Short title: Dynamic expressions of confidence

Abstract

Human observers can reliably report their confidence in the choices they make. An

influential framework conceptualizes decision confidence as the probability of a decision

being correct, given the choice made and the evidence on which it was based. This

framework accounts for three diagnostic signatures of human confidence reports, including

an opposite dependence of confidence on evidence strength for correct and error trials.

However, the framework does not account for the temporal evolution of these signatures,

because it only describes the transformation of a static representation of evidence into

choice and the associated confidence. Here, we combine this framework with another

influential framework: dynamic accumulation of evidence over time. We propose that

confidence reflects the probability of being correct, given the choice and accumulated

evidence *up until that point*. The resulting model predicts that the diagnostic signatures of

confidence depend on time; most critically, it predicts a stronger opposite dependence of

confidence on evidence strength and choice correctness as a function of time. We tested,

and confirmed, these predictions in human behaviour during random dot motion

discrimination, in which confidence judgments were queried at different points in time. We

conclude that human confidence reports reflect the dynamics of the probability of being

correct given the accumulated evidence and choice.

Author summary

Humans are able to report a sense of confidence in the accuracy of a choice. An

influential framework states that confidence reflects the probability that a choice is correct.

We combined human experimenting with computational modelling and extended this notion

in the time domain, thus to formally describe the dynamics of confidence. Both human data

and our model show that the sense of confidence depends on the point in time at which it is

queried. We conclude that human confidence reports reflect the dynamics of the probability

of a choice being correct.

Introduction

Human observers can provide very precise judgments about the confidence of their

choices. They often claim high confidence for correct choices and low confidence for errors.

Accurate confidence estimates are adaptive because confidence is used to regulate future

behaviour (Desender et al., 2019b, 2019a; van den Berg et al., 2016). An influential

framework posits that internal representations of decision confidence, and agents' overt

reports thereof, reflect the probability of being correct, given the choice made and given the

evidence on which it was based (Kepecs et al., 2008; Pouget et al., 2016; Sanders et al.,

2016). In this framework, both choice and confidence are directly based on the same

underlying computations. This principled approach predicts three key qualitative signatures

of confidence (Kepecs et al., 2008): Signature 1: an interaction between evidence strength

and choice accuracy, whereby confidence increases with evidence strength for correct

choices, but decreases for incorrect choices; Signature 2: confidence increases

monotonically with accuracy; Signature 3: a steeper increase in performance for high versus

low confidence trials as a function of evidence strength. These three signatures have been

observed in neural data (Kepecs et al., 2008), several implicit behavioural measures of

confidence (Braun et al., 2018; Kepecs et al., 2008; Sanders et al., 2016; Urai et al., 2017),

and explicit confidence reports of human observers (Fleming et al., 2018; Sanders et al.,

2016). An important limitation of this framework is that it is static: a fixed quantity of evidence

determines both the choice and associated confidence. Therefore, this framework does not

account for the dynamics of decision-making, the associated trade-off between speed and

accuracy, and their effect on confidence reports.

To address this issue, we combine this framework with an evidence accumulation

model. According to evidence accumulation models, perceptual decisions are based on a

gradual accumulation of noisy sensory evidence over time (Gold and Shadlen, 2007; Ratcliff

and McKoon, 2008). In two-choice tasks, a decision maker accumulates evidence for each

option, and the option for which the integrated evidence first crosses a decision threshold is

selected, indicating commitment to choice (Ratcliff and McKoon, 2008). The efficiency (i.e.,

signal-to-noise ratio) of the accumulation process is governed by the so-called drift rate. To

account for confidence within such a dynamic model, Kiani and Shadlen (2009) proposed

that confidence reflects the probability of being correct, given choice, evidence *and time*.

Although such conceptualization explains the scaling of confidence with evidence strength

(Kiani and Shadlen, 2009), with decision time (Kiani et al., 2014) and with evidence volatility

(Zylberberg et al., 2016), an often cited limitation of this account is that it cannot explain why

human confidence judgments are higher for correct than for error trials within a single level of

evidence strength (Pleskac and Busemeyer, 2010). Put differently, this model cannot easily

explain how humans become aware of their mistakes. In order to account for this, it has been

proposed that evidence continues to accumulate after the decision boundary has been

reached (Moran et al., 2015; Pleskac and Busemeyer, 2010; Resulaj et al., 2009; Van Den

Berg et al., 2016; Yu et al., 2015). Confidence then reflects (a transformation of) the

accumulated evidence after this period of post-decision accumulation. With non-zero drift

rate, such a model will on average accumulate further evidence in favor of the selected

choice when it was correct, whereas it will on average accumulate evidence for the non-

selected choice in case of an error (i.e., potentially leading to a change of mind; Van Den

Berg et al., 2016). Thus, the process of post-decision evidence accumulation allows the

model to detect its own errors in a graded fashion.

