Abstract

Filamentous fungal and oomycete plant pathogens that invade by direct penetration through the leaf epidermal cell wall, cause devastating plant diseases. Towards non-adapted filamentous pathogens, plant pre-invasive immunity is highly effective and durable. Pre- and post-invasive immunity correlates with the formation of evolutionarily conserved and cell-autonomous cell wall structures, named papillae and encasements. Yet, it is still unresolved how papillae/encasements are formed and whether these defense structures prevent pathogen ingress. Here we show that in *Arabidopsis*, the two closely related members of the SYP12 clade of syntaxins (PEN1 and SYP122) are indispensable for the formation of papillae and encasements. Moreover, loss-of-function mutants were hampered in pre-invasive immunity towards a range of taxonomically distinct non-adapted filamentous pathogens, underlining the versatility and efficacy of this defense. Complementation studies using SYP12s from the early diverging land plant, *Marchantia polymorpha*, showed that the SYP12 clade immunity function has survived 470 My of independent evolution. These results suggest that ancestral land plants evolved the SYP12 clade to provide a broad and durable pre-invasive immunity to facilitate

30 their life on land, and pave the way to a better understanding of how adapted pathogens overcome

31 this ubiquitous plant defense strategy.

Introduction

In response to attack by filamentous pathogens, plants assemble localized pre-invasive papillae and

post-invasive encasements at sites of attempted cell entry (Fig. S1A-B) (Hückelhoven and Panstruga,

2011). These conserved defense structures are thought to contain antimicrobial cargo that provide

effective and durable immunity against diverse filamentous pathogens, and fossil evidence suggests

that they appeared very early in the evolution of land plants (O'Connell and Panstruga, 2006; Krings

et al., 2007; Overdijk et al., 2016; Hansen and Nielsen, 2018). However, although their frequent

association with resistance to non-adapted pathogens is well-known, direct evidence that

papillae/encasements contribute to immunity to these pathogens is still lacking. The discovery that

the secretory syntaxin PEN1 is required for the timely formation of papillae to hamper penetration by

non-adapted powdery mildew fungi highlighted the key role played by membrane trafficking in plant

immunity (Collins et al., 2003; Nielsen et al., 2012; Nielsen and Thordal-Christensen, 2013). PEN1

(also referred to as syntaxin of plants 121 or SYP121) is a Qa-SNARE primarily located at the plasma

membrane. On the other hand, the ARF-GEF, GNOM, regulates recycling of PEN1 between the

plasma membrane and the *trans*-Golgi network, where it is needed for a fast papilla response (Nielsen

et al., 2012). Accordingly, PEN1 is thought to mediate membrane fusion both at the plasma membrane

and the *trans*-Golgi network. The ROR2 syntaxin in barley is orthologous to PEN1 (Collins et al.,

2003), suggesting that the pre-invasive immunity dependent on PEN1 or ROR2 was present in early

angiosperms before the divergence of monocots and dicots, spanning some 140 million years (My)

of evolution. Accumulation of GFP-PEN1 in response to attack by *Blumeria graminis* f.sp. *hordei*

(*Bgh*) is also seen for ROR2 in barley and highlights a likely conserved functionality in plant defense

against powdery mildews (Bhat et. al, 2005). The strong extracellular accumulation of GFP-PEN1

signal localized to fungal attack sites can be explained by the secretion of extracellular vesicles, also

known as exosomes, which accumulate to a high degree in both papillae and encasements (An et al.,

2006; Meyer et al., 2009; Nielsen et al., 2012). While exosomes are suggested to contain miRNAs

directed against the invading pathogen, their topology makes it difficult to associate syntaxin

functionality (Meyer et al., 2009; Hansen and Nielsen, 2018). GFP-PEN1 is generally considered a

valid exosomal marker yet the biogenesis pathway of PEN1-labeled exosomes remains unclear

