to the number of remaining basic amino acids. This interpretation is
216 supported by the approximately 50% reduction in the V_{\max} of the triple mutant
217 (Arg132Ala^{CDC}/ Arg133Ala^{CDC}/ Lys136Ala^{CDC}) relative to that of wild-type (Fig. 3D).
218 Beside these positively-charged amino acids, mutations in other hydrophilic amino
219 acids in this cavity (Asn325Gln, Asp343Ala in ATP11C) produce a large reduction in
220 apparent affinity for PtdEtn (Fig. 3E). Structural rigidity of the TM3-4 loop may also be
221 important, because the apparent affinity for PtdEtn is also reduced in the alanine
222 replacement of Trp323, which tethers the TM3-4 loop to the exoplasmic domain of
223 CDC50A (Fig. 1D, Fig. 3C). These structural and functional data therefore suggest that
224 this cavity is a priming site, responsible for the initial incorporation of phospholipids
225 from the membrane outer leaflet – the beginning of the transport pathway.

226 The TM3-4 loop in ATP11C is 6 or 5 amino acid longer than that of ATP8A1
227 and Drs2p, respectively, and less conserved compared with other parts of the protein
228 (Fig. S4). However, the hydrophilic and electro-positive nature of this cavity is
229 essentially the same, at least, for the three flippases whose structures have been
230 determined. Interestingly, some of mutations in the exoplasmic cavity had differing
231 effects on the apparent affinities for PtdSer and PtdEtn (Fig. 3D,E), suggesting that this
232 region does indeed associates with the transport ligands. This observation is consistent
233 with a previously reported chimeric study on yeast flippase Dnf1, in which amino acids
234 in the TM3-4 loop are shown to contribute to the ligand specificity²⁶.

235

236 **PtdSer occlusion site**

237 We also identified another PtdSer at the canonical occlusion site in the middle
238 of the membrane (Fig 4), the position of which is close to that of PtdSer occluded in the
239 ATP8A1 E2-P_i transition state. We modeled only a part of PtdSer (phospho-L-serine
240 moiety) at this position according to the observed electron density (Fig. 4A), the other
241 part including its acyl chains are likely disordered in the bulk lipid phase. Like other
242 flippases as well as cation-transporting P-type ATPases, the conserved proline (Pro356)
243 in the PVSM sequence (corresponding to a PISL motif in most of the other P4-ATPases)

244 gives a characteristic unwinding at the middle of TM4, enabling the accommodation of
245 a PtdSer head group at this position. The conduit ends at Val357 in the PVSM motif (Fig.
246 4B), which has been implicated as a gating residue for the phospholipids against the
247 cytoplasmic inner leaflet²⁷, similar to the glutamate residue in the corresponding PEGGL
248 motif of P2-type ATPases^{40,41}. Hydrophobic residue of Val98 (corresponding to Ile115
249 in ATP8A2) supports the gating residue Val357 on its cytoplasmic side, and these
250 hydrophobic amino acids form a tight seal as a cytoplasmic gate, which prevents the
251 penetration of the PtdSer head group to the cytoplasmic side in the outward-facing E2P
252 state. In fact, mutation of these amino acids severely impaired PtdSer- or
253 PtdEtn-dependent ATPase activity as well as PtdSer transport activity in the plasma
254 membrane (Fig. 4C-E), consistent with previous predictions for other flippases²⁶.
255 Mutation in the hydrophilic amino acids located at the cytoplasmic side of TM1
256 (Gln63Ala, Arg66Ala, Asn69Ala (corresponds to Asn220 in yeast flippase Dnf1)⁴²) also
257 showed reduced V_{\max} values for ATPase activity relative to wild-type. These amino
258 acids may contribute to the rigidity of the cytoplasmic gate, or are actually part of the
259 conduit for the inner leaflet when the cytoplasmic gate opens. Val357 in ATP11C
260 corresponds to Ile357 in ATP8A1, Ile364 in ATP8A2 and Ile508 in Drs2p, thus of
261 almost all the P4-ATPases only ATP11A and ATP11C have a valine residue in this
262 position (methionine in ATP8B3). In the case of ATP11C, mutation Val357Ile produces
263 a remarkable reduction in apparent affinity for PtdSer and PtdEtn, while V_{\max} is a bit
264 higher than that of wild-type (Fig. 4C). In fact, the transport activity of Val357Ile is
265 comparable to that of wild-type (Fig. 4E). In contrast, the ATPase activities of
266 Val357Ala and Val357Phe, and the transport activity of Val357Phe are significantly
267 reduced compared with those of wild-type. Evidently, correct size is important for
268 gating residue Val357. Mutagenesis studies also reveal the important contribution of the
269 conserved residues around the occlusion site (Phe72, Asn352) and TM5-6 (Lys880,
270 Asn881 and Asn912), all alanine mutants showed significant reductions in either V_{\max} or
271 apparent affinity for PtdSer and/or PtdEtn determined through ATPase activity profiles,
272 and transport activities as well, in good agreement with previous studies of ATP8A2^{27,43}.
273 Interestingly, Phe343 is not conserved among P4-ATPases, despite its close position to
274 the phospholipid head group. In other PtdSer-transporting P4-ATPases, including
275 ATP8A1, ATP8A2 and Drs2p, Phe343 in ATP11C is replaced with asparagine (Fig. S4),
276 and the hydrophilic residue actually contributes to PtdSer coordination in the ATP8A1
277 E2-P_i structure³¹. The Phe354Asn mutant in ATP11C showed significantly higher
278 affinity for PtdSer and PtdEtn relative to wild-type while keeping its V_{\max} of ATPase
279 activity and PtdSer transport activity comparable to wild-type level. Therefore, a

280 hydrophilic or smaller side chain in this position is favorable for the accommodation of
281 the aminophospholipid head group in the occlusion site. It can be speculated that
282 ATP11C has Val357 and Phe354 instead of the most conserved isoleucine and
283 asparagine of other PtdSer-dependent flippases, to fine-tune the PtdSer and PtdEtn
284 transport activity relevant to a plasma membrane flippase. As an important note,
285 mutations Val98Ala, Phe72Ala, Asn881Ala and Asn912Ala increases the apparent
286 affinity for PtdSer, but lower that for PtdEtn, relative to the wild-type (Fig. 4D),
287 therefore these mutants were able to discriminate PtdSer and PtdEtn.

288

289 **A transport model**

290 Two PtdSer molecules bound to both ends of the conduit found in the crystal
291 structure (Figs. 1,3 and 4) led us to put forward a transport model for the flippase, which
292 is distinct from other models proposed so far^{26,27,44} (Fig. 5). Translocation of the
293 phospholipid, either PtdSer or PtdEtn is initiated by its binding to the positively-charged
294 and hydrophilic cavity composed of the CDC50A exoplasmic domain and the ATP11C
295 TM3-4 loop (Fig. 3, Fig. S7). The electro-positive and hydrophilic nature of the cavity
296 likely attracts the head group of the phospholipid from the outer leaflet layer of the
297 membrane. The exoplasmic cavity connects to the longitudinal crevice along TM4 (Fig.
298 2, Fig. S6). Therefore, once the phospholipid head group is incorporated into the
299 exoplasmic cavity, it may diffuse along the crevice while keeping its hydrocarbon
300 chains projecting to the hydrophobic bulk lipid. Val349 in TM4 projects into the conduit
301 (Fig. 4AB). Its replacement with bulky phenylalanine (Val349Phe) severely impairs
302 PtdSer- and PtdEtn-dependent ATPase activity as well as PtdSer transport activity
303 relative to wild-type, in contrast to the moderate effects of alanine substitution (Fig.
304 4C-E). In addition, phenylalanine mutations of residues close to Val349 (Thr90Phe in
305 TM2 and Leu350Phe in TM4) also significantly lowers ATPase activity relative to the
306 wild-type. These amino acid residues are located between, and distant from, the two
307 substrate binding sites and clearly bulky substitutions impede diffusion of the
308 phospholipid head group from the exoplasmic cavity to the occlusion site. In the
309 occlusion site, the phospholipid head group must be coordinated by conserved
310 hydrophilic amino acids such as Asn352 and Asn881. The gating residue Val357 blocks
311 further penetration of the phospholipid to the cytoplasmic inner leaflet. PtdSer binding
312 to the occlusion site may be the signal to induce the conformational change required for
313 reaching the PtdSer-occluded E2-P_i transition state. Some of the hydrophilic amino
314 acids in the TM1-2 loop may join in the coordination of the head group, as observed in
315 the ATP8A1 E2-P_i structure (Fig. S6)³¹. Movement of TM1-2, as a result of the loop

316 involvement, adjusts the A domain to induce dephosphorylation of E2P. Attainment of
317 the E2 or E1 state, the next step, opens the cytoplasmic gate. A physical pathway from
318 the occlusion site to the inner leaflet need to be opened. Mutation of amino acid
319 residues around the cytoplasmic gate largely inhibited phospholipid dependent ATPase
320 activity (Fig. 4). Movement of the TM1-2 helix bundle outwards may be needed for the
321 phospholipid to move to the cytoplasmic inner leaflet, although this has not yet been
322 elucidated.