Characterizing confidence as the probability of being correct given choice, evidence

and elapsed time provides a powerful framework to understand human confidence

judgments. However, it remains unclear whether such a model also accounts for the three

diagnostic signatures of confidence identified by Sanders et al. (2016), and if so how these

signatures depend on the duration of post-decision accumulation. Here, we address this

question through the combination of simulations of a popular evidence accumulation model,

the drift diffusion model (DDM), and the analysis of human behavior in a perceptual decision

task. First, we show that these signatures of confidence dynamically depend on post-

decision processing time, a pattern that was also seen in human participants. Second, if

confidence is quantified after a period of post-decision accumulation, a stopping criterion is

needed, similar to the decision boundary for first-order choices. Here, using a manipulation of

evidence volatility, we shed light on the question whether human participants use a time-

based stopping rule (i.e., terminate sampling after a certain amount of time) or an evidence-

based stopping rule (i.e., terminate sampling after the accumulated evidence reached a

certain threshold value).

106   **Results**

107   **Dynamic signatures of confidence**

108   Following recent work that has modeled confidence as post-decision evidence

accumulation (Calder-Travis et al., 2020; Pleskac and Busemeyer, 2010; Van Den Berg et

al., 2016), we reasoned that confidence reports may differ, depending on whether they are

probed around the time of the response (Kiani and Shadlen, 2009; Zylberberg et al., 2016) or

only later in time, after additional post-decision processing (Moran et al., 2015; Pleskac and

Busemeyer, 2010; Yu et al., 2015). In both cases, we propose, confidence reflects the

probability of being correct, given the choice and accumulated evidence up until that point.

The heat map in Fig. 1A reflects the probability of being correct given evidence (Y-axis) and

time (X-axis), conditional on the choice (Kiani and Shadlen, 2009; Zylberberg et al., 2016).

The current heat map shows this probability conditional on reaching the upper boundary (i.e.,

an "up" choice). Note that the heat map is flipped over the abscissa when the lower boundary

is reached instead (i.e., a "down" choice). Thus, confidence in our model reflects the

probability of being correct, given choice, evidence (potentially post-choice) and time. With

respect to Signature 1 (an interaction between evidence strength and choice accuracy), our

model simulations show that confidence increases for both corrects and errors when

confidence is quantified at the time the bound is reached (Figure 1B), whereas the interaction

between evidence strength and choice accuracy emerges when confidence is queried later in

time (Figure 1C-D). In the following, we will test these predictions in human participants

during random dot motion discrimination with additional confidence ratings.

Figure 1. Quantifying decision confidence within an evidence accumulation framework. A.

Noisy sensory evidence is accumulated over time, until the decision variable reaches one of two

bounds (a or 0), corresponding to a left or right choice, respectively. After the decision variable

reaches a bound, evidence continues to accumulate. The heat map shows the probability of being

correct given time and evidence, conditional on reaching the upper boundary (i.e., making an "up"

response). Confidence is quantified as the probability of the choice being correct, given elapsed time

and the integrated evidence (i.e., represented by the color of the heat map). Confidence can be

*queried at different points in time. **B-D**. Model predictions about signature 1, an interaction between*

evidence strength and accuracy, depending on when in time confidence is quantified.

Perceptual decisions as noisy evidence accumulation

Twenty-six human participants were presented with dynamic random dot motion and

were asked on each trial to decide as fast and accurate as possible whether a subset of dots

was coherently moving towards the left or the right side of the screen (Gold and Shadlen,

2007). The difficulty of these decisions was manipulated by varying the proportion of

coherently moving dots. Five different levels of coherence were used, ranging from 0 up to

.4, all of which were randomly intermixed within a block. We also manipulated the volatility of

motion coherence over the course of a single trial. Specifically, on each frame, the input

coherence was either sampled from a Gaussian distribution with $SD = 0$ (low volatility), or

from a Gaussian distribution with $SD = .256$ (high volatility) around the generative coherence.

In the high volatility condition, additional noise is thus introduced in the decision process.

Previous work has shown that this manipulation, which speeds up RTs and increases

confidence, is diagnostic for an evidence-based stopping rule for immediate decisions

(Zylberberg et al., 2016). We here used this manipulation to shed light on the stopping rule

for delayed confidence reports.

In order to query the dynamics of post-decision processing and its influence on the

diagnostic signatures of confidence (cf. Figure 1B-D), confidence reports were collected in a

different way depending on the block (see Figure 2). In the *immediate condition* participants

jointly indicated their choice (left or right) and their level of confidence (guess correct,

probably correct or certainly correct) via a single response. In the *delayed condition*,

participants first indicated their choice (left or right), and then after a 1s blank screen or 1s of

continued motion (same coherence, volatility and motion direction as the initial stimulus) they

indicated the level of confidence in their choice on a six-point scale.

Figure 2. Experimental task. *Sequence of events in the experimental task. Participants decided, as*

fast and accurately as possible, whether the majority of dots were moving left or right. In the

immediate condition, they did so by jointly indicating their choice (left or right) and confidence (sure

correct, probably correct or guess correct) with a single response. In the delayed condition,

participants first indicated their choice with their thumbs (left or right), and after a 1s blank or 1s of

continued motion, they indicated the degree of confidence in their decision using a six-point

confidence scale (ranging from certainly correct to certainly wrong).

