

## 27 **Abstract**

28  
29 Introduction: Retinal implants have now been approved and commercially available for certain  
30 clinical populations for over 5 years, with hundreds of individuals implanted, scores of them closely  
31 followed in research trials. Despite these numbers, however, few data are available that would help  
32 us answer basic questions regarding the nature and outcomes of artificial vision: what do  
33 participants see when the device is turned on for the first time, and how does that change over time?

34  
35 Methods: Semi-structured interviews and observations were undertaken at two sites in France and  
36 the UK with 16 participants who had received either the Argus II or IRIS II devices. Data were  
37 collected at various time points in the process that implant recipients went through in receiving and  
38 learning to use the device, including initial evaluation, implantation, initial activation and systems  
39 fitting, re-education and finally post-education. These data were supplemented with data from  
40 interviews conducted with vision rehabilitation specialists at the clinical sites and clinical  
41 researchers at the device manufacturers (Second Sight and Pixium Vision). Observational and  
42 interview data were transcribed, coded and analyzed using an approach guided by Interpretative  
43 Phenomenological Analysis (IPA).

44  
45 Results: Implant recipients described the perceptual experience produced by their epiretinal  
46 implants as fundamentally, qualitatively different than natural vision. All used terms that invoked  
47 electrical stimuli to describe the appearance of their percepts, yet the characteristics used to  
48 describe the percepts varied significantly between participants. Artificial vision for these  
49 participants was a highly specific, learned skill-set that combined particular bodily techniques,  
50 associative learning and deductive reasoning in order to build a “lexicon of flashes” - a distinct

51 perceptual vocabulary that they then used to decompose, recompose and interpret their  
52 surroundings. The percept did not transform over time; rather, the participant became better at  
53 interpreting the signals they received. The process of using the device never ceased to be  
54 cognitively fatiguing, and did not come without risk or cost to the participant. In exchange,  
55 participants received hope and purpose through participation, as well as a new kind of sensory  
56 signal that may not have afforded practical or functional use in daily life but, for some, provided a  
57 kind of “contemplative perception” that participants tailored to individualized activities.

58  
59 Conclusion: Attending to the qualitative reports of participants regarding the experience of artificial  
60 vision provides valuable information not captured by extant clinical outcome measures. These data  
61 can both inform device design and rehabilitative techniques, as well as grant a more holistic  
62 understanding of the phenomenon of artificial vision.

## 63 64 **Introduction**

65  
66 Retinal prostheses are implantable microelectronic devices designed to replace the function of  
67 phototransducing cells within the eyes of individuals with retinal diseases such as retinitis  
68 pigmentosa. The devices capture light from a camera image and then transform and transmit those  
69 data in the form of electrical impulses to the remaining cells within the retina. In an ideal visual  
70 prosthesis, the electrical impulses would perfectly mimic the signals of the cells that have been  
71 lost, and the individual’s visual perception would be restored to what they remember of natural  
72 vision.

73  
74 Because it is difficult to replicate biological infrastructure with microelectrode arrays, the goal has  
75 been to create a simplified visual signal that would provide some functional benefit for the

76 recipient. Efforts to develop such a device have been undertaken by many groups over the past 50  
77 years [1-3]. More recent efforts have focused on the retina, with three devices having achieved  
78 commercial approval to date. The first to market was the Argus II epiretinal prosthesis (Second  
79 Sight Medical Products, Sylmar, CA) a 60-electrode device that has been implanted in  
80 approximately 300 individuals since its commercial approval in the EU in 2011, the US in 2013  
81 and in Canada 2015 [4-7]. Retinal Implant AG (Reutlingen, Germany) followed soon thereafter  
82 with the Alpha IMS and AMS implants – two versions of a 1500 electrode subretinal device that  
83 was first approved in the EU in 2013 and that has been implanted in approximately 70 individuals  
84 [8-9]. Finally, there was the IRIS II produced by Pixium Vision (Paris France), a 150-electrode  
85 epiretinal implant that received approval in the EU in 2016 [10]. Meanwhile, there many other  
86 retinal-based implants and alternative approaches for artificial vision in various stages of  
87 development [11-14].

88  
89 The companies that have produced the commercially-approved retinal devices have claimed that  
90 the devices can “provide useful vision” to individuals severely impacted by RP by allowing  
91 recipients to “distinguish and interpret patterns (...) recognize outlines of people, basic shapes and  
92 movement (...) and navigate more independently through the world.” [15]. However, the literature  
93 reporting clinical outcomes of these devices indicates that the reality is more complicated and  
94 ambiguous than these statements might convey [7-9,16-23]. No device recipient has achieved  
95 projected acuity goals, and even the best performing subjects have not improved to the level of  
96 “legal blindness” on standard measures of acuity. Because of this, manufacturers and associated  
97 clinical groups have developed novel test methods for “ultra-low vision,” including perception of  
98 light, light localization, direction of motion, as well as “real world” functional tasks such as object  
99 localization and recognition, sock sorting, sidewalk tracking and walking direction tests [5,8,24].

100 However, it is difficult to make sense of reported outcomes using measures given the novelty of  
101 the tasks and lack of consistency between the groups utilizing them, making comparative analysis  
102 between groups and devices difficult.

103  
104 Several guideline and consensus-building endeavors have been launched in recent years in order  
105 to address the issue of heterogeneity in outcomes [25,26,27]. Yet the question of which measures  
106 of visual function should be used to assess the outcomes of these early-stage devices remains an  
107 area of active debate. There is no agreement regarding the best way to report outcomes with these  
108 devices in part because it is unclear what kind of vision is being produced. It has thus become a  
109 reinforcing cycle: there isn't a good idea what artificial vision is "like" because there aren't good  
110 outcome measures, and there aren't good outcome measures because it is unclear what artificial  
111 vision is "like."

112  
113 Here, the authors assert that what is needed to move beyond this impasse is a more holistic,  
114 qualitative understanding of the perceptual experience associated with these devices. Extant  
115 research has overlooked the subjective accounts of users, both regarding the quality of the  
116 perceptual experience associated with these devices (i.e. what are the percepts generated by devices  
117 "like"), as well as the more general experience of what it is like to receive, learn to use and live  
118 with these devices. A handful of studies have included qualitative reports of elicited percepts as  
119 part of psychophysical tasks [8,22,28,29], and certain companies have included subject reports of  
120 objects they are able to discern in their daily life (e.g. Alpha IMS participant reported being able  
121 to see a smile [21], but nowhere is there a substantive account of what artificial vision "is like,"  
122 nor what it is like to use one of these devices (i.e. in what form does that smile reported by the  
123 Alpha IMS subject appear to them, and how did they use the device to achieve that?).