(Rutter and Innes, 2017). Loss of PEN1 or ROR2 delays, but does not prevent, the papilla response upon attack by the barley powdery mildew fungus *Bgh* in *Arabidopsis* or barley, respectively (Assaad et al., 2004; Böhlenius et al., 2010). In contrast, the deposition of encasements around developing intracellular pathogenic structures (IPS) is unaffected by the loss of PEN1 (Wen et al., 2011; Nielsen et al., 2017). Furthermore, although many other filamentous pathogens also penetrate directly through the plant epidermal cell wall, the PEN1 and ROR2-specific immunity appears dedicated towards the haustorium-forming powdery mildew and rust fungi (Collins et al., 2003; Jarosch et al. 2005; Lipka et al., 2005; Loehrer et al., 2008; Hoefle et al., 2009). Thus, the molecular mechanisms underlying papilla/encasement formation, as well as their role in general plant invasive immunity towards other filamentous pathogens, remain obscure.

PEN1 and ROR2 belong to the SYP12 clade of secretory syntaxins, which first appears in embryophytes and is conserved in all land plants (Slane et al., 2017). Consequently, the appearance of the SYP12 clade was proposed to play a key role in the terrestrialization of plants by enabling specialization of the secretory pathway (Sanderfoot, 2007). This is supported by the fact that four of the five SYP12 clade members in *Arabidopsis* function in specialized forms of polarized secretion, these being pre-invasive immunity towards powdery mildew fungi (PEN1), root hair tip growth (SYP123), and pollen tube tip growth (SYP124 and SYP125) (Collins et al., 2003; Slane et al., 2017; Ichikawa et al., 2014). Recently, PEN1 and SYP122, which is the closest homologue of PEN1, were suggested to mediate distinct but complementary secretory pathways during vegetative plant growth (Waghamare la., 2018). Indeed, *syp122* mutants show an altered cell wall composition but in contrast to *pen1* mutants there is no effect on the pre-invasive immunity towards *Bgh* (Assaad et al., 2004). Interestingly, the *pen1 syp122* double mutant is autoimmune, developing a severe necrotic phenotype and accumulating the defense hormone salicylic acid (Assaad et al., 2004; Zhang et al., 2007, 2008). However, prior to the onset of necrosis, *pen1 syp122* double mutant plants are indistinguishable from wild-type plants. This underlines that PEN1 and SYP122 likely mediate a highly specialized form of secretion whereas general secretion relies on the evolutionarily ancient Qa-SNARE SYP132 (Park et al., 2018; Karnahl et al., 2018). Moreover, the development of necrotic lesions in *pen1 syp122* double mutant plants are markedly delayed when the accumulation of salicylic acid is hampered (Zhang et al., 2007, 2008). Together, this suggests that the *pen1 syp122* double mutant autoimmune phenotype results from activation of nucleotide-binding leucine-rich repeat receptors (NLRs), immune sensors that recognize pathogen effectors, directly or indirectly, which

leads to a programmed cell death response (Schultz-Larsen et al., 2018; Wang et al., 2019a; Wang et al., 2019b; Horsefield et al., 2019; Wan et al., 2019). The autoimmune phenotype shows that while PEN1 and SYP122 have separate functions in the pre-invasive immunity towards *Bgh*, the two syntaxins also share a so far unresolved function which is likely related to defense and not general development.

Here we show that the formation of papillae and encasements in *Arabidopsis* requires either of the two SYP12 clade members, PEN1 and SYP122, because plants lacking both syntaxins are completely devoid of both types of defense structure. We show that PEN1 and SYP122 provide invasive immunity not only against the powdery mildew *Bgh* but also against distantly-related filamentous pathogens that invade host epidermal cells, namely the fungus *Colletotrichum destructivum* and the oomycete *Phytophthora infestans*. Complementation studies show that SYP12A from *Marchantia polymorpha* functions and behaves like SYP122 in *Arabidopsis*, thereby revealing a conserved ancestral mechanism. We conclude that papilla and encasement formation is mediated by a specialized function of the SYP12 clade of syntaxins and that these defense structures correlate with a broad and effective resistance towards filamentous pathogens that penetrate the epidermal cell layer. Moreover, we suggest that early land plants evolved the SYP12 clade of secretory syntaxins to provide a durable immunity that helped plants move on to land and possibly shape mutualistic plant-fungus interactions.