To unravel how coherence and volatility affected latent cognitive variables in the

decision process, we fitted choices and reaction times using a hierarchical version of the drift

diffusion framework (Wiecki et al., 2013). Because the effects of coherence and volatility

were not modulated by the timing of confidence reports (immediate vs delayed) for both RTs,

F < 1, *Bayes Factor (BF)* = .008, and accuracy, *F* < 1, *BF* = .01, the RT and accuracy data

were combined. First, as typically observed in random dot motion tasks, drift rates increased

monotonically with coherence level (see Figure 3A), with significant differences in drift rate

between all coherence levels (averaged across volatility levels), *p*s < .001. Estimated drift

rates did not depend on the level of evidence volatility, *p*s > .119. Second, as we predicted

(Zylberberg et al., 2016), our manipulation of within-trial evidence volatility was captured by

the within-trial drift variability parameter *σ* (see Figure 3B; Methods). When averaged over

different coherences, estimated within-trial variability was higher for high compared to low

volatility, $p = .014$ (pair-wise comparisons within each coherence value: 0% coherence: $p =$

.091; 5% coherence: $p = .049$; 10% coherence: $p = .259$; 20% coherence: $p = .106$; 40%

coherence: $p = .457$).

184   These model fits captured the patterns seen in behavioral data (Figure 3C-D).

Accuracy increased with the level of coherence (data: $F(4,22) = 267.48$, $p < .001$; model:

$F(4,22) = 619.57$, $p < .001$), whereas evidence volatility and the interaction between both

variables left accuracy unaffected (data: $Fs < 1$; model: $ps > .213$). Reaction times decreased

with increasing coherence levels (data: $F(4,22) = 30.68$, $p < .001$; model: $F(4,22) = 52.25$, p

$< .001$), and were shorter with high compared to low volatility (data: $F(1,25) = 9.10$, $p = .006$;

model: $F(1,25) = 17.91$, $p < .001$), an effect that was mostly pronounced at low coherence

levels (data: $F(4,22) = 13.21$, $p < .001$; model: $F(4,22) = 15.53$, $p < .001$).

*Figure 3. Model fits and task performance. **A.** Drift rate scales monotonically with the proportion of*

*coherently moving dots, but did not differ for high and low volatility conditions. **B.** Within-trial variability*

(σ) selectively varied as a function of evidence volatility, whereas it was unaffected by motion

coherence. Large dots: group averages; small dots: individual participants. Distributions show the

group posteriors. Statistical significance is reflected in overlap between posterior distributions over

*parameter estimates (Materials and Methods). **C-D.** Accuracy (C) and RTs (D) as a function of*

coherence and evidence volatility, separately for the empirical data (points and bars) and model fits

(lines and shades). Shades and error bars reflect SEM of model and data, respectively.

Post-decision accumulation explains dynamic signatures of confidence

204   Next, we used our model fits to obtain qualitative and quantitative predictions of

205   confidence reports about the three dynamic signatures of confidence. In order to create a

206   heat map reflecting the probability of being correct, we simulated a large number of trials and

207   calculated average accuracy for each combination of time and evidence. Confidence

208   predictions were quantified by reading out the values from this heat map (reflecting the

209   probability of being correct) for each combination of evidence, time, and choice.

210   *Signature 1: interaction between evidence strength and choice accuracy.* The first

diagnostic signature of confidence established previously (Kepecs et al., 2008), is an

increase of confidence with evidence strength for correct trials, but a decrease for error trials.

In the immediate condition, confidence increased with coherence level, $F_{(4,44.81)} = 15.62$, p

$< .001$. Crucially, there was also the predicted interaction between coherence level and

choice accuracy, $F_{(4,1990.70)} = 14.09$, $p < .001$. Confidence increased with evidence

strength for correct trials (linear contrast: $p < .001$), but there was no significant effect for

error trials (linear contrast: $p = .070$; see Figure 4A). In contrast, as visualized in Figure 1B,

the model predicts that when confidence is quantified at the time when the decision boundary

is reached, confidence scales with coherence, $F_{(4,25)} = 14.14$, $p < .001$, but there is no

interaction between coherence and choice accuracy, $F_{(4,125.02)} = 1.03$, $p = .39$.

The above mismatch can easily be remedied by assuming that choice and confidence

cannot be computed simultaneously, for example due to a brief refractory period (Marti et al.,

2015; Pashler, 1994). Indeed, when confidence was calculated with a small temporal delay

(100 ms, Figure 1C; see Methods), the model did predict the interaction between coherence

and choice accuracy, $F(4,200) = 84.05$, $p < .001$. As in the behavioral data, the model with

the small temporal delay predicted increasing confidence with coherence for correct trials

(linear contrast: $p < .001$), but not for error trials (linear contrast: $p = .541$; Figure 4A). In the

remainder, we will continue with predictions from the model with temporal delay.