124  
125 A greater understanding of the qualitative experience associated with retinal implants is  
126 indispensable to the development of visual prostheses and related technologies, as well as to our  
127 understanding of vision more generally. More complete accounts of participants' perceptual  
128 experience can inform training and rehabilitation strategies, as well as aid in the development of a  
129 more accurate model of artificial vision. This will be of use to researchers and manufacturers  
130 developing these devices (e.g. comparing predictions of artificial vision to actual subject reports to  
131 allow feedback necessary for successful iterative development of these devices), as well as to  
132 potential participants and their families (a more accurate model of what artificial vision is like  
133 would better inform their decision regarding receiving a similar device). Finally, as far as subjective  
134 experience is the *sine qua non* of consciousness, subjective reports provide a kind of understanding  
135 that even the most detailed mechanistic accounts of the biological underpinnings of vision or  
136 complete battery of behavioral measures could ever capture.

137  
138 Here we bring to bear the theoretical and methodological tools of cultural anthropology in order to  
139 address larger questions regarding perceptual experience of visual sensory prostheses. We build  
140 upon a growing body of literature in the social sciences that focuses on “disability” and ways of  
141 experiencing prosthetics (e.g. prosthetic arms, wheelchairs, cochlear implants) [30-33]. This body  
142 of work is founded on the assumption that the cultural environment of a subject shapes her  
143 perceptual experience [34-41]. By using the tools of ethnography and attending to the beliefs and  
144 practices of our interlocutors – here recipients of visual prostheses and rehabilitation specialists -  
145 we offer an account of how the design and implementation of a complex medical technology  
146 translates into perceptual experience.

147  
6

148 We present our findings regarding the perceptual experience associated with epiretinal implants in  
149 the context of getting, learning to use and live with the device. We then discuss the implications of  
150 these data for informing the considerations of both those who are producing and receiving these  
151 devices. In addition to presenting novel insights regarding an important new genre of  
152 neurotechnology, the study serves as a case example of how perceptual data - and the  
153 phenomenological and ethnography methods utilized to capture them - can be used to think more  
154 about the processes and effects of emerging medical technologies.

155

## 156 **Methods**

157

158 This research was conducted as a part of ethnographic fieldwork that both authors completed for  
159 their respective dissertation projects on the experience of retinal implant recipients. Author  
160 Cordelia Erickson-Davis (CED) is an MD PhD candidate in the Stanford School of Medicine and  
161 Anthropology Department with 15 years of experience working in medicine and clinical research.  
162 She has training in ethnographic methods with a special focus in phenomenological interviewing  
163 and institutional ethnography. Author Helma Korzybska (HK) is a PhD candidate in Anthropology  
164 at Paris Nanterre University, at the Laboratory of Ethnology and Comparative Sociology (LESC).  
165 She has training in cultural anthropology and is specialized in phenomenological ethnography.  
166 Both authors were involved in recruitment and data collection, and both were trained in qualitative  
167 research, research governance, ethics, and adhered to standard ethnographic procedures.

168

169 The study utilized an ethnographic approach in order to explore the experience of individuals  
170 receiving and working with epi-retinal prosthesis devices. The authors performed thematic analysis  
171 using data collected from: 1) individual, semi-structured interviews with implant recipients, visual  
172 rehabilitation staff and industry researchers, as well as of 2) field notes the authors took based on

173 their observations of the interactions of those individuals at those sites. Ethnography is a  
174 methodological approach committed to providing in-depth accounts of everyday lived experience  
175 and practice. Ethnographic inquiry centers around participant observation - when one lives and  
176 works with the communities they are studying, taking careful note of the daily interactions and  
177 practices. It also includes archival research as well as both formal and informal interviews.  
178 Qualitative research methods such as these allow researchers and participants to discover and  
179 explore topic areas without predetermined questions. In-depth, semi-structured interviews allow  
180 for the collection of valuable information in diverse settings, while observation provides useful  
181 context and additional information that participants may be unable or unwilling to share [42,43].

182  
183 This study was conducted in accordance with guidelines for the Consolidated Criteria for Reporting  
184 Qualitative Research (COREQ) [44]. and was approved by the Stanford University institutional  
185 review board (protocol number 33528), the Paris Nanterre University review board and CNIL  
186 General Data Protection Regulation (GDPR) (declared under MR0017220719) as well as at the  
187 individuals at hospital sites. The ethics evaluation committee of Inserm, the Institutional Review  
188 Board (IRB00003888, IORG0003254, FWA00005831) of the French Institute of medical research  
189 and Health, has reviewed and approved this research project (HK).

## 190 191 **Participants**

192  
193 Purposive sampling sought to recruit individuals receiving implant devices over the two year period  
194 of the study, as well as staff of varying experience of working with implant recipients at the two  
195 hospital sites (one in London, UK and one in Paris, France). Sampling continued until sufficient  
196 data were obtained to address the research aims, which was determined by agreement of the  
197 authors.

198  
199 Information about the ethnographic projects was presented by the authors to hospital staff at the  
200 respective sites. Permission for the authors to sit in to observe and speak to participants was  
201 requested of the hospital administrators, the participants as well as the vision rehabilitation  
202 specialists and company staff. Additional permission and verbal consent was requested of the  
203 participants before each observed session and interview.

204  
205 All implant recipients who were asked over the two-year period agreed to speak with the authors  
206 and permitted them to observe their training. This resulted in a total of 16 implant recipients  
207 consisting 11 men and 5 women between the ages of 45 and 80 years. Thirteen of the subjects were  
208 based at a hospital in Paris and were French-speaking, and 3 of the implant recipients were based  
209 at a hospital in London, UK. These 16 participants had received either Argus II or IRIS II epi-  
210 retinal devices. In addition, interview and observational data were collected with 8 vision  
211 rehabilitation specialists (four at the French hospital, four at the British hospital) as well as 8  
212 industry researchers from Pixium Vision and Second Sight. Nine of these participants will be  
213 presented in this article, we anonymously called them: Douglas, Vincent, Isabelle, Arthur, Eve,  
214 Thomas, Danny, Benoit, and Mathew.

215  
216 Pseudonyms are used for all participants to protect anonymity. Transcripts from interviews with  
217 French-speaking participants were translated from French to English by HK.

218  
219 **Interview**

220  
221 Using an exploratory descriptive qualitative methodology, individual, in-depth interviews were  
222 conducted with implant recipients, vision rehabilitation specialists and industry researchers from

223 both companies at the two hospital sites. Open ended, semi-structured interviews were conducted  
224 and all participants were interviewed by one of the two authors. Face-to-face interviews were  
225 conducted at an agreed-upon place, at the hospital during the days of their trainings. On occasion  
226 follow up questions were asked of participants over the phone. These interviews were either tape  
227 recorded upon patient agreement and subsequently transcribed, or notes were taken directly during  
228 informal conversations.

## 229 **Data analysis**

230  
231  
232 The data were analyzed using Interpretative Phenomenological Analysis (IPA) [45]. This particular  
233 form of qualitative analysis was selected because of its emphasis on how participants experience  
234 their world. The process of analysis derives themes or categories from the data itself, rather than  
235 using predefined categories. These data were supplemented with observational data collected by  
236 the authors, translated into field notes that were then subject to qualitative coding methods [46].