Results

The role of PEN1 in timely papilla deposition in response to *Bgh* attack prompted us to investigate the involvement of other syntaxins in invasive immunity, notably SYP122 that shares a currently unknown function with PEN1. This shared function is apparent from the autoimmune lesion-mimic phenotype of the *pen1 syp122* double mutant (Assaad et al., 2004; Zhang et al., 2007, 2008). Yet, during the first ~two weeks of growth, the *pen1 syp122* mutant develops no visible symptoms, leaving a short window in which to study the interaction with *Bgh* before the onset of necrosis. From analysis of unattacked plants, we found that the *pen1 syp122* mutant developed spontaneous callose deposits despite of the wild-type like appearance (Fig 1A-B). Callose is a polysaccharide (beta-1,3-glucan) secreted in response to various biotic and abiotic stresses and is a major constituent of papillae and

encasements. Although the deposition of callose is not required to block the penetration event by *Bgh*

per se, it serves as a reliable visual marker for easy detection of papillae and encasements (Ellinger

et al., 2013). We found that in response to attack by *Bgh*, plants lacking PEN1 and SYP122 were

unable to form papillae at sites of unsuccessful attack by fungal appressoria, as visualized by detection

of callose (Fig 1C-D). Surprisingly, while the appressorial germtube did not induce a papilla response

in *pen1 syp122* mutants, we observed large callosic deposits induced by the non-invasive primary

germ tube, which were not observed in any other genetic background (Fig 1D, F-G and Fig S1A).

Thus, SYP122 seems to play a complementary role to PEN1 in papilla formation. However, despite

being unable to form a papilla at the attempted entry site, the *pen1 syp122* mutant remains capable of

generating focused depositions of callose elsewhere and seems to be highly sensitive to signals

released by *Bgh*.

In response to a successful penetration attempt by *Bgh*, the host cell initiates post-invasive immunity

where an encasement forms as an extension of the pre-existing papilla (Fig. S1B). The encasement

expands and, eventually, completely encloses the IPS and likely prevents the pathogen from

proliferating. Previous observations have shown that although *pen1* mutants display a delayed papilla

formation response to attack by *Bgh*, these plants seem unaffected in their ability to form encasements

when successfully penetrated (Assaad et al., 2004; Wen et al., 2011; Nielsen et al., 2017). In contrast

to our observations of unsuccessful penetrations sites, the successful penetration of *pen1 syp122* cells

induced a strong but diffuse, unfocused accumulation of callose at the fungal entry site (Fig. 1E-G).

Interestingly, we did not observe any encasement-like structures. Instead, the callosic deposits in the

pen1 syp122 mutant were superficial and did not extend inwards from the outer surface of the host

cell following the growing IPS. This would suggest that the penetration event triggers a strong callose

response but formation of the encasement is dependent on a functional overlap of the PEN1 and

SYP122 syntaxins.

The lack of papillae and encasements in the *pen1 syp122* mutant, prompted us to investigate the

secretion of exosomes in response to *Bgh* attack. We speculated that the plant exosomal marker

TET8-GFP (TETRASPANIN 8), which accumulates in response to attack by *Botrytis*, would also

accumulate in response to attack by *Bgh* (Boavida et al., 2013; Cai et al., 2018). In unattacked

epidermal cells of wild-type plants, we found TET8-GFP to localize mainly on the plasma membrane

(Fig. 2A). TET8-GFP signal focally accumulated in response to attack by *Bgh* (Fig. 2B). In unattacked

epidermal cells of the *pen1 syp122* mutant, the TET8-GFP localization was similar to that seen in

wild-type plants whereas attack by *Bgh* did not induce focal accumulation of TET8-GFP (Fig. 2C-

D). Thus, the general localization of TET8-GFP was not affected in the *pen1 syp122* mutant. Only in the event of fungal attack where TET8-GFP is transported to the infection site in wild-type plants, this did not occur in the double mutant, supporting the idea that PEN1 and SYP122 play a specific role in invasive immunity.