In both delayed conditions, confidence scaled with coherence level (blank condition:

$F(4,51.8) = 5.49$, $p < .001$; extra evidence condition: $F(4,4571.1) = 4.75$, $p < .001$). In both

conditions, there was also an interaction between coherence and choice accuracy (blank

condition: $F(4,3625.6) = 53.38$, $p < .001$; extra evidence condition: $F(4,4568.7) = 71.45$, $p <$

$.001$). Within the correct trials, confidence increased with coherence levels (blank and extra

evidence conditions, linear contrasts: $p < .001$. Instead, within the error trials, confidence

decreased as a function of coherence (blank and extra evidence conditions, linear contrasts:

$p = .001$). This interaction was captured by a model which terminated post-decision

accumulation after a fixed amount of time (cf. Figure 1D; Materials and Methods). This model

also showed the scaling of confidence with coherence ($F(4,69.79) = 39.9$, $p < .001$), as well

as the interaction with choice accuracy ($F(4,225) = 1634.3$, $p < .001$). Similar to the human

data, confidence increased with coherence for correct trials (linear contrast: $p < .001$) and

decreased for error trials (linear contrast: $p < .001$; figure 4B). Finally, there was a three-way

interaction between coherence, choice accuracy and interrogation condition (data:

$F(8,13466.5) = 18.22$, $p < .001$, model: $F(4,475) = 161.54$, $< .001$).

Figure 4. Three dynamic signatures of confidence. A. Signature 1: an interaction between

evidence strength and choice accuracy. *When confidence is quantified shortly after the decision*

bound has been reached ("immediate"), both model and data show an interaction between evidence

strength and choice accuracy in the immediate condition. The same pattern was observed for the

delayed condition, although the interaction effect was clearly much stronger here. **B. Signature 2:**

monotonically increasing accuracy as a function of confidence. *Both model and data show a*

monotonic scaling of accuracy depending on the level of confidence. **C. Signature 3: Steeper**

psychometric performance for high versus low confidence. *Both model and data show a steeper*

psychometric performance for trials judged with high versus low confidence. Notes: data for the

delayed conditions are averaged over blank and extra evidence conditions. All plots show empirical

data (black points and bars) and model predictions (grey lines and shades). Shades and error bars

reflect SEM of model and data, respectively.

Signature 2: Monotonically increasing accuracy as a function of confidence. The

second diagnostic signature of confidence is that it monotonically predicts choice accuracy.

Indeed, an approximately linear relation between confidence and mean accuracy was

observed in the data for both the immediate condition, $b = .13$, $t(29.92) = 12.82$, $p < .001$, the

delayed blank, $b = .12$, $t(27.29) = 16.12$, $p < .001$, and the delayed extra evidence condition,

$b = .13$, $t(23.33) = 15.45$, $p < .001$. This pattern was also captured by the model in the

immediate condition, $b = .12$, $t(26.4) = 11.76$, $p < .001$, and in the delayed condition, $b = .12$,

$t(26) = 25.05$, $p < .001$ (see Figure 4B). Note that these slopes did not differ depending on

the moment in time when confidence was queried (data: $X^2 = 2.03$, $p = .363$; model: $X^2 =$

3.76, $p = .152$).

Signature 3: Steeper psychometric performance for high versus low confidence. The

third diagnostic signature of confidence is that the relation between accuracy and evidence

strength should be steeper for trials judged with high versus low confidence. The model

predicts that this difference should be larger for the delayed compared to the immediate

condition (Figure 4C). To test this prediction, confidence reports were divided into high or low

using a split-median, separately per participant. As expected, the interaction between

coherence and confidence in predicting accuracy was observed both in the immediate

condition (data: $X^2(4) = 30.9$, $p < .001$; model: $X^2(4) = 2212.4$, $p < .001$), and in the delayed

condition (data: delayed blank: $X^2(4) = 84.15$, $p < .001$, extra evidence: $X^2(4) = 56.64$, $p <$

$.001$; model: $X^2(4) = 9018.7$, $p < .001$; see Figure 4C). Finally, there was a significant three-

way interaction between coherence, confidence and interrogation condition (data: $X^2(8) =$

24.51, $p = .002$; model: $X^2(4) = 228.90$, $p < .001$).

Evidence volatility dissociates time-based and evidence-based stopping criteria

If confidence is quantified after additional post-decision processing, a stopping rule

has to be implemented determining at which point in time confidence is quantified. In the

previous simulations, following previous research a time-based stopping rule was

implemented (Pleskac and Busemeyer, 2010; Yu et al., 2015). Specifically, confidence was

quantified after a specified amount of time has passed. An alternative implementation,

however, is that the stopping rule for confidence reports is evidence-based, just like the

stopping rule for the preceding choice process (Moran et al., 2015). According to this

evidence-based stopping rule, after reaching the initial choice threshold, agents impose a

second threshold and a delayed confidence report is given when this second threshold is

reached. Because the static signatures discussed before do not arbitrate between the two

delayed confidence stopping criteria (see Supplementary Materials), we next turn towards

our manipulation of evidence volatility. Previous work has shown that an evidence-based

model can explain the volatility effect on confidence for immediate confidence judgments

(Zylberberg et al., 2016). We reasoned that the same manipulation could be used to

disentangle a time-based versus an evidence-based stopping rule for delayed confidence

judgments.