237  
238 Analysis of the research data identified key themes or findings in the experiences of prosthesis  
239 users, discussed under the headings of 1) getting the device 2) learning to use the device and 3)  
240 living with the device. These headings follow the general chronology of receiving one of these  
241 devices, though individual findings that are discussed under each heading are drawn from analysis  
242 and consideration of all observational and interview data as a whole.

## 243 **Results**

### 244 **Getting the device**

#### 245 246 **Election and eligibility**

247  
248  
249

250 To be eligible to receive one of these devices the individual must have bare light perception or no  
251 light perception (in order to warrant the risk of the device further damaging any residual vision).

252  
253 The individuals we observed and spoke with – as well as the majority who have elected to receive  
254 these devices – were diagnosed with retinitis pigmentosa, a group of disorders that involves the  
255 gradual degeneration of the eye’s light-sensitive cells. These individuals had fully functioning  
256 visual systems before the first symptoms appeared – often in adulthood – and had functioned in the  
257 world as sighted persons until they were no longer able. Those who were older at disease onset  
258 often did not learn the compensatory or assistive techniques that are more readily available to  
259 younger people with visual impairments (e.g. schools for the blind, which teach braille and other  
260 techniques)

261  
262 Individuals have unique life histories and reasons for wanting the device, but commonalities  
263 underlying most of their stories was the desire for greater independence and autonomy, to  
264 contribute to research for future generations (a hereditary disease, some of the individuals had  
265 children who had since been diagnosed), and a desire to challenge themselves. Whether it be an  
266 assistive tool with which to supplement their mobility, something that would allow them to return  
267 to the workforce or allow them greater social connection to individuals around them, the  
268 individuals we spoke with desired greater agency and connection within the world around them.  
269 We also found that participants often expressed wanting to prove their capability (to themselves as  
270 well as others), as a kind of psychological emancipation from the “handicap” status they  
271 unwillingly represented.

272

273 According to industry researchers we spoke with, the most important predictor of device success  
274 is subject selection; in particular the psychological profile individual subjects who elect to get the  
275 device. The ideal subjects, these researchers said, were soldiers and former athletes. They had the  
276 endurance and commitment to “do what it took” to get through the training. They had a self-  
277 sacrificial mentality and often a stoicism that made them attractive participants. These individuals  
278 were referred to by clinical researchers as “fighters” (“*des battants*”). “Excellent” candidates who  
279 were neither soldiers nor athletes but who were thought to have the qualities of a “fighter” included  
280 individuals who held jobs that involved challenging cognitive tasks (e.g. a computer scientist or a  
281 teacher). Other predictors of “successful” participants included shorter disease duration and  
282 younger age. A “reasonable” participant was someone who both met the diagnostic criteria and  
283 whom they judged to have “realistic” expectations. Tempering expectations, we would hear many  
284 of these researchers say, is a crucial factor in subject selection and preparation. Subjects who had  
285 accepted or come to terms with their low vision condition often do best, a rehabilitation specialist  
286 stated. They are more likely to accept the difference between the reality of artificial vision to what  
287 they might have been expecting it to be like.

288

## 289 **Implantation**

290

291 Both of the epiretinal devices consist of an external (wearable) and internal (surgically implanted)  
292 component. The external equipment includes custom glasses that house a video microcamera  
293 connected by a wired cable to a processing unit. The processing unit transforms video from the  
294 camera to data that are then transmitted to the surgically placed internal implant, which receives  
295 power wirelessly coil and electronics case either a 60 or 150-electrode array that is fixed to the  
296 inner surface of the retina. Wireless communication from the external processing unit stimulates  
297 electrodes within the array to emit small electrical pulses that excite remaining viable inner retina

298 cells. Unlike the wearable part of the device that can be cleaned or repaired, if there is a problem  
299 with the internal component, there is not much that can be done to adjust or repair, and will only  
300 be “explanted” if absolutely necessary.

301  
302 In receiving one of these devices, recipients underwent a 2-6 hour surgery (depending on the device  
303 and the surgeon’s experience) under general anesthesia [47]. It then takes approximately four  
304 weeks to heal from the surgery, during which most participants reported that they didn’t mind the  
305 aftereffects of the surgery so much as their inability to go about their daily activities and sleep on  
306 their side [48]. Mostly we found the recipients were eager for the four weeks to be up and for the  
307 device to be activated.

308  
309 **Initial activation**

310  
311 A number of weeks after implantation, but before the camera is turned on, the device is aligned  
312 and activated in order to make sure the device fits correctly, that the base components are  
313 functioning, and to introduce the subject to the perception invoked with electrical stimulation. They  
314 follow with the “systems fitting,” in which global thresholds or settings for the stimulation  
315 parameters that yields a reliably “good” perception are determined (first amplitude followed by  
316 phase duration and frequency). The subjects’ expectations are tempered once again at this point:  
317 they are told that this is not when they will “see” (they are told this will be when the camera is  
318 turned on). Nevertheless we came to learn that this two-day period is associated with significant  
319 change and learning, as the participant learns to identify the signal, or “phosphene” – the building  
320 block of artificial vision.

321

322 The devices are built and rehabilitation protocols implemented with the expectation that activation  
323 of a single electrode will produce a single point of light - a phosphene – ideally with a low threshold  
324 of activation and a brightness that corresponds to the amplitude of the electrode. If each electrode  
325 produces a single, isolated point of light, it would allow a visual image to be recreated using a  
326 pixel-based approach, assembling phosphenes into objects and images similar to an electronic  
327 scoreboard (Fig 1) [49,50].

328  
329 **Fig 1. Scoreboard model of pixel doctrine. (HK)**

330  
331 While many early-stage research studies have reported that implant-elicited percepts are quite  
332 variable in appearance (18,51-54), the narrative of punctate, light-colored phosphenes and the  
333 scoreboard model dominated in the literature until only recently [49,50,55]. Indeed while  
334 projections have been updated with more nuanced knowledge of the effects of electrical stimulation  
335 on different cell types in various stages of degeneration and reorganization [56,57], the devices and  
336 rehabilitation protocols are still designed and built on the assumption that the quality of artificial  
337 vision produced depends on the spatial acuity of the array, as determined by electrode size, number  
338 and spacing, where each electrode will ideally produce a circumscribed phosphene.

339  
340 During the course of our observations we would explicitly ask the participant to describe the  
341 percept associated with stimulation, either during the protocol or after the session was over, and  
342 found there to be significant variability and ambiguity in this reeducative process. In UK  
343 participants who were explicitly asked by the author (CED) during activation, many reported  
344 “glitter” or “sparkles” during single electrode stimulation. One subject called their percepts “cheese  
345 puffs” that whizzed by laterally; another compared them to “exploding, pink popcorn;” for yet

346 another they appeared as red diamonds, sometimes in a cluster, sometimes single (even if only one  
347 electrode was being activated). French participants met by the author (HK) usually stuck with the  
348 terms the rehabilitation specialists used: “flashes” or “signals”, or “flickering lights”  
349 (“*clignotements*”).