We noticed that the spontaneous callose deposits formed in the lesion-mimic *pen1 syp122* mutant, made it difficult to compare pre- and post-invasive immunity responses during attack by *Bgh*. Furthermore, successful penetration of epidermal cells in *pen1 syp122* by *Bgh* resulted in a fast-developing cell death response which could, arguably, compromise encasement formation. To overcome the difficulties of working with the *pen1 syp122* mutant, we made use of the partially rescued triple mutant, *fmo1 pen1 syp122* (Fig. S1C; Zhang et al., 2008). Flavin-dependent-monooxygenase1 (FMO1) enables *Arabidopsis* plants to generate N-hydroxypipecolic acid, which plays a central role in pathogen-inducible plant immunity (Hartman *et al.*, 2018). Similar to introducing a number of SA-signalling mutations, the loss of FMO1 clearly relieves the downstream effects of the *pen1 syp122* lesion-mimic mutant macroscopically. However, importantly, these mutations do not affect pre-invasive immunity towards *Bgh*, thereby clearly separating the two phenotypes mechanistically (Zhang et al., 2007 and this work). Moreover, *fmo1 pen1 syp122* plants did not display the large callosic deposits induced by the non-invasive primary germ tube. In response to attack by *Bgh*, we found that *fmo1* control plants formed papillae at the site of attack which were indistinguishable from wild-type as visualized by detection of callose (Fig. 3A-C and Fig. S2A-D). Instead, plants lacking PEN1 and SYP122 were unable to form discrete papillae at sites of unsuccessful fungal attack. To support these findings, we also tested the ability of these plants to accumulate papillary H_2O_2 in response to attack by *Bgh* using DAB (Thordal-Christensen *et al.*, 1997). Similar to the staining of callose, the accumulation of H_2O_2 is used as a convenient marker of the defense structure. In accordance with observations on callose deposition, we found that *fmo1 pen1 syp122* plants failed to accumulate papillary H_2O_2 (Fig. 3D-F). Thus, these results confirmed that plants lacking PEN1 and SYP122 failed to form papillae at sites of attack by *Bgh*.

Similar to the papilla response, we found that *fmo1* mutants reacted like wild-type plants in response to successful penetration by *Bgh*, as visualized by the detection of callose encasements around the IPS (Fig. 4A-C and Fig. S2E-H). In stark contrast to this, *fmo1 pen1 syp122* plants were unable to create an encasement around the developing IPS when penetrated by *Bgh*. To rule out the possibility that the lack of these defense structures is due to a host cell death response, dead cells stained by Trypan blue were excluded from our observations. Similar to our observations on papilla formation,

we also assessed the ability of these plants to accumulate H_2O_2 in response to successful penetration

by *Bgh* using DAB. We found that in *fmo1 pen1 syp122* plants, successful penetration by *Bgh* induced

a diffuse, superficial accumulation of H_2O_2 but we did not observe encasement-like structures (Fig.

4D-E). This supported our finding that plants lacking PEN1 and SYP122 failed to form encasements

at sites of attack. As SYP122 appears to have a significant, albeit less important, role in papilla and

encasement formation, we wondered if the complete absence of these defense structures would lead

to an increase in penetration frequency as compared to the delayed papilla response described for the

pen1 mutant. We found a significant increase in fungal penetration frequency on *fmo1 pen1 syp122*

plants when compared to *pen1* single and *fmo1 pen1* double mutant plants (Fig. 4F). This supports

our previous finding of a minor, but significant PEN1-independent contribution to pre-invasive

immunity that relates to proper formation of the encasement (Nielsen et al., 2017). Taken together,

these observations show that the *Bgh*-induced formation of papillae and encasements at attack sites

is dependent on a functional overlap between the PEN1 and SYP122 syntaxins.