323 Translocation of the phospholipid across the two leaflets is energetically
324 extremely unfavorable due to the amphiphilic nature of phospholipids⁴⁵, and the rate of
325 spontaneous phospholipid flip-flop is order of several hour to several days. In our
326 envisaged translocation mechanism, the most energy-consuming step may be moving
327 the hydrophilic head group from the outer membrane surface to the transport conduit. In
328 this step the phospholipid head group needs to disconnects from the polar interactions
329 formed with neighboring phospholipids, surrounding membrane proteins as well as
330 water molecules, and also needs to change its orientation approximately 90° from a
331 vertical to horizontal orientation in the lipid bilayer. The structure and resulting
332 transport model answer the fundamental question in the translocation mechanism of
333 flippase -how phospholipid reaches the transport conduit from the outer leaflet. The
334 hydrophilic surface of the exoplasmic cavity interior provides an environment similar to
335 the water-facing membrane surface and lowers the energetic barrier required for
336 acquisition of the phospholipid head group. Many membrane transport proteins seem to
337 employ a common strategy for the translocation of their specific substrates; the
338 environment of the substrate binding site of the protein mimics that of the location from
339 whence the substrate comes. Flippases are not an exception, and this strategy is applied
340 in the most energy-consuming step in the sequence of the lipid flipping process by the
341 ATP11C-CDC50A complex.

342

343 **Acknowledgement**

344 We thank M. Taniguchi for technical assistance, Dr. T. Nishizawa for sharing
345 unpublished results of the ATP8A1 structure and Dr. D. McIntosh for improving the
346 manuscript. This work was supported by Grants-in-Aid for the Scientific Research
347 (17H03653), Basis for Supporting Innovative Drug Discovery and Life Science
348 Research (BINDS) from Japan Agency for Medical Research and Development
349 (AMED), Takeda Science Foundation (to K.A.); Core Research for Evolutional Science
350 and Technology from JST (JPMJCR14M4, to S.N. and K.A.); Grants-in-Aid for
351 Scientific Research (S), the Japan New Energy and Industrial Technology Development
352 Organization (NEDO), and the Japan Agency for Medical Research and Development
353 (AMED) (to Y.F.). This work is a part of a project (2018B2703 and 2019B2707) at
354 SPring-8. This research is partly supported by the Platform Project for Supporting Drug
355 Discovery and Life Science Research (BINDS) from AMED under Grant number
356 JP18am0101070.

357

358 **Author Contributions** Y.F., S.N. and K.A. designed the study. H.N. and K.A. were
359 responsible for protein expression. H.N. purified and crystallized the protein. H.N. K.S.
360 and K.A. performed biochemical analysis. H.N., K.H. and K.A. collected X-ray
361 diffraction data. K.H. merged X-ray diffraction data. K.I. and K.A. analyzed the
362 structure. K.I. and K.A. interpreted the structure. H.N. K.S. and K.A. wrote the
363 manuscript with agreement of all authors.

364

365 **Author Information**

366 Atomic coordination and structure factors for the structures reported in this work have
367 been deposited in the Protein Data Bank under accession number NXXX.
368 Correspondence and requests for materials should be addressed to K.A.
369 (kabe@cespi.nagoya-u.ac.jp).

370

371 **Materials and Methods**

372 **Protein expression and purification**

373 Human *ATP11C* (NCBI: XM_005262405.1)⁴ was sub-cloned into a hand-made
374 vector as described previously¹³. Both of the amino terminal 7 amino acids (Δ N7) and
375 the carboxyl terminal 38 amino acids (Δ C38) of hATP11C were truncated, and the Flag
376 epitope tag (DYKDDDDK), hexa-histidine tag, the enhanced green fluorescence protein
377 (EGFP) followed by a tobacco etch virus (TEV) protease recognition sequence were
378 attached to the amino terminal of the deletion mutant (ATP11C_cryst). Human *CDC50A*

379 cDNA (NCBI: NM_018247.3) was sub-cloned into the vector independently. The
380 Asn190Gln and Ser292Trp double mutation was introduced into the construct to
381 regulate its glycosylation status (CDC50A_QW). The former mutation is simply aimed
382 to prevent *N*-linked glycosylation. The latter is to eliminate *O*-linked glycosylation at
383 Ser292 and at the same time to increase the efficiency of *N*-linked glycosylation at
384 Asn294⁴⁸, because these residues appeared to be glycosylated alternatively. The
385 heterodimer composed of ATP11C_cryst and CDC50A_QW was successfully expressed
386 in the plasma membrane using baculovirus-mediated transduction of mammalian
387 Expi293 cells (Thermo) for 48 h at 31.5 °C as described previously^{28,46}. The harvested
388 cells were directly solubilized with 1.5 % (w/v) *n*-decyl β -D-maltoside in a lysis buffer
389 containing 40 mM MES/Tris (pH 6.5), 200 mM NaCl, 2 mM Mg(CH₃COO)₂, 1 mM
390 ATP, 1 mM dithiothreitol, 0.1 mM ethylene
391 glycol-bis(2-aminoethylether)-*N,N,N',N'*-tetraacetic acid (EGTA) and protease inhibitor
392 cocktail (Roche) on ice for 20 min. After removing the insoluble material by
393 ultracentrifugation (200,000×g for 1h), the supernatant was mixed with anti-Flag M2
394 affinity resin (Sigma-Aldrich) for 1 h at 4 °C. The resin was washed with 20 column
395 volumes of buffer consisting of 20 mM MES/Tris (pH 6.5), 200 mM NaCl, 5% (v/v)
396 glycerol, 1 mM Mg(CH₃COO)₂, 0.1 mM ATP, 0.1 mM EGTA and 0.03% octaethylene
397 glycol monododecyl ether (C₁₂E₈, Nikko Chemical). Flag-EGFP tagged ATP11C was
398 eluted with 0.2 mg/ml Flag peptide (Sigma-Aldrich) in the wash buffer. Eluted proteins
399 were incubated with TEV protease and MBP-fusion endoglycosidase (EndoHf, New
400 England Biolabs) at 4 °C overnight. Released affinity tags containing Flag-EGFP were
401 removed from the mixture by a Ni-NTA resin (QIAGEN). The non-absorbed fractions
402 were concentrated and subjected to a size-exclusion column chromatograph using a
403 Superose6 Increase column (GE Healthcare), equilibrated in a buffer comprising 20 mM
404 MES/Tris (pH 6.5), 1%(v/v) glycerol, 50 mM NaCl, 5 mM MgCl₂, and 0.03% C₁₂E₈.
405 Peak fractions were collected and concentrated to 10 mg/ml. See Fig. S1 for the purity
406 of the sample at each step. The concentrated ATP11C samples were mixed with 1 mM
407 ADP, 0.5 mM BeSO₄, 1.5 mM NaF, and 0.1 mg/ml dioleoyl phosphatidylserine (DOPS),
408 and added to the glass tubes in which a layer of dried dioleoyl phosphatidylcholine
409 (DOPC) had formed, in a lipid-to-protein ratio of 0.2. C₁₂E₈ was added to the glass
410 tubes in a protein-to-detergent ratio of 0.5 to 2.0, and the mixture was incubated
411 overnight at 4 °C in a shaker mixer operated at 120 rpm²⁹. After removing the insoluble
412 material by ultracentrifugation, lipidated samples were subjected to crystallisation. Note
413 that the effect of truncation of the both terminal amino acids of ATP11C, the double
414 mutation introduced to CDC50A and deglycosylation of CDC50A on the PtdSer- and