350

351 Sometimes the phosphenes were obvious to the participant right away, as in the case of the  
352 participant Douglas, yet still difficult to describe:

353

354 Therapist M.: [electrode activation] Do you see anything?

355 Douglas: Yes!

356 Company researcher S.: Please describe it

357 D: Half circles within circles. Quite bright, yellow, moved to the right... (he indicates  
358 with a passing index finger through the air). Almost a crescent shape, with a halo around  
359 it....

360 M: [using a list developed by the company with a list of potential descriptors] Is it as  
361 bright as the sun, bright as a lightbulb, a candle or a firefly?

362 D: ...not as bright as the sun, but brighter than a light bulb.

363 [They move down the list of possible descriptors and hand him a few tactile boards that the company  
364 constructed to aid in the participant describing size and shape. Each board has three possible size  
365 choices in one of three shape choices: 2cm, 3cm and 5 cm circles, oblong circles or rods (Fig 2).]

366  
367 **Fig 2. Perception evaluation boards.** To assist subjects in describing their phosphenes during initial activation, they  
368 were presented boards with different forms carved out: circular shapes and sizes for the blind person to touch and  
369 choose from. (HK)

370

371 Douglas the participant feels his options and declares that it didn't resemble any of the options  
372 exactly, but if he had to choose it most closely resembled an oblong rod and was the biggest of the  
373 three, maybe 5cm at arm's length. They then moved down the rest of the list, giving him various

374 options for the appearance, with D struggling to pick the descriptor which fit his experience best.

375 Then they stimulate again on the same electrode with the same stimulation parameters.

376 D: Yep, I saw something (he describes it with the options they provide him. It is oblong,  
377 maybe even rectangular; again, it moves to the right, was dimmer than last time, and was  
378 2cm - smaller than the first)

379 M (moving down the checklist): was it flickering?

380 D: yes, both were flickering.

381 D: [They activate a third time and go down the list of descriptors] half circles within circles,  
382 moving to the right, yellow, bright as a light bulb, 2cm, flickering.

383 Next they move onto the second step of the protocol: 10 consecutive stimulations on the same  
384 electrode. Douglas must answer which of the 10 they are applying electrical stimulation and which  
385 ones they aren't. Yes or no, they ask him, do you see anything? He gets 10 out of 10 correct, each  
386 with resounding "no" and "yes."

387  
388 For others the initial activation may provide a signal that is more ambiguous or difficult for the  
389 participant to identify.

390  
391 (translated from French)

392 Therapist: "Here we're going to stimulate the implant a little, and you're going to tell us  
393 what you perceive." "Sometimes you won't see anything and that's normal, just let us  
394 know."

395 The exercise starts:

396 "beep" The sound indicated a stimulation has been sent to the implant.

397 Vincent: "Nothing. I hear the sound but that's all."

398 "beep"

399 V: "I felt something in the front."

400 "beep, beep"

401 V: “Something...a little flash.”  
402 “beep”  
403 V: “Something on the right.”  
404 “beep”  
405 V: “Still on the right.”  
406 “beep”  
407 V: “A little flash here.”  
408 “beep”  
409 V: “Yes.”  
410 T: “What about here?”  
411 V: “Mmm. It can’t be on the left, right? Since the implant is on the right.”  
412 T: “Yes, it can.”  
413 “beep”  
414 V: “Here it’s clearer.” “Small flash.”  
415 “beep”  
416 V: “Even clearer.”  
417 (...)  
418 V: “This is harder.” “The flashes are smaller.”  
419 Company researcher: “That’s normal, we’re starting with the lower thresholds.”  
420 (...)

421  
422 In this situation, Vincent struggles to answer the exercise with “correct answers”, first by trying to  
423 locate the sensation. Experiences of this type show how unclear the sensations are, and how  
424 difficult it can be for participants to learn to recognize what the perception is “supposed to be like”.  
425 This ambiguity can be stressful for participants, further complicating their perceptual experience

426 with the pressure and concentration required. Within the session, the uncertainty seemed to worry  
427 Vincent, who repeatedly questions the therapist about the final aspect of the sensations he would  
428 be able to expect with time, demonstrating how this can affect participants.

429  
430 V: “Is this what it’s going to be like, later on?” - He asks for the second time...

431 V: “Looking makes me tired. And when it’s very small it becomes really hard!”

432 (...)

433 The company researcher asks him about his perception:

434 “Do you have a sensation?”

435 “Yes.” Vincent answers shortly.

436 Then he asks yet again about what kind of perception he’ll have later on. “I’ll be seeing shadows,  
437 is that right?” The rehabilitation therapist tells him that he’ll have to learn to “integrate” and  
438 associate the flashes. Vincent says that sometimes he sees things but he’s not sure that that’s it [the  
439 flashes].

440  
441 The reasons for ambiguity or uncertainty are multiple: 1) Description: on one hand it is difficult to  
442 describe “the quality” one’s visual experience the way it is for anyone to describe the qualia or  
443 “what it is like” of conscious experience. 2) Discernment: It also may be difficult to discern: the  
444 signal is being produced within a “background” of visual distortion that characterizes blindness  
445 (that is, it is not a calm backdrop of darkness on which these phosphenes make their appearance,  
446 but instead can be a stormy sea of light and shadow, color and shape). 3) Difference: finally, it may  
447 also be that these signals are something significantly different than natural vision, and for that  
448 reason the same vocabulary that we use for natural vision just might not do.

449

450 **Learning to use the device**

451  
452 **Presentation of the device**  
453  
454 When individuals are ready to commence with camera activation, the device is presented to them  
455 and they are instructed on its use. The external component newly introduced at this stage consists  
456 of the visual interface, a headset made-up of opaque glasses with an integrated video camera, and  
457 a “pocket computer,” or a visual processing unit that is housed in a little black box that is connected  
458 to the headset by a cable. The processing unit is about 4-5 inches and can be hung around the neck,  
459 carried in the pocket, or attached to the belt, and has various control switches that allow the device  
460 to be turned on and off switched between the different perceptual modes (i.e. depending on the  
461 device there are between 3 to 4 different image processing modes e.g. white-on-black, inverse  
462 (black-on-white), edge detection, and motion detection).

463

464 **Bodily techniques: “Seeing through the camera”**

465  
466 After presentation of the device it is explained to the individual that they will be required to utilize  
467 certain bodily techniques in order to use the device - alignment of their eyes and head with the  
468 camera and scanning movements of their head. That is, the camera is effectively their new eye, and  
469 so an awareness and alignment of their head, camera, and eyes is essential to orient themselves in  
470 space via the signal. They are first taught to try and keep their eyes pointed straight with respect to  
471 their head position, using the analogy of a hand-held telescope.

472         Second, they are told to practice training the camera on whatever they wish to look at in  
473 space. Because the camera is not where their eye or pupil is - instead located a few inches away, in  
474 the middle of their brow ridge (above the nose, between the two eyes) - they must learn to adjust  
475 all movements and estimations of objects in space by those few inches. The trainers often tell the

476 participants to draw a line from the camera to the object in space with their index finger, to get the  
477 hang of the discrepancy.