Figure 5. Within-trial evidence volatility arbitrates between an evidence-based and a time-based

stopping rule. Immediate confidence (A and C) and delayed confidence (B and D) as a function of

coherence and evidence volatility, separately for the empirical data (points and bars) and model

predictions (lines and shades). A and B show average confidence, C and D show differences between

low and high evidence volatility. The inset on the top right shows two potential stopping criteria for

post-decision processing: post-decision accumulation can stop after a fixed period of time (i.e., a

vertical time-based rule) or when a fixed amount of evidence is reached (i.e., a horizontal evidence-

based rule). Notes: shades and error bars reflect SEM of model and data, respectively.

For *immediate confidence reports*, model predictions closely capture the pattern seen

in human confidence ratings (see Figure 5A). Confidence monotonically increased with

coherence levels (data: $F(4,22) = 27.47$, $p < .001$; model: $F(4,22) = 27.68$, $p < .001$), and was

higher with high evidence volatility (data: $F(1,25) = 41.19$, $p < .001$; model: $F(1,25) = 9.90$, p

= .004). Similar to RTs, the effect of evidence volatility on confidence was most pronounced

with low coherence values (data: $F(4,22) = 4.46$, $p = .008$; model: $F(4,22) = 30.79$, $p < .001$).

To easily interpret this effect, Figure 5C shows differences between the low and high volatility

condition. As can be seen, for both model and data, confidence was increased with high

evidence volatility, particularly with low coherence values.

For *delayed confidence* reports, the data favored the evidence-based stopping rule

over the time-based stopping rule (see Figure 5B and 6D). The data and both models

showed a monotonic increase of confidence with coherence levels (data extra evidence:

$F(4,22) = 46.67$, $p < .001$; data blank: $F(4,22) = 33.38$, $p < .001$; time-based model: $F(4,22) =$

60.83, $p < .001$; evidence-based model: $F(4,22) = 46.03$, $p < .001$), and an interaction

between coherence and volatility (data extra evidence: $F(4,22) = 10.39$, $p < .001$; data blank:

$F(4,22) = 8.42$, $p < .001$; time-based model: $F(4,22) = 11.94$, $p < .001$; evidence-based

model: $F(4,22) = 23.50$, $p < .001$). However, evidence volatility affected confidence in the

data and the model with the evidence-based stopping rule (extra evidence: $F(1,25) = 23.78$,

$p < .001$; blank: $F(1,25) = 28.69$, $p < .001$; evidence-based rule, $F(1,25) = 8.96$, $p = .006$), but

not with the time-based stopping rule, $F < 1$. Finally, in the human data, delayed confidence

reports were similar irrespective of whether post-decision evidence or a blank screen was

presented following the choice (data not shown). This was further confirmed by an analysis

including post-decision evidence (extra evidence or blank), which did not show a three-way

interaction, $F < 1$, $BF = .037$.

Figure 5D suggests that the effect of volatility on confidence for the lowest coherence

values is even stronger than predicted by the model with the evidence-based stopping rule.

This is most likely because the sigma parameter, which captures evidence volatility, was

estimated based on choices and RTs only (i.e., not based on confidence). Therefore, our

predictions about immediate and delayed confidence are entirely constrained by the decision

process itself. Some evidence hints at the possibility that post-decision accumulation is

different from pre-decision accumulation (Yu et al., 2015). In the current context, it could

therefore be that post-decision processing from memory amplifies noise in the sampling

process. Indeed, when simulating the model with an evidence-based stopping rule using a

slightly increased sigma value in the high volatility condition ($\sigma = .575$), it captures the pattern

in the data even more tightly (see Figure 5D). This finding is in line with the possibility that

post-decision accumulation is not fully determined by the pre-decision choice process.

Discussion

Normative models explain the sense of confidence in a decision as the probability of a

choice being correct. Although such formalization is principled and fruitful, it remains unclear

whether and how it can account for dynamic expressions of confidence. To investigate this,

we formalized confidence within an evidence accumulation framework as the probability of

being correct, given the accumulated evidence up until that point. We tested model

predictions concerning three diagnostic signatures of confidence, most notably an interaction

between evidence strength and choice accuracy, both for immediate and delayed confidence

reports. There was a close correspondence between model and human data for all three

signatures, showing that these signatures of confidence depend on the time at which

confidence is queried.

Dynamic signatures of decision confidence

Static models have conceptualized confidence as the probability of being correct

(Kepecs et al., 2008; Maniscalco and Lau, 2012; Sanders et al., 2016). Intuitively, when

option A has a high (vs low) probability of being the correct answer, the model will give

response A with high (vs low) confidence. One advantage of such a formalization is that it

predicts three qualitative signatures of confidence (Sanders et al., 2016). A limitation of such

an account is that this framework is inherently static, and therefore does not take time into

account. To resolve this, we relied instead on a dynamic evidence accumulation framework

to probe these different signatures across time. We are not the first to account for confidence

within an evidence accumulation framework (Kiani et al., 2014; Moran et al., 2015; Pleskac

and Busemeyer, 2010; Ratcliff and Starns, 2013; Zylberberg et al., 2016). Previous work has

conceptualized immediate confidence as the probability of being correct given evidence and

elapsed time (Kiani et al., 2014; Kiani and Shadlen, 2009; Zylberberg et al., 2016). Choices

are formed when evidence reaches a fixed decision threshold, and both choice and

confidence are quantified when this threshold is reached. As shown in Figure 1B, such a

model does not predict an interaction between evidence strength and choice accuracy, a

prediction at odds with many existing datasets. To account for this, in the current approach

we allowed the evidence to continue accumulation following boundary crossing. By

quantifying confidence across time, our model was able to account for these discrepancies.