415 PtdEtn-dependent ATPase activity were negligible compared with wild-type without
416 endoglycosidase treatment.

417

418 **Gene editing for CDC50A**

419 The CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats)-Cas
420 (CRISPR-associated) system with pX330 vector (Addgene) was used to edit the
421 CDC50A gene in HEK293S GnT1- cells as described⁴. The sgRNA sequences for
422 human CDC50A were as follows; 5'-CACCGGGCAACGTGTTTATGTATTA-3' and
423 5'-AAACTAATACATAAACACGTTGCC-3'. Target protospacer sequences are
424 underlined.

425

426 **Crystallization and data collection**

427 Crystals were obtained by vapour diffusion at 20°C. The lipidated 10 mg/ml protein
428 sample obtained either from Expi293 cell or CDC-KO cells, containing 1 mM ADP, 0.5
429 mM BeSO₄, 1.5 mM NaF, and 0.1 mg/ml DOPS was mixed with reservoir solution
430 containing 10% (v/v) glycerol, 14-17% PEG4000, 0.4 M MgSO₄, and 2 to 5 mM
431 β-mercaptoethanol. Crystals made using protein samples purified from Expi293 cells
432 grew in a thin plate-like shape with the dimensions of 800 × 500 × 50 μm in 2 weeks. In
433 contrast, crystals from CDC-KO cells grew as small crystals usually less than 50 μm
434 with a polyhedron shape. These crystals were picked up with LithoLoops (Protein Wave
435 Corporation), and flash frozen in liquid nitrogen. The crystals were harvested in the
436 presence of 10% (v/v) glycerol, 14-17% PEG4000, 0.4 M MgSO₄, 4 mg/ml DOPS, 20
437 mM MES/Tris (pH 6.5), 50 mM NaCl, 5 mM MgCl₂, 5 mM β-mercaptoethanol, 2%
438 C₁₂E₈, 1 mM ADP, 0.5 mM BeSO₄ and 1.5 mM NaF. Note, when crystals were
439 harvested in the absence of DOPS, a few percent approximately of crystals gave X-ray
440 diffraction better than 4Å. In the presence of 4 mg/ml DOPS, however, the number of
441 well-diffracting crystals mostly increased to approximately 30% of all harvested crystals.
442 Despite the different crystal morphologies of the crystals obtained from Expi293 cells
443 and CDC50A KO cells (Fig. S1), the crystals show the same space group (*P*2₁2₁2₁) and
444 unit cell size (*a* = 100.5Å, *b* = 232.8Å, *c* = 492.9 Å, $\alpha = \beta = \gamma = 90^\circ$).

445 X-ray diffraction data were collected at the SPring-8 beamline BL32XU, BL41XU and
446 BL45XU. For the large plate-like crystals obtained from Expi293 cells, X-ray
447 diffraction data were collected by helical scan method⁴⁹, or by irradiating micro-focus
448 beam from the direction perpendicular to the *c*-axis by monitoring crystals on 90° bent
449 LithoLoop (Fig. S1). Crystals from CDC-KO cells were too small to collect full data set
450 from each crystal, and well-diffracted crystal could not be determined from its

451 morphology. Therefore, multiple crystals were mounted on a $\phi 1$ μm LithoLoop, and the
452 raster scan was performed to identify well-diffracted crystals. After selecting target
453 crystals, 10° small-wedge data were collected from each individual crystal (Fig. S1).
454 Total 1,588 crystals were used for the data collection and some of them were performed
455 automatic manner by using ZOO system⁵⁰.

456

457 **Structural determination and analysis**

458 All the diffraction data from individual 1,588 well-diffracting crystals were processed
459 and merged using automatic data processing system KAMO⁴⁷ with XDS⁵¹. Structure
460 factors were subjected to anisotropy correction using the UCLA MBI Diffraction
461 Anisotropy server⁵² (<http://services.mbi.ucla.edu/anisotropy/>). The structure was
462 determined by molecular replacement with PHASER, using a homology model based
463 on the cryo-EM structure of the E2P state of ATP8A1 (PDB ID: 6K7L) as a search
464 model. Cool⁵³ was used for cycles of iterative model building and Refmac⁵⁴ and
465 Phenix⁵⁵ were used for refinement. The final crystallographic model of BeF_x-bound
466 human ATP11C at a 3.8Å resolution, refined to R_{work} and R_{free} of 0.29 and 0.36 was
467 deposited in the PDB with accession code PDB: 6LKN. Figures were prepared using
468 UCSF Chimera⁵⁶ and PYMOL (<https://pymol.org>).

469

470 **Activity assay using recombinant proteins**

471 To measure the ATPase activity, Flag-EGFP tag connected by the TEV cleavage site to
472 the N-terminal tail of ATP11C_cryst was used to estimate its expression level by
473 fluorescence size-exclusion column chromatography (FSEC)⁵⁷. The original and
474 additional mutant complexes of ATP11C_cryst and the CDC50A_QW were expressed
475 using the BacMam system and purified in a smaller batch format as described above
476 except for TEV protease digestion and endoglycosidase treatment. The purified proteins
477 (the purity of samples used for the ATPase measurement was comparable to lane 4 of
478 SDS-PAGE in Fig. S1) were subjected to an ATPase activity assay as described
479 previously⁵⁸. Briefly, partially purified ATP11C (wild-type or mutants) was suspended
480 in buffer comprising 40 mM HEPES, 2 mM MgCl₂, 2 mM ATP, 2% glycerol, 100 mM
481 NaCl, 0.03 mg/ml C₁₂E₈ (pH 7.0 adjusted by Tris) and indicated concentrations of
482 phospholipids (DOPS or POPE, dissolved as 10 mg/ml stock in 2% C₁₂E₈), in 96-well
483 plates. Reactions were initiated by incubating the samples at 37 °C using a thermal
484 cycler, and maintained for 1h. Reactions were terminated, and the amount of released
485 inorganic phosphate was determined colorimetrically using a microplate reader
486 (TECAN). Samples used for the ATPase measurement were analyzed by FSEC with

487 monitoring with Trp fluorescence (Ex 280 nm, Em 320 nm) monitoring, and peak
488 fluorescence values were determined. The peak values of samples were compared to
489 that of a fully purified sample used for the crystallization whose protein concentration
490 was accurately determined by UV absorption, and protein concentrations for each
491 measured sample were estimated. The phospholipid concentration-dependent ATPase
492 activities were plotted, and data fitted as described previously⁴³ to estimate apparent
493 affinities ($K_{0.5}$) and V_{max} using PRISM4 software. For all measurements, data were
494 duplicated at twelve different phospholipid concentrations for a single measurement,
495 and at least three independent measurements were conducted for each mutant. The $K_{0.5}$
496 and V_{max} values plotted in Fig. 3 and 4 are mean and S.D.s estimated from at least three
497 independent measurements, and representative ones are shown in Fig. S5. Note, the
498 PtdSer- or PtdEtn-dependent specific ATPase activities of ATP11C_cryst-CDC50A_QW
499 complex were almost the same as those of wild-type. We therefore refer to
500 ATP11C_cryst-CDC50A_QW as wild-type in the activity assay for simplicity.