478 Lastly, the participant is instructed on how to move their head to scan the environment.  
479 This head scanning serves two purposes. The first large scanning movements allow a participant  
480 to get a sense of the space and objects around them. The other is because the percept fades if the  
481 image remains stationary. Indeed, the retinal cells adapt to the stimulation pattern on the retina after  
482 a few seconds, resulting in the participants must make constant scanning movements with their  
483 head in order to move the camera and refresh the image. The naturally sighted viewer accomplishes  
484 this “refresh” via microsaccades - tiny movements of the eyes of which we are unconscious.

485 Thus, when encountering new environments, the participants are encouraged to begin by  
486 making large scanning movements, moving their head to the farthest possible reaches in each  
487 direction - to maximize their perceptive range - followed by increasingly small movements, to  
488 refresh the image as they zone in on an object or certain features of interest. As depicted in Fig 3,  
489 the visual field that the implant covers is quite reduced – no more than 20 degrees (about the width  
490 of two hands, outstretched), and so the participant must scan the environment, recomposing their  
491 partial views within their minds eye. Using the device thus requires the participant to use each  
492 bodily movement with the goal of capturing an optimal signal of the device; a process that is not  
493 intuitive to the participant; in this way it requires that they rethink the concept of “seeing.”

494  
495 **Fig 3. Square representation of the vision field accessed through the prosthesis.** On the left you can see that it’s  
496 only a portion of the whole image, and on the right you can see how the “square image” might be perceived through  
497 the device (prior to being converted into electrical pulses that would result in phosphenes) (HK).

498  
499 **Camera activation**

500  
501 Two weeks after the initial activation and systems fitting, the time comes to turn the camera on.  
502 The subject is told that this is when they will begin to gain back a kind of functional vision, and so

503 it is a time that is often greeted with a lot of excitement. News media and camera crews who are  
504 interested in the sensational aspect of these devices are often told to come to this session.

505  
506 When the camera is activated and all of the electrodes can be activated together, we found  
507 participants reported that things became much more chaotic and “noisy.” The mass of flashing  
508 lights coalesces, and the vocabulary subjects use when describing their percepts focuses on changes  
509 in the overall signal: e.g. “stronger,” “more signal,” “busy,” “calm.”

510  
511 The first task that is performed when the camera is activated is tracking and localization – often  
512 with a piece of white paper, or the beam of a flashlight on the wall of a dark room. The participant  
513 is asked to indicate if and when they see the light, and if possible, in which direction it is moving.  
514 This process is also marked by significant ambiguity.

515

516 (translated from French)

517 Company researcher: Could you tell us when you start to have luminous signals?

518 (...)

519 Therapist: Move your head a little bit downwards. Do you see something now?

520 Rehabilitation therapist passes the sheet in front of Isabelle.

521 Isabelle: I see luminous signals

522 T: Are they moving?

523 I: It’s blinking a little.

524 T: It’s blinking a little?

525 He says while he passes the again.

526 I: Yes. Here again.

527 T: Ok. And when you say that here, they are doing it again, does it mean that its moving,  
528 that it's stable, that it's in front of you?

529 I: Yes, it's in front of me, it appears and then it disappears.

530 (...)

531 Exercise is repeated another time.

532 T: Could you describe what you saw?

533 I: Sort of a curvy shape.

534 T: Ok. Was there movement?

535 I: No.

536 T: And if you had to describe it?

537 I: It's rather round and its blinking.

538 (Therapist passes the sheet in front of Isabelle)

539 I: Here, another signal

540 T: It's just a flash, a light in front of you?

541 I: Yes, just a flash.

542 (...)

543  
544 The movement of the paper is associated with **something** – a “flash” ...in a “curvy shape.” This  
545 “something” is the first step. With the therapist’s guidance, suggesting certain expressions to  
546 describe the sensations, the individual learns to define “movement” with the device associated to a  
547 sensation appearing then disappearing in different spots, and hence comes to recognize its  
548 trajectory. The main idea is that with time, the individual will learn to identify shapes. The hope is  
549 that the flash(es) that correspond(s) to the paper will be different than flash(es) associated with a  
550 different object; that over time, an individual will develop **a lexicon of flashes** corresponding to  
551 various shapes and objects. The next step is to build out this lexicon.

552  
553 **Building a lexicon: simple geometries**  
554  
555 The first phase of this learning protocol takes place in the radically simplified context, where the  
556 participants is seated in front of a computer screen or a table covered in a black cloth. This  
557 simplified, high contrast situation is considered an ideal environment for the device in which they  
558 use a “building blocks” approach, inspired by simple geometries, to learn to identify simple shapes  
559 that they will later use to “decompose” more complex visual spaces. That is, this training is based  
560 on the logic that the visual environment can be deconstructed into a series of simple geometric  
561 shapes that can then be assembled into the mind of the individual and reinterpreted into a coherent  
562 visual scene.

563  
564 The first exercises consist of presenting simple shapes to the participants and have them learn to  
565 use their bodily techniques to first locate the objects, and later to identify those objects. In a typical  
566 training task, the trainer will place an object – say a white styrofoam ball – in the middle of the  
567 black table, and then instructs the individual on using the eye, head and camera alignment and head  
568 scanning techniques, giving them hints and reminders until the individual is ready to locate the  
569 object, by reaching out and touching it. Through repeated trial and error attempts, the individual  
570 learns to interpret the signals they are receiving in conjunction with the movements of their head.  
571 The subjects are also handed the ball, encouraged to sense of how “ballness” corresponds to the  
572 signals they receive. Over the course of a session, different-sized balls are used, progressing to  
573 different shapes (ball versus rod, ball versus ring, etc. – Fig 4), and then low vision computer  
574 monitor tasks (e.g. grating acuity – Fig 5). Through associative learning, the subject learns to pair  
575 the kind of signal they receive with a certain shape, a skill which they can later use to decipher the  
576 environment.

577  
578 **Fig 4. Pictures of a training context for the first exercises.** Recurring shapes used during these exercises are:  
579 rectangles (or a sheet of white paper), circles (or a white ball), squares, half circles (or a banana), and later during what  
580 is called the “grating test,” an acuity measure that is performed regularly throughout the protocol, as it is used as a  
581 reference point and outcome measure. (photos by HK)

582  
583 **Fig 5. Examples of screen representations for the contrast grating acuity test.** The participants are asked which  
584 of four directions the lines are pointing, using progressively narrower spacing. (HK)

585  
586 Here again, for some subjects these tasks are easier or more straightforward, usually depending on  
587 whether the signals they are receiving intuitively resemble, or take the shape of their previous visual  
588 memories of the objects (i.e. if the signals they receive in association with the ball are “ball-like,”  
589 or if lines are “linear.”). For some, there is a larger discrepancy between the stimulus and their  
590 visual memory.