To further dissect the overlapping functions of PEN1 and SYP122 in immunity, we tested host cell

responses to another, non-adapted fungal pathogen, namely *C. destructivum* (an ascomycete fungal

pathogen causing alfalfa anthracnose disease). The initial invasion strategy of *C. destructivum* is very

similar to that of *Bgh* (Latunde-Dada et al., 1997). Nevertheless, while host cell responses include

papilla formation, the highly effective pre-invasive immunity of *Arabidopsis* towards non-adapted

Colletotrichum species such as *C. destructivum* does not require PEN1 (Shimada et al., 2006; Yang

et al., 2014). Moreover, attack by *C. destructivum* did not induce accumulation of GFP-PEN1, GFP-

SYP122 or TET8-GFP at sites of attempted penetration (Fig. S3A-C). Nonetheless, we found that

plants lacking both PEN1 and SYP122 showed a dramatic decrease in the ability to form papillae at

sites of unsuccessful penetration (Fig. 5A-C). In contrast to *Bgh*, the host cell response to penetration

by *C. destructivum* only rarely resulted in the formation of a detectable encasement. Nevertheless,

penetrated host cells did respond by accumulating callose in and around the site of penetration. In

fmo1 pen1 syp122, the responses varied from no detectable callose to a faint diffuse accumulation of

callose at the penetration site (Fig. 5D-E and Fig. S3D-F). Moreover, the lack of host cell responses

correlated with a remarkable increase in penetration frequency by *C. destructivum* on *fmo1 pen1*

syp122 plants (Fig. 5F and Fig. S3F-G). Thus, invasive immunity towards *C. destructivum* requires a

syntaxin function shared by PEN1 and SYP122 and this correlates with the lack of defense structure

formation in response to attack.

Finding that PEN1 and SYP122 facilitate a pre-invasive immunity that extends to a fungal pathogen
other than powdery mildews, we speculated that this immunity could be a general defense mechanism
effective against an even wider range of direct penetrating filamentous pathogens. One such pathogen
is *P. infestans* (the potato blight pathogen), which, as an oomycete, is thought to have evolved
completely independently of true fungi (Lévesque, 2011). Similar to the above observations for *C.*
destructivum, pre-invasive immunity towards *P. infestans* in *Arabidopsis* does not rely on a functional
PEN1 (Lipka et al., 2005). Instead, Rodriguez-Furlán et al. (2016) reported that loss of the root-hair
specific SYP123 affects the penetration rates by *P. infestans*. However, SYP123 was suggested to
regulate rhizobacterial priming of induced systemic resistance and is unlikely to be directly involved
in the pre-invasive response in leaves. We observed that attempted penetration by *P. infestans* did not
lead to accumulation of either GFP-PEN1, GFP-SYP122 or TET8-GFP at the site of attack (Fig. S4A-
C). As expected, penetration attempts by *P. infestans* incited papilla formation in all genotypes,
except for *fmo1 pen1 syp122* (Fig. 6A-C). Successful penetration by *P. infestans* was often followed
by host cell death. Nevertheless, we found that host cells expressing PEN1 and/or SYP122 could
initiate a strong accumulation of callose and form an encasement around the IPS. In the *fmo1 pen1*
syp122 triple mutant, the penetrated cell, as well as neighboring cells, responded with a diffuse callose
accumulation but encasement of the IPS was not seen (Fig. 6D-E). Similar to our observations with
C. destructivum, *fmo1 pen1 syp122* plants displayed elevated penetration frequencies when attacked
by *P. infestans* (Fig. 6F and Fig. S4D). Surprisingly, we could not detect an increase in penetration
events by *P. infestans* in the *syp123* mutant, even when in combination with *pen1*. Taken together,
these findings show that PEN1 or SYP122 are required for papilla and encasement responses, which
mediate immunity towards these phylogenetically distant, non-adapted filamentous pathogens.
Moreover, it is striking that the functionality of PEN1 and SYP122 in immunity does not correlate
with the ability of these syntaxins to visibly accumulate at attack sites.