501

502 **Flippase assay**

503 Flippase activity was determined as described⁵⁹. In brief, *ATP11A-ATP11C*
504 double-deficient WR19L mutant (*DKO*) cells were transformed with retroviruses
505 carrying cDNA for human FLAG-tagged CDC50A and EGFP-tagged wild-type ATP11C
506 or mutants. The stable transformants were then subjected to cell sorting for EGFP with
507 FACSARIAII (BD Biosciences), cells at the same EGFP-intensity were sorted, and
508 expanded. Amounts of EGFP-tagged proteins and their localization to the plasma
509 membrane were verified by Western blotting and a confocal microscope (FV-1000D;
510 Olympus), respectively. For the flippase assay, *DKO* cells and its transformants
511 expressing wild-type ATP11C or mutants were incubated with 1 μ M NBD-PS
512 (1-oleoyl-2-{6-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino]hexanoyl}-*sn*-glycero-3-phosp
513 hoserine for 3 min at 20 °C in Hanks' balanced salt solution (HBSS) containing 1 mM
514 MgCl₂ and 2 mM CaCl₂. The cells were collected by centrifugation, resuspended in
515 HBSS containing 5 mg/ml fatty acid-free BSA to extract nonincorporated lipids, and
516 analyzed by FACSCanto II (BD Biosciences).

517

518 **Thermal stability**

519 Purified samples were incubated at the indicated temperatures for 10 min in the
520 presence of 40 mM HEPES, 100 mM NaCl, 2 mM MgCl₂ (free) with 1 mM BeSO₄, 3
521 mM NaF (BeF) and/or 0.1 mg/ml DOPS (PtdSer). After incubation, samples were
522 cooled on ice and denatured aggregates removed using a membrane filter (pore size 0.22

523 μm), and the resulting filtrates were analyzed by size-exclusion column chromatography
524 using Superose 6 Increase 10/150 GL (GE healthcare). Peak values at the retention time
525 for the complex were plotted as a function of incubation temperature, and their T_m
526 values estimated.

685 **Figures**

686
 687 Fig. 1. Crystal structure of ATP11C-CDC50A complex.
 688 (A) Reaction scheme of phospholipid (PL) translocation coupled with ATP-hydrolysis.
 689 Cartoons represent molecular conformations of ATP11C-CDC50A complex (inward- or
 690 outward-, and open or occluded states). (B) PL-dependent ATPase activity by the purified
 691 ATP11C-CDC50A complex. Specific ATPase activities in the presence of
 692 DOPS (red), POPE (blue) or DOPC (black) were plotted as a function of their
 693 concentrations. DOPS gave the highest ATPase activity, POPE showed intermediate,
 694 while there was no detectable ATPase activity in the presence of DOPC. (C) Overall
 695 structure of the outward-open E2P state of ATP11C-CDC50A complex in ribbon
 696 representation. Color of the ATP11C gradually changes from the N-terminus (purple) to
 697 the C-terminus (red). CDC50A subunit is shown in grey ribbon, and attached N-linked
 698 glycans were displayed as green sticks. A DOPS molecule (PtdSer) and its hydrophilic
 699 phosphoserine part are shown as spheres in the exoplasmic cavity and the occlusion site
 700 in the middle of the TM domain, respectively. Three cytoplasmic domains are indicated
 701 with different colors, and caspase recognition sequences at the N domain surface are
 702 indicated in red. Gray ribbon in the N domain thus indicates the region that is removed
 703 after the caspase cleavage. (D) Closed view of the exoplasmic region of CDC50A
 704 subunit. Surface represents electron density map (1.5σ). Lobe A (light grey) and lobe B
 705 (dark grey) are shown in different colors, and TM3-4 loop is shown in blue with Trp323
 706 side chain fitted into the map. N-linked glycans (green) are highlighted. (E,F) Close-up
 707 of the N domain (light blue) from two different viewpoints. Surface shows electron
 708 density map at 1.0σ contour level. Three caspase recognition sites (I, II and III) and the
 709 region in between them (Gly466-Asn477) are indicated in red and grey, respectively.

710

711

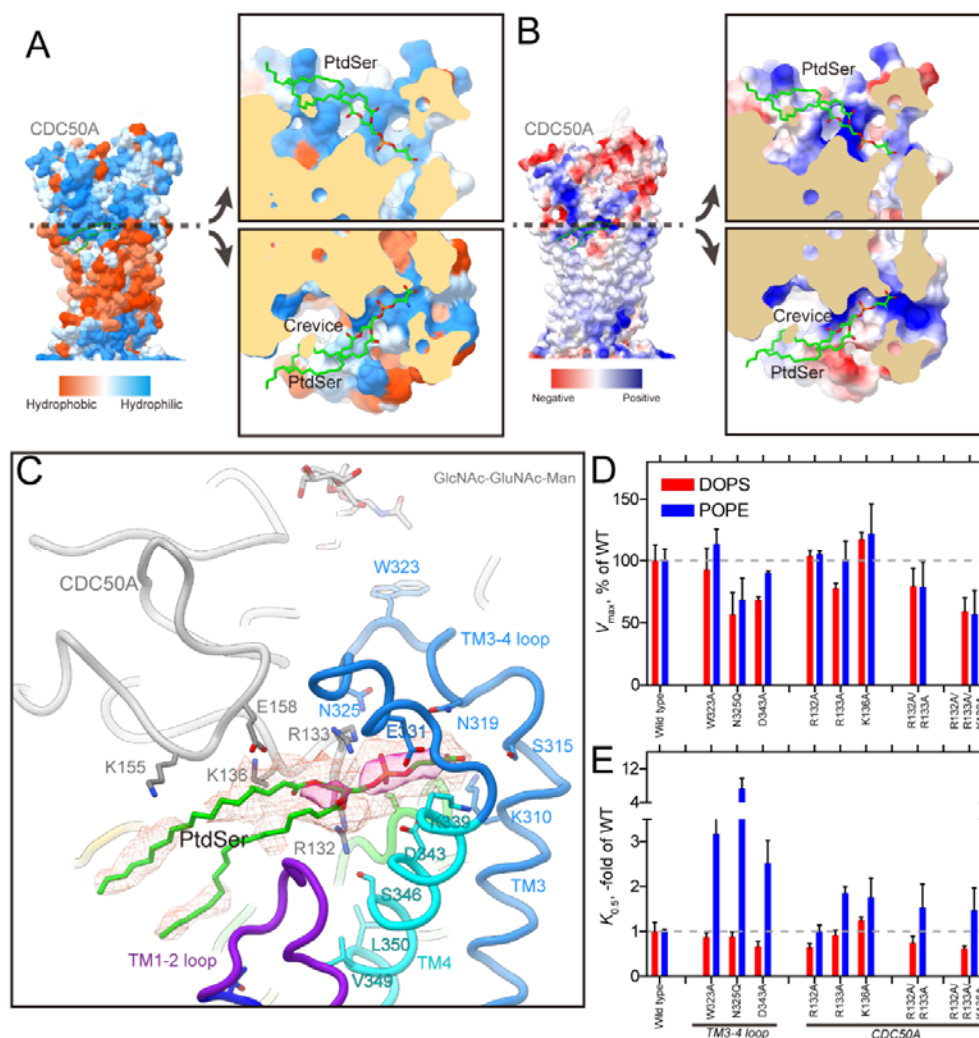

712

713 Fig. 2. The crevice in the TM region.

714 (A) Surface representation of the ATP11C-CDC50A complex shows the crevice in the
715 TM region. Green spheres with CPK coloring represent phosphoserine at the occlusion
716 site in the crevice, and PtdSer bound to the exoplasmic cavity. Surfaces of the atomic
717 model of ATP11C and CDC50A are shown in blue and grey, respectively. (B) Close-up
718 view of the membrane crevice indicated as a dotted box in A. The crevice is mostly
719 composed of TM2, TM4 and TM6. Pro94 makes a kink at the exoplasmic side of TM2
720 (yellow dotted lines), which exposes the unwound region of TM4 (PVSM, shown in
721 spheres) to the lipid bilayer phase. (C) PtdSer- or PtdEtn-dependent ATPase activities
722 of wild-type (same as in Fig. 1) and Pro94Ala mutant as indicated in the figure. (D)
723 Thermal stabilities of purified ATP11C-CDC50A complex determined by FSEC (see
724 Methods). Peak values in the FSEC analysis were plotted as a function of treatment
725 temperature in the absence (free) or presence of indicated substrates.