591  
592 On whether the gratings look like lines, Arthur one of the more “successful” recipients describes  
593 the way he remembers lines to look:

594 “It’s not what you remember...[instead] you learn to identify [the grating lines] with ‘linear’  
595 because you know that’s the way it’s supposed to be.”

596  
597 **Decomposing space**

598  
599 The subject is then asked to put these skills of simplified geometries to work during the second  
600 phase of the training, in orientation and mobility tasks. They begin in the hallway outside of the  
601 training room, where they are encouraged to rethink the environment through an arrangement of  
602 lines. Recalling the vertical, horizontal and diagonal lines they were taught to identify on the  
603 computer screen, individuals are led to reconstruct space mentally, according to the basic angles  
604 composing it. The vision therapists are told by the companies to assume that the hallway is  
605 transformed by the device into a high contrast, black-and-white scene (Fig 6) and they coach them

606 accordingly, encouraging them to look for the lines of the hallway and its borders, as well as of the  
607 walls interspersed with the rectangles of the doors.

608  
609 **Fig 6. Decomposing visual space according to lines.** The rehabilitation therapists are told by the companies to assume  
610 that the hallway is transformed by the device into a high contrast, black-and-white scene. The rehabilitation specialist  
611 then uses this visual to help guide the implant recipient (graphic representation by HK).

612  
613 During reeducation, participants navigate down the hallway, following one of the black lines on  
614 the side. The vision therapist walks along beside them, tracking the translation of the video camera  
615 image into electrode activation on a laptop they tow alongside them on a wheeled walker. The idea  
616 is to help participants recognize key elements of the environment that they can then associate with  
617 previously learned content in order to guess the object it could likely represent. This is most often  
618 done using the previously learned line strategy. For example, if the person is in an urban  
619 environment and following the edge of the sidewalk, when the “signal” appears, the series can be  
620 reduced to the following group of possibilities: “pole”, “post”, “tree”. If they direct the video-  
621 camera upwards, they will be able to decipher objects usually situated above, such as branches at  
622 the top of a (vertical) tree, or a sign at the top of a (vertical) post. Having a very small visual field,  
623 means that participants must try to “follow the line” with the device - added to the continuous small  
624 head movements imitating micro saccades – which makes it all the more difficult for participants  
625 to visualize the “line” as a whole (Fig 3).

626  
627 **Recomposing the environment: deciphering the “puzzle”**

628  
629 The subjects are asked to put all of the skills and techniques they have been developing together in  
630 order to “recompose” the environment. They are encouraged to practice at home, where they can  
631 rely on familiar contexts, to identify known objects around their house. It is more difficult when  
632 going outside to try and recognize new or unfamiliar objects. The subjects need to use their  
633 previously acquired blindness skills and multisensory abilities to get themselves in the right spot,

634 and then use the head scanning motions and deductive techniques to detect an object in front of  
635 them (e.g. a pole). They may be able to detect the shape, and depending on contextual cues, make  
636 a guess at what it is. It is often only by pairing the new information from the implant with other  
637 senses – auditory cues – that the individual is able to make any sense of it.

638  
639 For example, deciphering a car in an environment involves pairing the signals associated with  
640 “headlights” with the sound of the car approaching or driving off; for one subject deciphering a  
641 “sidewalk” consists of pairing the feel of the sidewalk with the “shimmering lights” that were  
642 associated with the sunlight reflecting off the line of cars parked next to it.

643  
644 Early on, sensory signals may contradict each other; this new sensory signal may interfere with  
645 auditory or tactile information that the subject had adapted to use to navigate, interfering with their  
646 navigation [19]. Thus the multisensory training also takes time, as the subject learns to suppress or  
647 realign certain senses with the new signals they are receiving. Participants describe the  
648 recomposition, or reinterpretation, of the signals as the most difficult part of device use. While the  
649 signals can be considered “visual” as far as they consist of light and sensation at a distance, because  
650 they are so different from what the subject remembers of visual appearance, it can take considerable  
651 time and effort to interpret. In certain cases, the signal remains so ambiguous – or can interfere  
652 with integration of the other senses - that the participant will never be able to use it in a complex  
653 visual scene, certainly not with the device by itself.

654  
655 “Seeing” is thus a process of recomposing and deciphering the tangle of signals they get from the  
656 device, integrating with other sensory signals and visual memory. How do participants describe  
657 seeing an object? Participants might explain “I see a car,” or “I see a tree” – as is publicized in the

658 company-based videos and publications – but if asked to describe their process, one begins to get  
659 a sense how multimodal it is.

660

661 Two subjects describe this (translated from French):

662  
663 “What surprised me most were the cars. (...) There’s plastic in the front, the hood is metal, and then  
664 the window and....they are not equally luminous. (...) The bumper is in front and the hood is  
665 horizontal, and the window is like this [she says drawing a diagonal with her hand]. So it doesn’t  
666 reflect light in the same way. (...) When one sees a car [with natural vision] it’s a whole, a shape.  
667 And you can see it as a whole. But **I** have to put it back together like a puzzle. That, plus that, plus  
668 that (...): makes a car. It’s weird at first, but now I’m integrated in this way.” - Eve, participant

669

670 “For a tree, I don’t see the trunk, only a vision of the tree, so I see something like a vertical line. I  
671 move my head a little, and see a vertical line...then, while zooming like this [with the controls], I  
672 move my head upwards, and then I see full of little flashes. So then I know they are branches.” [he  
673 explains that flashes = leaves] - Thomas, participant

674

## 675 **Living with the device**

676

### 677 **What artificial vision is “like”**

678 One can think about this in terms of the “gestalt” of artificial vision. The participant is faced with  
679 a mass of flickering flashes on a background of shifting light, shadow and shape (depending on  
680 their Charles Bonnet Syndrome, condition in which individuals who have lost their sight experience  
681 visual hallucinations). Through this periscope view of the environment, and through a series of  
682 movements of the head that they use in conjunction with their visual memory and other senses,  
683 participants try and construct a cohesive picture of the visual environment that they can then  
684 interpret. All visual stimuli become reduced to flashes of varying intensity occurring in two-

685 dimensional space (i.e. there is no depth information). The act of attending to this shifting visual  
686 scape (and pairing it with reassembling and interpretation) is something that requires intense focus  
687 and concentration, requiring that the individual direct their attention simultaneously to a large  
688 variety of sensory information from different senses at the same time.

689  
690 We purposefully did not identify and differentiate between the two different devices here because  
691 we did not find participant experience to vary significantly by device. That is, while we did find  
692 there to be significant inter-individual variability in perceptual experience, whether it was Argus II  
693 or IRIS II did not seem to matter, and this was despite the difference in number of electrodes (60  
694 vs 150, respectively). This accords with published literature on clinical outcome measures  
695 comparing other visual prosthesis devices - the Argus II and the Alpha IMS, which not only  
696 differed in terms of the number of electrodes (60 vs 1500) but also in terms of location on the retina  
697 (epiretinal vs subretinal), without any significant difference in clinical outcomes between the two  
698 (despite a projected 7-fold increase in acuity by the Alpha IMS) [23].