Specifically, our model was able to explain signature 1, an interaction between evidence

strength and choice accuracy, in the immediate condition, as seen in behavioral data, by

assuming that immediate confidence is quantified with a small temporal delay from the

choice, suggesting a brief refractory period (Marti et al., 2015; Pashler, 1994). Thus, an

important novel insight of the current work is that some form of post-decision evidence

accumulation is necessary, even to explain immediate confidence reports.

Previous modelling work has unraveled boundary conditions of this first diagnostic

signature, the interaction between evidence strength and choice accuracy. Model simulations

have shown that this interaction disappears if stimuli are only probabilistically related to

choices (Adler and Ma, 2018), and if the static model has knowledge about evidence

strength on the single-trial level (Rausch and Zehetleitner, 2019). Remarkably, however, no

previous work has unraveled the role of time in this signature. The current work overcomes

this limitation, by incorporating the notion of confidence reflecting the probability of being

correct within a dynamic evidence accumulation framework. Our model simulations show that

at the time of the boundary crossing, confidence increases with evidence strength for both

corrects and errors, whereas the interaction effect only emerges with time. Crucially, this

pattern was also observed in the empirical data. This has important consequences for

studies relying on this signature to identify brain regions coding for decision confidence

(Kepecs et al., 2008; Kepecs and Mainen, 2012).

Post-decision processing terminates using an evidence-based stopping rule

Post-decision evidence accumulation has been proposed as a mechanism explaining

confidence (Moran et al., 2015; Pleskac and Busemeyer, 2010; Van Den Berg et al., 2016)

and biases in confidence judgments (Navajas et al., 2016). It remains unclear, however, how

such a model decides when to stop accumulating evidence. The decision process itself is

believed to terminate once the accumulated evidence reaches a decision boundary.

Likewise, our data favored an evidence-based stopping rule (i.e., the sampling process

terminates when a certain level of evidence has been reached), while it was incompatible

with a time-based stopping rule (i.e., sampling terminates after a certain time has elapsed).

Only the evidence-based rule could explain increased confidence with high evidence

volatility. Intuitively, high evidence volatility increases (immediate) confidence because the

injection of noise in the decision process speeds up RTs (Zylberberg et al., 2016), and faster

RTs are associated with higher confidence. The model with an evidence-based stopping rule

for delayed confidence judgments similarly predicts higher confidence with high evidence

volatility, because the noise again pushes the decision variable towards a certain level of

evidence (i.e., a second bound). This effect does not appear with a time-based stopping rule,

however, because the noise only affects the evidence (i.e., how fast is a certain level of

evidence reached), but not the timing of post-decision accumulation itself. Therefore, using a

time-based stopping rule the effects of evidence volatility are averaged out, and no

differences in confidence are predicted. In sum, a second important insight of the current

work is that human participants also use an evidence-based stopping rule in delayed

confidence judgments.

Sources of post-decisional evidence accumulation

The hypothesis that confidence is affected by post-decisional evidence accumulation

has evoked a strong interest in neural signatures of post-decisional processing (Fleming et

al., 2018; Murphy et al., 2015; Yu et al., 2015). For example, recent neuroimaging work has

linked this process of post-decision evidence accumulation to a specific neural signal in the

EEG (Murphy et al., 2015), that is sensitive to fine-grained levels of decision confidence

(Boldt and Yeung, 2015; Desender et al., 2019b). One question that has been largely

overlooked so far, is what kind of information determines post-decisional evidence

accumulation. For example, external information could drive post-decisional evidence

accumulation (Fleming et al., 2018). Alternatively, internal sources, such as additional

evidence from the sensory buffer (Resulaj et al., 2009) or resampling from memory

(Vlassova and Pearson, 2013), could determine such accumulation. To contrast these two

possibilities, the current work featured conditions with and without additional external

evidence during the post-decisional period. Interestingly, confidence judgments were highly

similar between these two conditions. This demonstrates that, at least in our current

experimental design, participant benefit exclusively from internal resampling of the earlier

evidence, whereas continued external sampling has no measurable influence. This does not

imply that post-decisional evidence will never play a role in confidence. For example, in a

recent study that de-correlated the strength of pre-decisional and post-decisional evidence

(i.e., so that sometimes post-decision evidence was highly informative when pre-decision

evidence was not), external post-decisional evidence did have a reliable effect on confidence

(Fleming et al., 2018). Presumably, the correlational structure of post- versus pre-decision

evidence determines whether sampling continues or not.

Conclusion

The current work quantified confidence within an evidence accumulation framework

as the probability of being correct given the accumulated evidence up until that point. Both

model and data showed that three key signatures of confidence depend on the point in time

when confidence is queried. Finally, post-decision confidence reports were best explained by

an evidence-based stopping rule.