726

727

728

729

Fig. 3. Exoplasmic cavity

730

(A,B) Surface representations of the atomic model of ATP11C-CDC50A according to

731

their hydrophobicity (A) or Coulombic surface potentials (B). Each model was sliced at

732

the plane where the phosphate moiety of PtdSer is located, along with the membrane

733

plane, and opened up to show the surface of the exoplasmic cavity interior. Color codes

734

as indicated in the figures. (C) PtdSer binding cavity in detail. Some hydrophilic amino

735

acids surrounding PtdSer are shown as sticks. Color codes as in Fig. 1. Red mesh and

736

transparent red surface represent the 2Fo-Fc electron density maps around the PtdSer

737

molecule with contour levels of 1.0σ and 2.0σ , respectively. (D,E) The V_{max} and

738

apparent affinity for PtdSer or PtdEtn derived from the ATPase activities of indicated

739

mutants. The ATPase activity per mg of purified protein was determined and analyzed in

740

the presence of varying concentrations of PtdSer or PtdEtn (Representatives shown in

741

Fig. S7). The V_{max} is shown as a percentage of the wild-type value (D). The apparent

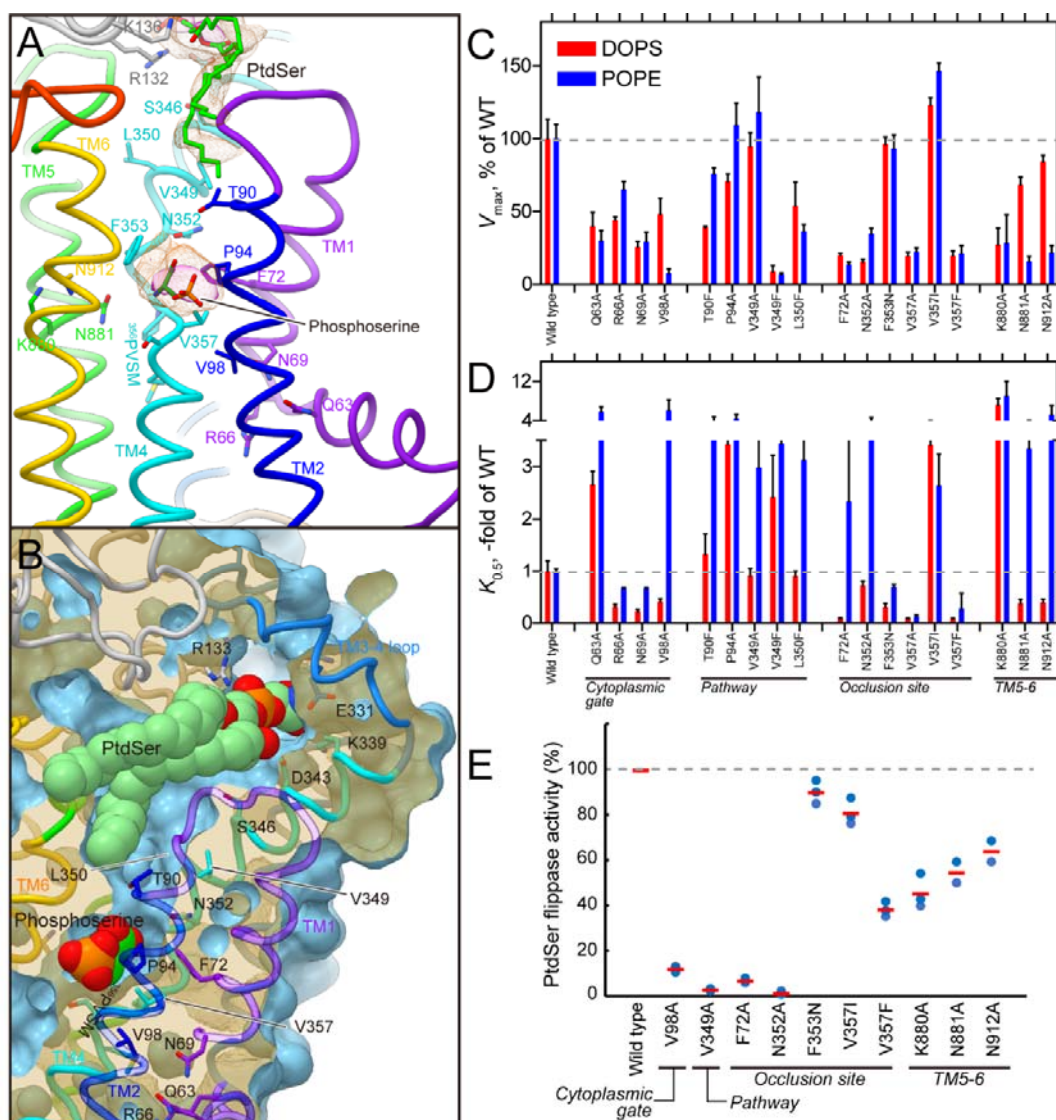

742

affinities for phospholipids are expressed as the concentration giving half-maximum

743

activation ($K_{0.5}$), and plotted as x-fold of wild-type values (E).

744

745
 746 Fig. 4. Transmembrane PtdSer occlusion site
 747 (A) PtdSer occlusion site in detail, viewed from perpendicular to the membrane plane.
 748 Figure is displayed as in Fig. 3C. Phospho-L-serine (stick, green with CPK color) is
 749 modeled according to the observed electron density. (B) Phospholipid conduit along
 750 with TM4. Surface of the atomic model (light blue) is shown with superimposed ribbon
 751 model. Only surface model is clipped by the different plane at the position where TM4
 752 is located, so as to show how the conduit runs along TM4. Its clipped surface is seen as
 753 transparent wheat color. Figure is drawn from TM1 and 2 viewpoint, with exoplasmic
 754 side-up. (C,D) V_{max} and $K_{0.5}$ for indicated mutants determined from their PtdSer- or
 755 PtdEtn-dependent ATPase activities, as described in Fig. 3. (E) The PtdSer flippase
 756 activity. *ATP11A-ATP11C* knock-out (*DKO*) T-lymphoma cells expressing wild-type
 757 ATP11C or indicated mutants were incubated with 1 μ M NBD-PS for 3 min.
 758 Experiments were performed two or three times, and flippase activity for NBD-PS is
 759 shown as a percentage to that of wild-type ATP11C. Horizontal red bars denote
 760 averages.