699  
700 **Artificial vision is electric**  
701 Overall, across all subjects, artificial vision was described using terms that invoked electric stimuli.  
702 English subjects most commonly reported a “light show,” “lots of flashing lights” and/or  
703 “fireworks.” In French subjects the most recurring words are “*clignotements*” (translates into  
704 “flashing”, or “blinking lights”), “*signaux lumineux*” (“luminous signals”), “*petits flashes*” (“small  
705 flashes”), “*scintillement*” (“shimmering”). Participants frequently used metaphors to try to describe  
706 these perceptions: “Eiffel tower lights”; “Christmas lights”, and “camera flash.”

707  
708 **Artificial Vision is “different”**

709 When asked how artificial vision compared to what they remember natural vision to be like, many  
710 subjects responded with a variation of what one subject, Danny, reported: “first off, you need to  
711 understand that it is fundamentally different than natural vision.” Indeed, one vision rehabilitation  
712 specialist who had worked with scores of Argus II participants said that the overwhelming response  
713 is that artificial vision is “different” than the individual expected to be. She stated that she has yet  
714 to meet someone who reports the experience was exactly what they expected it would be, even  
715 after their expectations are tempered in the process of being vetted for the device.

716

### 717 **Use (or disuse) over time**

718 Over months to years, outside of the rehab facilities and clinical trial testing rooms, participants  
719 reported a variety of experiences. The device can fail prematurely (as in case of IRIS I & IRIS II),  
720 or keep working for the expected lifetime of the device (durability studies in Argus II show over  
721 8,5 years) [58]. Some subjects report that after they use it to get a sense of the familiar objects in  
722 their own home, they feel they don’t have a use for it, and report having a “so what” stage after 1-  
723 2 years, where individuals are disappointed by the device. For this reason, many subjects just stop  
724 using their device after a spell. One researcher said of the 12 subjects he had worked with on a  
725 study, two years later none of them used the device. These observations join those on experiences  
726 with other prosthetic technologies such as cochlear implants or prosthetic arms, often abandoned  
727 (temporarily or definitively) because of their inconvenience and unnatural qualities [32,59].

728

729 Indeed, as with prosthetics mentioned above, of everyone we spoke to – even the companies  
730 ‘banner’ subjects – all mentioned that the process of using the device in daily life never ceased to  
731 be intensely cognitively fatiguing : both because of the continuous and intense focus they must  
732 invest in what becomes an actual perceptive activity (natural vision usually doesn’t require such

733 effort) and because of the nature of the sensations produced, inherently different from “natural  
734 vision” as we know it. It is for this reason that participants who continue to use the device tend to  
735 stick to the “contemplative function” aspect of the device – using it in conditions that are not “too  
736 bright,” nor “too busy”- and for tasks that are not of consequence.

737  
738 Therefore others report continuing to use the device – not as a functional aid as much as for the  
739 aesthetic pleasure of looking at various objects in the world through the device (to experience the  
740 world at a distance), or as a tool for cognitive stimulation. Some subjects spoke of a certain  
741 “pleasure” of “watching” the leaves of a tree shimmer, or perceiving how high the Louvre pyramid  
742 is (it wasn’t built until after that particular participant lost their vision). This was referred to by one  
743 participant - Benoit - as “contemplative function” of the retinal implant. He describes that he only  
744 uses the device for skiing, which he is passionate about, but not so much to help him ski (as he  
745 relies on his skiing partner and not on the device) but rather to have additional sensation during the  
746 experience. Participants sometimes tailor this contemplative use towards individualized activities  
747 and hobbies.

748  
749 **Percept doesn’t change over time**  
750 All participants, and all vision rehabilitation specialists who worked with the participants, were  
751 clear about the fact that the quality of the percept does not change over time as the individual learns  
752 to use the device - and this extends over the course of years for some subjects. That is, regarding  
753 one of the most important questions for the development of these devices – whether the individual  
754 can transform the imperfect signal through perceptual learning over time – we learn that no, they  
755 don’t seem to. Instead, one just learns to interpret the signal that is provided.

756  
757 **Psychosocial effects**

758 Something that all of the subjects we spoke to brought up in terms of their experience – often  
759 without prompting - was the significant psychosocial effects they encountered by participating in  
760 the trials. These effects can be considered as threefold:

761  
762 First, participants can be disappointed in the beginning by the difference of artificial vision from  
763 what they were expecting. Even with a change in the rhetoric the researchers learned to employ  
764 over time, stressing that the kind of vision these subjects would get would be different than natural  
765 vision they remembered, the subjects all said they were unprepared for just how different it was.

766  
767 Second, a common theme that arose time and again was the way in which subjects treat failure of  
768 the device as a personal defeat. Whereas subject successes are claimed by the company to be a  
769 product of the device, failures are more often than not put upon the shoulders of the subjects. For  
770 example, we have the case of Mathew. When Mathew’s device stopped functioning he was told  
771 that it was “his eye” that wasn’t working and not the device, a projection of responsibility that he  
772 took personally and found to be unfair, as no evidence was presented to him of why his eye should  
773 stop working. Or in other cases where, when progress stalls, the subjects are told it is because they  
774 need to be practicing more at home – that it is their brain that sees and constant training is needed  
775 for this to happen.

776  
777 Finally, there are also the psychosocial effects linked to both benefits and difficulties associated  
778 with the change in social relationships experienced in getting one of these devices. It seems that  
779 one of the biggest benefits of getting one of these devices that participants and researchers alike  
780 spoke of - whether the device works or not - is the job, role and purpose it gives participants: to  
781 receive attention, to have a use, to be surrounded by a community. This ethos was reflected by a

782 clinical coordinator at one of the companies: “we’re giving these individuals a job, a purpose, and  
783 they all really responded to that... these individuals are given attention and a community of  
784 supporters that revolve around them; you have a research group who is indebted and grateful to  
785 you for your services. That is what you get out of participating in the trials.” But then, when the  
786 device stops working or the trial concludes – one loses all of this; not only one’s new sensory  
787 relation with the world, but also the role, the job, the identity, the community. More than one  
788 subject talked about the difficulties encountered when the device stops working. “It is like going  
789 blind and losing the possibility of sight all over again” one participant, Arthur reported.

790  
791 It is notable, however, that even in subjects who were disappointed by the quality of the perceptual  
792 experience they received, and in spite of the psychological difficulties – everyone we spoke with  
793 wanted to be considered for the next generation device. In many cases they were hesitant to discuss  
794 their difficulties or complaints lest it endanger their consideration by the companies for the next  
795 generation device.