PEN1 and SYP122 belong to the SYP12 clade of secretory syntaxins, which evolved during plant
terrestrialization and is conserved in all land plants (Sanderfoot, 2007; Slane et al., 2017). To evaluate
whether the immunity function of the SYP12 clade is also evolutionarily conserved among land
plants, we investigated the response of the early diverging land plant *Marchantia* to attack by non-
adapted filamentous pathogens. Consistent with previous findings, the germinating spores of *Bgh*
were not able to properly differentiate a penetration hypha or appressorium on *Marchantia* thalli (Fig.
S5A; Takikawa et al., 2013). Similarly, most spores of *P. infestans* germinating on *Marchantia*
seemed unable to identify a host cell and direct an attack. Nonetheless, occasional sites of attempted

and successful penetrations were detected, to which the host cell responded by forming papillae and encasement-like defense structures, respectively (Fig. 7A and Fig. S5B). Thus, neither *Bgh* nor *P. infestans* were suitable for studying non-host interactions in *Marchantia*. In contrast, *C. destructivum* spores germinated and developed characteristic darkly melanized appressoria on the thallus surface. In response to attack, *Marchantia* epidermal cells formed callose-containing papillae similar to those found in *Arabidopsis* (Fig. 7B). However, we never detected successful penetration of *Marchantia* cells by *C. destructivum*. A previous report that the *Marchantia* syntaxin MpSYP13B accumulates in response to colonization by *P. palmivora* prompted us to test whether candidate MpSYPs also accumulate in response to *C. destructivum* (Carella et al., 2018). However, despite inducing papillae, attack by *C. destructivum* did not induce focal accumulation of any of the four MpSYPs tested (Fig. 7C-F; Kanazawa et al., 2016). Thus, the cellular responses of *Marchantia* to *C. destructivum* were similar to those that we observed in *Arabidopsis*.

In contrast to PEN1 and SYP122 in *Arabidopsis*, MpSYP12A seems to be essential in *Marchantia*, thereby eliminating the possibility for studying pre-invasive immunity in knock-out lines (Kanazawa et al., 2020). Instead, to evaluate whether the immunity function of the SYP12 clade is evolutionarily conserved among land plants, we introduced GFP-fused versions of the two *Marchantia* SYP12s (*i.e.* MpSYP12A and MpSYP12B) into the *Arabidopsis pen1 syp122* mutant. GFP-MpSYP12A fully suppressed the necrotic and dwarfed phenotypes of *pen1 syp122* plants, while GFP-MpSYP12B only partially suppressed these phenotypes (Fig. S5C-D). In contrast, expression of either of the two SYP13 clade members, MpSYP13A and MpSYP13B, failed to rescue the *pen1 syp122* mutant. This suggests that MpSYP12A shares the PEN1/SYP122 overlapping function and that MpSYP12B does so incompletely. Because MpSYP12A complements the growth phenotype of *pen1 syp122* at the macroscopic level, we decided to test how these plants react to attack by *Bgh*. We found that MpSYP12A completely, and MpSYP12B partially, restored both papilla and encasement responses (Fig. 8A-B and Fig. S6, S7). As explained above, the papillary accumulation of GFP-PEN1 in response to attack by *Bgh* is also seen for ROR2 in barley and highlights a likely conserved functionality in plant defense against powdery mildews (Bhat et. al, 2005). In contrast, neither GFP-SYP122 nor the two GFP-MpSYP12s accumulated in papillae at sites of attempted penetration (Fig. 8C and Fig. S8). However, all the tested SYPs accumulated in the encasement matrix at sites of successful penetration (Fig. 8D and Fig. S9). Interestingly, pre-invasive immunity towards *Bgh* was not restored by GFP-MpSYP12A. Instead, the penetration frequency of *Bgh* was similar to that of

plants expressing GFP-SYP122 (Fig. 8E). Thus, MpSYP12A resembles SYP122, and not PEN1, both in its localization and functionality. In support of this, GFP-MpSYP12A fully restored immunity towards both *P. infestans* and *C. destructivum* (Fig. 8F and Fig. S10A-B). Also when tested with the adapted filamentous pathogens *Golovinomyces orontii* and *Colletotrichum higginsianum*, penetration frequencies were similar to plants expressing PEN1 and SYP122 (Fig. S10C-D). As described for PEN1 and SYP122, focal accumulation of GFP-MpSYP12A or GFP-MpSYP12B was not observed at unsuccessful attack sites by either *C. destructivum* or *P. infestans* (Fig S11). Taken together, these results reveal a conserved SYP12 clade functionality that has survived 470 My of independent evolution. Moreover, our findings suggest that the PEN1-specific immunity towards powdery mildew fungi evolved at a later stage of land plant evolution.