761

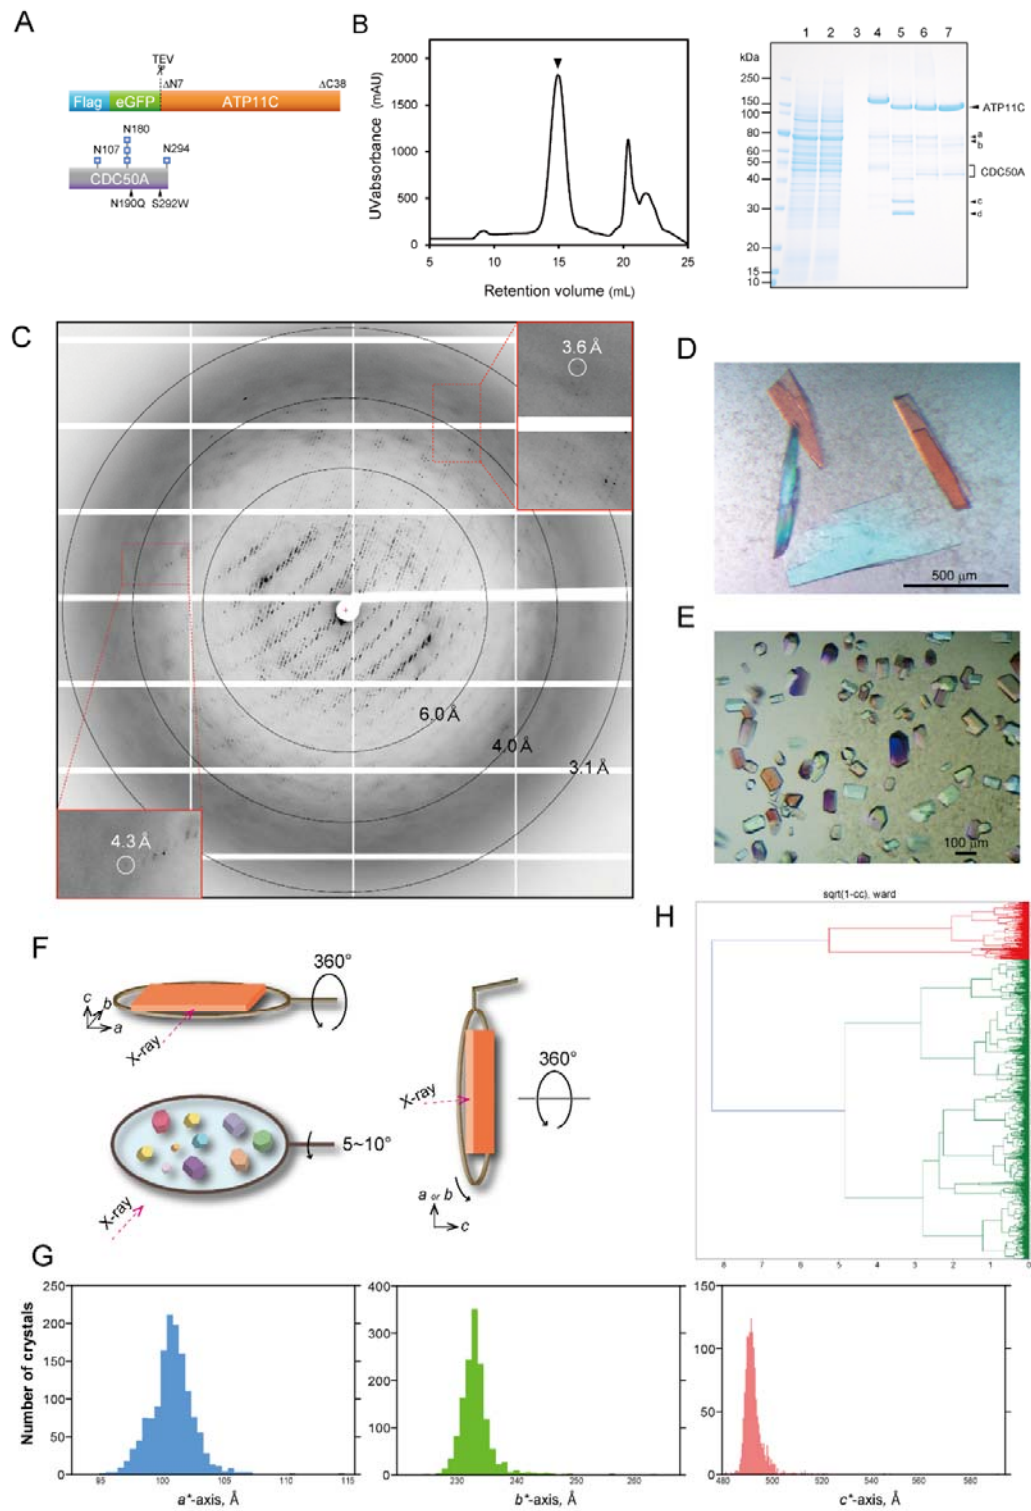

Fig. 5. A phospholipid transport model for ATP11C

(A) Schematic drawing of the transport mechanism by ATP11C-CDC50A complex. In the outward-open E2P state (present structure), phospholipid enters from the surface of outer leaflet to the exoplasmic cavity by changing its orientation (upper left). Trapped phospholipid head group diffuses along the membrane crevice with its hydrophobic tails extending out to the hydrophobic core of the bilayer (upper right). When the phospholipid head group reaches Val357 in the middle of the membrane, the phosphate head group is occluded by closing the crevice with the TM1-2 helix bundle (lower right). This process is coupled with dephosphorylation of E2P as seen in the ATP8A1 E2-P_i transition state structure. Complete dephosphorylation may further open the cytoplasmic gate, and phospholipid is translocated to the cytoplasmic inner leaflet (lower left). (B) Close-up view of the membrane crevice indicated as dotted box in A. Phospholipid headgroup traverses from positively-charged exoplasmic cavity to the occlusion site near Val357 along with TM4.

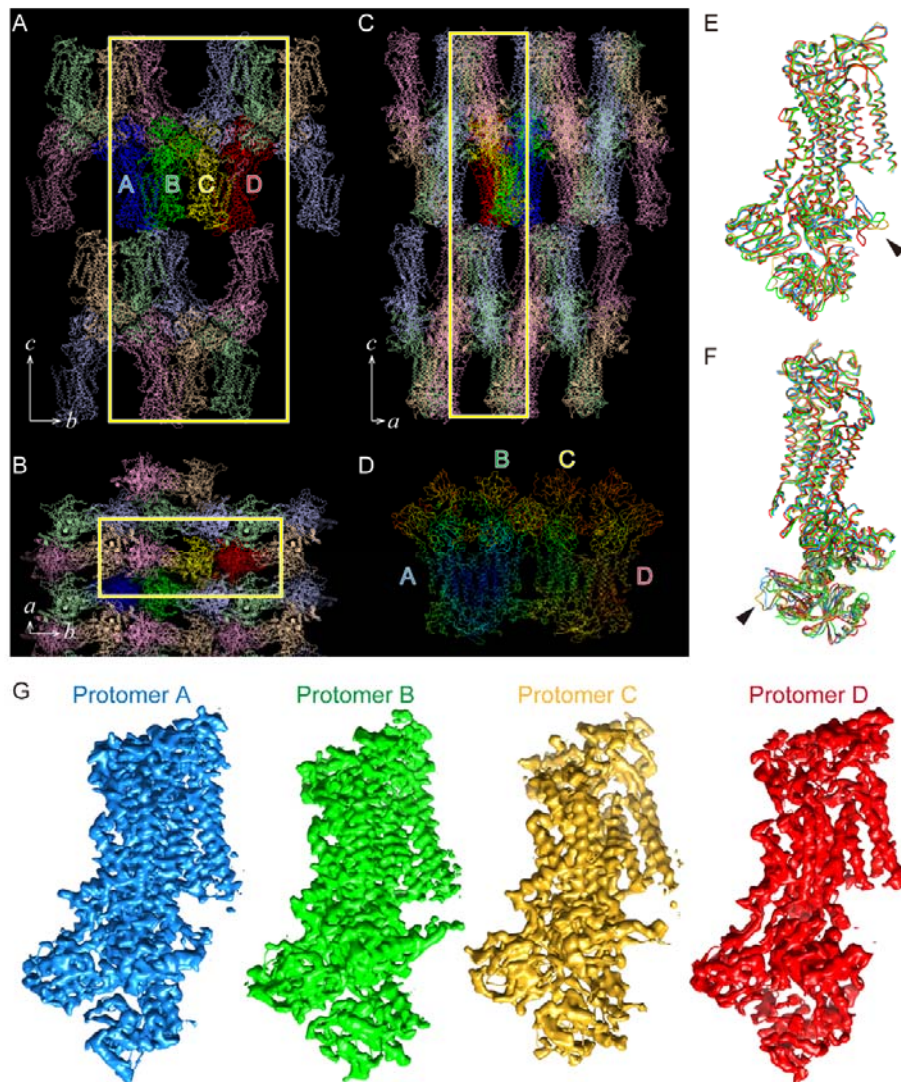

780

781

782 Fig. S1. Structural determination of ATP11C-CDC50A complex

783 (A) Construction of TP11C and CDC50A used in crystallization. See Methods for