## 796 **Discussion**

797  
798 We undertook ethnographic research with a population of retinal prosthesis implant recipients and  
799 vision rehab specialists, documenting the process of getting, learning to use and living with these  
800 devices.  
801

802  
803 We found that the perceptual experience produced by these devices is described by participants as  
804 fundamentally, qualitatively different than natural vision. It is a phenomenon they describe using  
805 terms that invoke electric stimuli, and one that is ambiguous and variable across and sometimes  
806 within participants. Artificial vision for these subjects is a highly specific learned skillset that

807 combines particular bodily techniques, associative learning and deductive reasoning to build a  
808 “lexicon of flashes” - a distinct perceptual vocabulary - that they then use to decompose, recompose  
809 and interpret their surroundings. The percept does not transform over time; rather, the participant  
810 can better learn to interpret the signals they receive. This process never ceases to be cognitively  
811 fatiguing and does not come without risk nor cost to the participant. In exchange participants can  
812 receive hope and purpose through participation, as well as a new kind of sensory signal that may  
813 not afford practical or functional use in daily life, but for some provides a kind of “contemplative  
814 perception” that participants tailor to individualized activities. We expand on these findings below  
815 to explore what they mean in terms of the development and implementation of these devices, as  
816 well as for our understanding of artificial vision as a phenomenon.

817  
818 What does it mean that the participants describe artificial vision as being fundamentally,  
819 qualitatively “different” than natural vision? We believe that acknowledging that artificial vision  
820 is a unique sensory phenomenon might not only be more accurate, but it may also open up new  
821 avenues of use for these devices. That is, we found that artificial vision - the process of building a  
822 “lexicon of flashes” – consists of a process of associational learning in which the participant comes  
823 to remember how certain patterns of phosphenes correspond to features of the environment. While  
824 “visual” in terms of being similar to what participants remember of the experience of certain kinds  
825 of light, as well as by offering the possibility of being able to understand features of the  
826 environmental surround at a distance, artificial vision was described as both qualitatively and  
827 functionally different than the “natural” vision the participants remember. It is in this way that the  
828 sensory experience provided by these devices could be viewed as less a restoration or replacement  
829 and more a substitution; that is, as offering an entirely different or novel sensory tool. By shifting  
830 from the rhetoric of replacement or restoration to substitution we believe it could widen the bounds

831 in which researchers and rehabilitation specialists think and operate with regard to how these  
832 devices are designed and implemented, potentially liberating a whole new spectrum of utility  
833 through the novel sensations these devices produce. Likewise this shift could change the  
834 expectations of individuals receiving these devices, including addressing the initial disappointment  
835 that was expressed by many of our participants when they encountered just how different the  
836 signals were to what they were expecting.

837  
838 Second, acknowledging artificial vision as a unique sensory phenomenon also helps us understand  
839 the importance of qualitative description. The process of learning to use the device is a cooperative  
840 process between the rehabilitation specialist and the participant, with the specialist guiding the  
841 participant to attend to their perceptual experience and interpret it in specific ways. This process  
842 begins with the participant learning to recognize how the basic unit of artificial vision – the  
843 phosphene – appears for them, and then describe that to the rehab specialist. The specialist then  
844 uses this information to guide the participant in learning how the phosphenes correspond to features  
845 of the environment. It is a continuous and iterative communicative practice between the participant  
846 and specialist that evolves over many months, during which stimuli are encountered, the participant  
847 responds, and the specialist gives corrective or affirming feedback (with more or less description  
848 by the participant and guidance by the specialist depending on the dynamic and need). The process  
849 is so specific to the dynamic between participant and specialist that it can be considered to be “co-  
850 constructed” within their interactions.

851  
852 Because each participants’ qualitative experience is so distinct (phosphenes differ significantly  
853 between participants so that no participants’ perceptual experience is alike [60]) each process is  
854 tailored to the individual participant by specific specialists. We found that certain vision

855 rehabilitation specialists inquire in more depth about a participant’s qualitative experience than  
856 others, using different methods, styles and techniques, and this can result in a different experience  
857 – and thus outcome - for the participants. Our findings are based on reports captured either by  
858 directly asking the participants about their experience or observing descriptions that were part of  
859 the rehabilitation process but that were by and large not recorded by the specialists nor relayed  
860 back to the companies, early stage researchers nor the individuals being implanted. That is, we  
861 found that there is no protocol in place for capturing or sharing participant’s qualitative reports,  
862 including within the companies (between various clinical sites). Yet these kinds of data are  
863 essential to understanding these devices as well as in learning about artificial vision more generally,  
864 and thus deserve careful consideration by both researchers and clinicians who are developing and  
865 implanting these and similar devices, as well as to individuals and their families who are  
866 considering receiving them.

867  
868 The better vision rehabilitation specialists are able to understand the participant’s qualitative  
869 experience, the more they are enabled to assist them in learning to use the device. The more early  
870 stage researchers know about how the parameters of the device correspond to perceptual  
871 experience, the better they are able to optimize design and implementation strategies. Finally,  
872 communicating these data to individuals and their families who are considering being implanted is  
873 essential. It would contribute to a more accurate understanding of the qualitative experience and  
874 process they are signing on for, and thus is an important part of informed consent. It would also  
875 help to address certain psychosocial difficulties we found participants to experience. For instance,  
876 we found that that the participant’s percept does not change over time - that instead the participant  
877 becomes better able at interpreting the signal they receive. It is a subtle distinction, but a profound  
878 one in terms of conditioning expectations around these devices – both of the researchers and the

879 participants. We found that current rhetoric employed by researchers and vision rehab specialists  
880 regarding neuroplasticity and the ability for participants to transform the signal with enough  
881 practice has created a situation in which failure of the participant to significantly transform the  
882 signal over time is perceived as a failure of the participant (behaviorally, where the participant is  
883 deemed to have insufficiently practiced using of the device, and/or physiologically, where the  
884 problem is located within the participant's eye or visual system). By shifting the expectation that  
885 it is not the percept itself, but the participant's ability to use the percept over time that can improve,  
886 one can potentially avoid and address the psychosocial distress that we found some participants  
887 experienced as a result.

888  
889 This study had several limitations, first and foremost the number of participants limited by small  
890 study populations and availability of subjects. Future studies of these devices would do well to  
891 include similar qualitative reports from participants, either as primary focus or as supplement to  
892 other outcome measures. In addition, qualitative reports are only one type of data and are not  
893 meant to replace other forms of data being collected on these devices. Rather, we believe deserve  
894 special attention because they have been heretofore neglected in the literature despite their potential  
895 to provide valuable information not captured by normative functional outcome measures.  
896 Qualitative data about participants' perceptual experience can both inform device design and  
897 rehabilitative techniques, as well as grant a more holistic understanding of the phenomenon of  
898 artificial vision. In addition to contributing to the larger body of work on visual prostheses, this  
899 study serves as a case example of the kind of data mobilized by qualitative, ethnographic  
900 methodology – in particular phenomenological inquiry - in study of brain machine interface  
901 devices.

902

## 903 **Acknowledgments**

904  
905 The authors would like to individually thank all the anonymized persons from the hospitals'  
906 personnel, as well as the people interviewed working for companies Pixium and Second Sight, and  
907 finally and most importantly the RI participants who graciously accepted to be observed and  
908 interviewed ; who have all made this study possible.