Discussion

We have revealed a highly conserved role for the SYP12 clade of plant syntaxins in mediating the formation of pre- and post-invasive defense structures and provide immunity to highly diverged filamentous pathogens. *Arabidopsis* plants lacking both PEN1 and SYP122 were incapable of forming papillae and encasements in response to attack by the non-adapted pathogens *Bgh*, *C. destructivum* and *P. infestans*, as based on staining for callose and H_2O_2, resulting in highly elevated penetration frequencies. Instead, these plants would respond to attack with diffuse and unfocused accumulations of callose and H_2O_2. It is noteworthy that although the *pen1 syp122* double mutant lacks these defense structures, epidermal cells are still able to respond to pathogen-derived signals in a polarized fashion as seen in the response to the non-penetrative primary germ tube of *Bgh*. This underlines that neither the general ability to secrete callose, generate H_2O_2, nor the underlying mechanism needed for polarized secretion are dependent on PEN1 and SYP122. Instead, we suggest that the PEN1/SYP122-dependent papillae and encasements are defense structures that enable a focused secretion, specifically aimed at blocking the ingress of filamentous pathogens. In support of this, knock-down of StSYR1 in potato, a homolog of PEN1, results in reduced papilla formation in response to *P. infestans* (Eschen-Lippold et al., 2012). A more indirect role of syntaxins in pre-invasive immunity is the regulation of rhizobacterial priming of induced systemic resistance by the root-hair specific SYP123 (Rodriguez-Furlán et al. 2016). The induction of systemic resistance could affect the speed by which PEN1/SYP122 dependent papillae/encasements form in response to attack. However, as we failed to see an effect of SYP123, we could not pursue this question further. We are

unsure of the reason for this discrepancy between our results and those reported by Rodriguez-Furlán

et al. (2016), but we speculate that differences in the soil composition and microbiome could play a

role in this. Instead, we have shown here that loss of papillae/encasements correlates with the loss of

general pre-invasive immunity. Yet, it is difficult to explain how these cell wall depositions would

prevent invasion by pathogens secreting cell wall degrading enzymes. Also, we find it unlikely that

accumulation of callose, H_2O_2, syntaxins or even TET8 would have a direct effect on the pathogen.

This is supported by our observations that neither PEN1, SYP122 nor TET8 accumulate in response

to attack by *C. destructivum* or *P. infestans*, despite the formation of papillae. Instead we support the

idea that papillae and encasements serve as defense structures that contain a mixture of exosomes,

toxic metabolites and/or antimicrobial enzymes and peptides that mediate immunity (Kwon et al.,

2008). It is likely that these cargo molecules are delivered in a PEN1 and SYP122 dependent manner

to the site of attack to form papillae/encasements and thus prevent pathogen ingress.

Previous studies on the interaction between *Arabidopsis* and *Bgh* have revealed that pre-invasive

immunity correlates with the timely formation of papillae. This fast response likely requires the

recycling of papilla material in a process involving PEN1 and GNOM (Nielsen et al., 2012). In

contrast, although SYP122 also locates to the plasma membrane and interacts with the same SNARE

partners as PEN1, *syp122* mutants show a wild-type response to *Bgh* (Assaad et al., 2004; Pajonk et

al., 2008). Previous studies have shown that PEN1 and SYP122 mediate the secretion of distinct cargo

subsets, which may explain their differing contributions to pre-invasive immunity (Waghmare et al.,