784 details. (B) Purification of ATP11C-CDC50A complex. Lane 1: solubilized cell lysate,
785 lane 2: pass-through of Flag resin, lane 3: wash fraction, lane 4: elution by Flag peptide
786 (subjected to ATPase assay), lane 5: TEV proteinase- and endoglycosidase-treated
787 sample, lane 6: pass-through fraction of Ni-NTA and amylose resin, lane 7: concentrated
788 peak fractions by size-exclusion chromatography (arrowhead in the left panel).
789 Arrowheads on the right indicated as follows, a: HSP70, b: EndoHf, c: cleaved eGFP, d:
790 TEV proteinase. The elution profile of ATP11C-CDC50A complex by size-exclusion
791 column chromatography is shown on the left. (C) Representative X-ray diffraction
792 obtained from a plate-like crystal shown in D. Diffraction spots better than 3.6Å were
793 obtained along the c^* -axis, whereas these are limited to around 4~6Å in directions along
794 with a^* - and b^* -axes, thus strongly anisotropic. (D,E) Three-dimensional crystals
795 obtained from the samples purified from Expi293 cells, showing thin, but large
796 plate-like crystals (D). In contrast, small crystals were obtained from CDC50A-KO cells
797 (E). (F) Data acquisition strategy. We employed normal type LithoLoops for helical
798 scan data acquisition from large single crystals. However, because crystals showed
799 strong anisotropy, we also collected data sets by irradiating X-ray beam from the
800 direction perpendicular to the c -axis by using 90° bent type LithoLoops. For the small
801 but well diffracting crystals obtained from CDC50A-KO cells, data from each
802 individual crystals was collected for 10°. All of these crystals showed identical unit cell
803 size and symmetry regardless of crystal morphologies and expression cell types, as seen
804 in the histograms of unit cell dimensions (G). All diffraction data from 1,588 crystals
805 were finally merged into a single data set (H), and used for the molecular replacement.

806

807 Fig. S2. Crystal packing.

808 (A-C) An asymmetric unit contains four protomers (A, B, C and D) shown in blue,

809 green, yellow and red, respectively. Their symmetry-related molecules are shown in

810 light colors. Yellow boxes indicate unit cells view from different direction in A-C as

811 indicated in the figures. (D) Molecules in the asymmetric unit are displayed according

812 to their temperature factors. Colors gradually change from blue (16) to red (283). (E,F)

813 Comparison of the molecular conformation of four protomers. Arrowheads indicate loop

814 structures, the conformations of which are variable among the four protomers. (G)

815 $2F_o - F_c$ electron density maps of the four protomers at the same contour level of 1.5σ .

816

830

835 edited. Cytoplasmic domains (A, pink; P, green; N, light blue), secondary structures
836 (α -helices, β -sheets and TM helices) and mutations introduced for the crystallized
837 construct (Δ N7, Δ C38) are indicated above the alignment. The degree of conservation
838 among evaluated sequences is indicated below the alignment. Acidic, basic, hydrophilic
839 or hydrophobic amino acids are indicated as red, blue, green and black characters,
840 respectively. Gene and protein ID is as follows; human ATP11C
841 (NCBI: XM_005262405.1), human ATP11A (Uniprot: P98196-1), human ATP8A1
842 (UniProt: Q9Y2Q0-2), bovine ATP8A2 (Genebank: GQ303567.3), and *Saccharomyces*
843 *cerevisiae* Drs2 (UniProt: P39524-1).
844