Acknowledgments

The authors want to thank Peter R Murphy for advice on the modeling and Niklas

Wilming, Cristian Buc Calderon and Konstantinos Tsetsos for fruitful discussions. This

research was supported by an FWO [PEGASUS]² Marie Skłodowska-Curie fellowship

(12T9717N, to K.D.), DFG grants DO 1240/2-1 and DO 1240/3-1 (to. T.H.D.), and a

Research Council-Flanders grant G010419N (to K.D and T.V.).

 Methods

 Participants

Thirty participants (two men; age: $M = 18.5$, $SD = .78$, range 18 – 21) took part in

return for course credit. All participants reported normal or corrected-to-normal vision and

were naïve with respect to the hypothesis. All but four participants were right handed. Four

participants were excluded because their performance was not different from chance level in

the immediate condition (as assessed by a binomial test). All data have been made publicly

available via the Open Science Framework and can be accessed at osf.io/83x7c. Non-

overlapping analyses of these data have been published elsewhere (Desender et al., 2019a).

Ethics Statement

Participants provided written informed consent before participation. All procedures

were approved by the local ethics committees at Ghent University.

Stimuli and apparatus

Stimuli were presented in white on a black background on a 20-inch LCD monitor with

a 75 Hz refresh rate, using Psychtoolbox3 (Brainard, 1997) for MATLAB (The MathWorks,

Natick, MA). Random moving white dots were drawn in a circular aperture centered on the

fixation point. The current experiment was based on code provided by Kiani and colleagues

(2013). Parameter details can be found there.

Procedure

Participants completed a random dot motion task in which they additionally rated the

confidence in their response. Each experimental trial started with a fixation dot for 750ms

followed by random dot motion that lasted until a response was made, with a maximum of 3

seconds. On each trial, the proportion of coherently moving dots was either 0, .05, .1, .2 or

.4. In each block, there was an equal number of leftward and rightward movement. In the low

evidence volatility condition, this proportion was the same on every timeframe within a trial.

In the high evidence volatility condition, the proportion of coherently moving dots was on

each timeframe sampled from a Gaussian distribution with mean equal to the generative

distribution of that trial and a standard deviation of .256. There were three different

interrogation conditions. In the *immediate* condition, participants jointly indicated their

response and their level of confidence. The numerical keys '1', '2', '3', '8', '9', and '0' on top

of the keyboard mapped onto 'sure left', 'probably left', 'guess left', 'guess right', 'probably

right', and 'sure right', respectively. In the *delayed blank* condition, participants indicated their

response (left or right) by pressing 'c' or 'n' with the thumbs of their right and left hand,

respectively. Then, a blank screen was presented for 1s, after which the following six

confidence options were presented on the screen: 'sure correct', 'probably correct', 'guess

correct', 'guess error', 'probably error', 'sure error' (reversed order for half of the participants).

Participants had unlimited time to indicate their level of confidence by pressing one of the

corresponding numerical keys (i.e., '1', '2', '3', '8', '9', and '0') on top of the keyboard. The

delayed extra evidence condition was similar to the delayed blank condition, except that now

1s of continued random motion was presented during the 1s interval between the response

and the confidence judgment. The continued motion had the same direction, the same

motion coherence and the same level of evidence volatility as the pre-decisional motion.

The entire experiment comprised twelve blocks of sixty trials each, including three

practice blocks. In the first practice block, participants only indicated the direction of the dots

(i.e., no confidence), and each trial stopped after a response was given. Only coherence

levels of .2 and .4 were presented. When participants made an error, the message 'Error'

was shown on the screen for 750ms. This block was repeated until mean accuracy exceeded

75%. The second practice block was similar, except that now the full range of coherence

levels was used. This block was repeated until mean accuracy exceeded 60%. Block three

served as a last practice block, and was identical to the main experiment. No more feedback

was presented from this block on. Each participant then performed three blocks of each

interrogation condition, with the specific order depending on a Latin square. Before the start

of block seven and block ten (i.e., start of a new interrogation condition), participants

performed eight practice trials with .4 coherence using the procedure of the subsequent

block, to get familiarized with the response keys. These eight trials were repeated until

accuracy exceeded 75%. After each block, participants received feedback about their

performance in that block, including mean response time on correct trials, mean accuracy,

and the absolute value of the correlation between accuracy and confidence. Participants

were motivated to maximize these three values.

Statistical analyses

Behavioral data and model predictions were analyzed using mixed regression

modeling. This method allows analyzing data at the single-trial level. We fitted random

intercepts for each participant; error variance caused by between-subject differences was

accounted for by adding random slopes to the model. The latter was done only when this

significantly increased the model fit. RTs and confidence were analyzed using linear mixed

models, for which F statistics are reported and the degrees of freedom were estimated by

Satterthwaite's approximation (Kuznetsova et al., 2014). Accuracy was analyzed using

logistic linear mixed models, for which X^2 statistics are reported. Model fitting was done in R

(R Development Core Team, 2008) using the lme4 package (Bates et al., 2015).