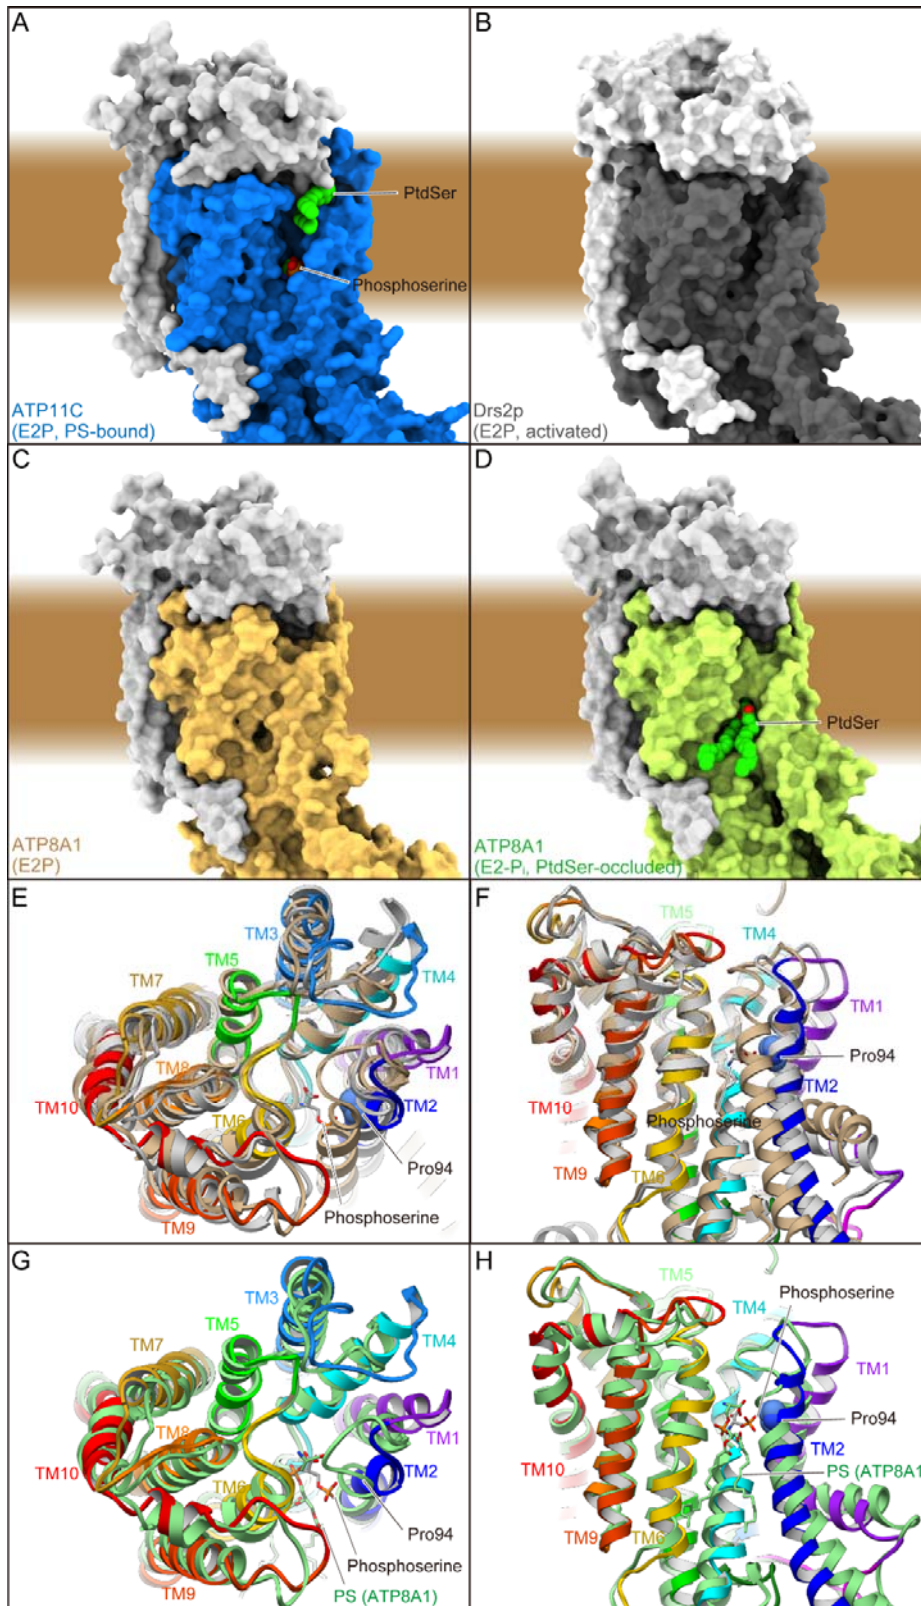

845

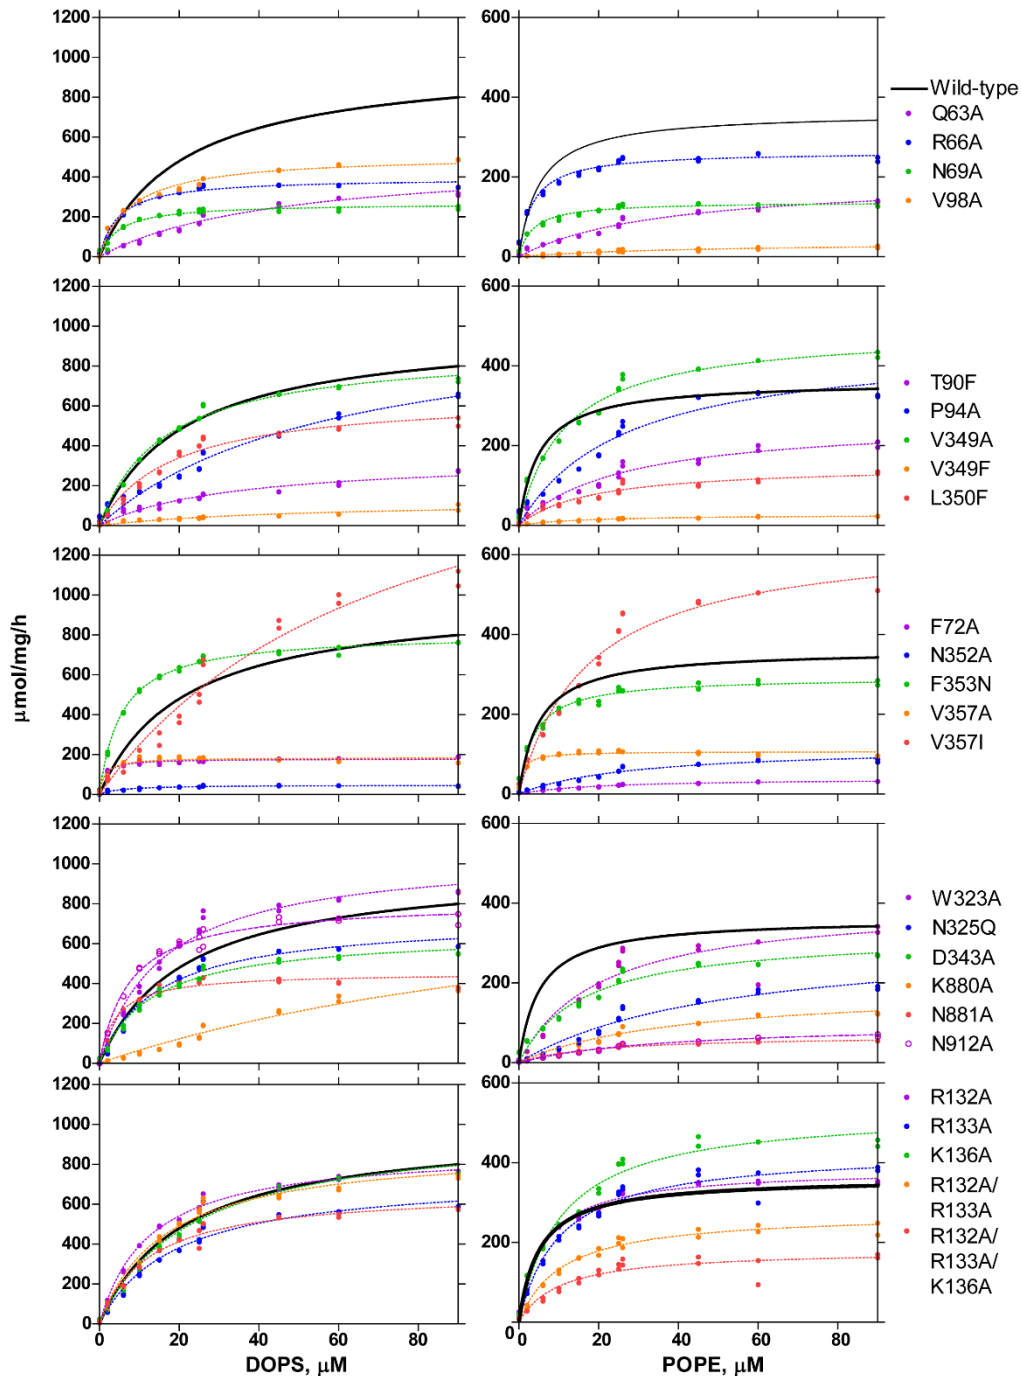

846 Fig. S5. Cytoplasmic domains

847 (A-D) Comparison of the relative orientation of the cytoplasmic domains viewed along
848 with the membrane plane. Cytoplasmic domains of ATP11C are shown in worm models
849 with the same colour code as in Fig. 1C (A). Atomic models of Drs2p in E2P activated
850 form (B, grey), ATP8A1 E2P form (C, orange) and ATP8A1 E2-P_i form (D, yellow) are
851 superimposed on the ATP11C structure according to their P domain structures to show
852 relative orientations of A and N domains. (E-G) Azimuthal position of the A domain is
853 compared. A domain of Drs2p (E), ATP8A1 E2P state (F) and E2-P_i state (G), and these
854 models are superimposed on the ATP11C structure (only A domain is highlighted in
855 magenta, and others are shown in transparent colors) as in A-D. Dotted arrow indicates
856 the different azimuthal positions between ATP11C E2P state and ATP8A1 E2-P_i state.
857 Phosphate analogue BeF_x (red spheres) and DGES/T motif (sticks) in ATP11C structure
858 are highlighted in all figures.

859

861 Fig. S6. Comparison of membrane crevices
862 (A-D) Surface representation of the atomic models of ATP11C E2P state (A), Drs2p
863 E2P activated form (B), ATP8A1 E2P (C) and E2-P_i state (D). PtdSer and phosphoserine
864 are indicated as spheres. Brown background indicates approximate location of the lipid
865 bilayer. (E-H) Comparison of the TM helix arrangement in ribbon representation.
866 Atomic models of ATP11C (color codes as in Fig. 1), Drs2p (light grey) and ATP8A1
867 (tan) are aligned according to their TM helices (E,F). ATP8A1 E2-P_i transition state
868 (light green) is also compared with ATP11C E2P state (G,H) Only catalytic subunits are
869 shown in the figure, viewed from the exoplasmic side (E,G) or perpendicular to the
870 membrane plane with exoplasmic side up (F,H). Phosphoserine (sticks) and Pro94
871 (spheres) in ATP11C, and PtdSer occluded in ATP8A1 E2-P_i state (sticks) are indicated
872 in the figure.

873

874 Fig. S7. Phospholipid-dependence of ATPase activity for mutants.

875 ATPase activities of indicated mutants are plotted as a function of DOPS (left) or POPE

876 (right) concentration. Mutants are categorized as follows; cytoplasmic gate (1st row),

877 surface of the membrane cleft (2nd row), occlusion site (3rd row), TM3-4 loop at

878 exoplasmic cavity and residues in TM5 and 6 (4th row), and CDC50A exoplasmic

879 domain facing the cavity (5th row). ATPase activity for the wild-type enzyme is shown

880 in all graphs as a control (black lines).

884 **Table S1. Data collection and refinement statistics**

885 †The diffraction data are anisotropic. The resolution limits given are for the *a**, *b** and
886 *c** axes, respectively.

887 ‡Statistics for the highest-resolution shell are shown in parentheses.

888 *Statistics for the highest-resolution shell are not given due to the strong anisotropy.