Drift diffusion model

Fitting. Drift diffusion model parameters were estimated using hierarchical Bayesian

estimation within the HDDM toolbox (Wiecki et al., 2013). The HDDM uses Markov-chain

Monte Carlo (MCMC) sampling, which generates full posterior distributions over parameter

estimates, quantifying not only the most likely parameter value but also uncertainty

associated with each estimate. Due to the hierarchical nature of the HDDM, estimates for

individual subjects are constrained by group-level prior distributions. In practice, this results

in more stable estimates for individual subjects. For each model, we drew 100.000 samples

from the posterior distribution. The first ten percent of these samples were discarded as

burn-in and every second sample was discarded for thinning, reducing autocorrelation in the

chains. Group level chains were visually inspected to ensure convergence, i.e. ruling out

sudden jumps in the posterior and ruling out autocorrelation. Additionally, all models were

fitted three times, in order to compute the Gelman-Rubin R hat statistics (comparing within-

chain and between-chain variance). We checked and confirmed that all group-level

parameters had an R hat between 0.98-1.02, showing convergence between these three

instantiations of the same model. Because individual parameter estimates are constrained by

group-level priors, frequentist statistics cannot be used because data are not independent.

The probability that a condition differs from another can be computed by calculating the

overlap in posterior distributions.

When fitting the data (choices and reaction times), both drift rate (v) and decision

bound (a) were allowed to vary as a function of coherence and evidence volatility, whereas

non-decision time (ter) was fixed across conditions. According to our hypothesis, the effect of

evidence volatility will be expressed in the within-trial variability parameter (σ). When fitting

the DDM this parameter is fixed (i.e., to .1 in the Ratcliff Diffusion model or to 1 in the

currently used HDDM). Because σ is a scaling factor, after fitting the model, we next scaled

drift rate, decision bound and within-trial variability for each condition so that decision bound

was equal to 1. Thus, this is approach allows estimating within-trial variability. Note that

under this approach, an implicit assumption is that the decision bound does not differ

between the different conditions.

Simulations. Using the estimates obtained from the HDDM fit, predictions were

generated using a random walk approximation of the diffusion process (Tuerlinckx et al.,

2001). This method simulates a random walk process that starts at z*a (here, *z* was an

unbiased starting point of .5) and stops once the integrated evidence crosses 0 or a. At each

time interval *t*, a displacement Δ occurs with probability *p* and a displacement -Δ with

probability *1-p.* Both quantities are given in equation (1).

$$p = \frac{1}{2}\left(1 + \frac{\mu\sqrt{\tau}}{\sigma}\right)$$

(1)

$$\Delta = \sigma\sqrt{\tau}$$

Drift rate is given by μ, and within-trial variability is given by σ. In all simulations τ was

set to 1e-4. In order to construct the heat map representing the probability of being correct

shown in Figure 1, 300.000 random walks without absorbing bounds were generated, with

drift rates sampled from a uniform distribution between zero and one. This assured sufficient

data points across the relevant part of the heat map. Subsequently, the average accuracy

was calculated for each (response time, evidence) combination, based on all trials that had a

data point for that (response time, evidence) combination. Smoothing was achieved by

aggregating over evidence windows of .01 and τ windows of 2.

To generate model fits for choices and RTs and model predictions for confidence, we

used the parameters obtained by the HDDM fit. For each combination of coherence levels,

within-trial evidence volatility and interrogation condition, we simulated 5000 trials per

participant. Both immediate and delayed confidence predictions were obtained by reading

out the probability of being correct from the heat map given RT and evidence, conditional on

the response given. Model predictions about confidence were then converted from a

continuous scale to a categorical scaling by dividing them into three (immediate condition) or

six (delayed condition) equal-sized bins. For the immediate condition, confidence predictions

were obtained without any post-decision accumulation. In the adapted version confidence

was quantified with a small temporal delay of .1s; other (small) values led to very similar

results. For delayed confidence predictions with a time-based stopping rule, after reaching

the decision bound, the random walk process continued for one second (i.e., the duration of

the ITI) plus the average response speed of confidence judgments in that condition minus

the non-decision time of that condition. For the evidence-based stopping rule, after the

evidence crosses *a*, an evidence-based stopping rule (i.e., a horizontal boundary) was

placed at *a + a*.125* and 0 (or similarly at –a*.125 and *a* if evidence initially crossed 0), and

confidence was quantified at the time when the continued evidence accumulation crossed

this second-order threshold. To project model confidence onto the same scale as human

confidence, we used a linear transformation.

585   **Supplementary Materials**

Diagnostic confidence signatures with an evidence-based stopping rule.

Model predictions about the diagnostic confidence signatures for the delayed

condition were quantified using a time-based stopping rule. Here, we report that these

predictions were highly similar when using an evidence-based stopping rule instead. First,

this model also predicted that confidence scales with coherence, $F(4,225) = 84.43$, $p < .001$,

as well as the interaction between coherence and choice accuracy, $F(4,225) = 232.31$, $p <$

$.001$, reflecting increasing confidence with coherence levels for correct trials (linear contrast:

$p < .001$) and decreasing for error trials (linear contrast: $p < .001$). Second, this model also

predicted a monotonic positive relation between confidence and mean accuracy, $b = .06$,

$t(129) = 20.42$, $p < .001$.