2018). Based on the work presented here, it is now evident that PEN1 and SYP122 functionally

overlap in the formation of papillae and encasements. In contrast to SYP122, PEN1 therefore serves

two functions in pre-invasive immunity. The first mediates a fast mobilization of papilla material

specifically in response to powdery mildew attack, while the second function is shared with SYP122

and contributes to a more general papilla/encasement response to filamentous pathogens (Fig. 9). As

suggested previously, the powdery mildew-specific function is likely related to the ability of PEN1

to shuttle between the plasma membrane and *trans*-Golgi network, which is less prominent for

SYP122 (Hansen and Nielsen, 2018; Nielsen and Thordal-Christensen, 2012; Nielsen and Thordal-

Christensen, 2013). Consequently, PEN1 could function at the *trans*-Golgi network, receiving

vesicles from the plasma membrane that mediate the fast GNOM-dependent recycling of papilla

material, warding off the powdery mildew fungus. We envisage that the PEN1 function shared with

SYP122 is at the plasma membrane, where either of the two syntaxins receive the membrane material

and vesicular cargo required for papilla/encasement formation. In contrast to the fast-acting, PEN1 dependent papilla response explained above, the slow-forming papilla uses either PEN1 or SYP122 already present at the site of attack in the plasma membrane and does not necessitate a fast recycling of the syntaxin itself. This second function could therefore help to explain why PEN1 and SYP122 do not accumulate at sites of attack by *C. destructivum* and *P. infestans* although both syntaxins clearly mediate pre-invasive immunity. The pathway that delivers cargo for the slow-forming papilla is also to be involved in delivering cargo for the encasement, because the formation of neither is affected by the lack of PEN1. Therefore, we speculate that the differences in papilla content based on observations of GFP-PEN1, GFP-SYP122 and TET8-GFP, result from the involvement of distinct pathways for delivering cargo vesicles to the papilla. Alternatively, as the accumulation of some papilla cargos are triggered by only a subset of pathogens, the host cell might be able to differentiate the response according to the attacker. Nonetheless, these pathways share a common requirement for PEN1 or SYP122 to mediate vesicle fusion with the plasma membrane at pathogen attack sites. In addition, because some spores fail to penetrate, even in the complete absence of papillae and encasements, pre-invasive immunity towards filamentous pathogens could also involve other molecular pathways that act independently of PEN1 and SYP122. In this regard, pre-invasive immunity mediated by PEN2 and PEN3, as well as the resistance gained by loss of MLO, are of particular interest, since both pathways seem to function independently of PEN1 (Lipka et al., 2005; Stein et al., 2006; Kuhn et al., 2017). Yet, it remains to be elucidated if these pre-invasive immunity pathways also function independently of SYP122.

The SYP12 clade of plant secretory syntaxins is thought to have evolved during colonization of the land and is conserved in all land plants so far examined (Slane et al., 2017). Because terrestrialization presented enormous challenges to plants, the SYP12 clade was suggested to have acquired specialized roles in secretion needed to facilitate this transition (Sanderfoot, 2007). This is consistent with the previously identified functions of PEN1 (powdery mildew resistance), SYP123 (root hair tip growth) and, SYP124 and SYP125 (pollen tube tip growth) all being associated with specialized forms of polarized secretion (Collins et al., 2003; Slane et al., 2017; Ichikawa et al., 2014). In addition, PEN1 promotes K^+ uptake by direct interaction with the RYxxWE motif found in a subset of Kv channels (Karnik et al., 2017). However, powdery mildews, roots hairs and pollen tubes did not exist until long after the onset of plant terrestrialization. Also, the interaction motifs needed for Kv channel interaction, is restricted to vascular plants (Karnik et al., 2017). Therefore, this knowledge gives little

insight into the original function of the SYP12 clade. Our discovery that SYP12A from *Marchantia* can complement SYP122, but not PEN1, in *Arabidopsis* reveals a conserved syntaxin functionality spanning 470 My of independent evolution. In accordance with this, MpSYP12A showed a localization behavior identical to that of SYP122. Therefore, the functionality of the original SYP12 clade syntaxins is likely to have been similar to that of MpSYP12A and SYP122. At a later stage of plant evolution, PEN1 has acquired an additional specialized function in powdery mildew resistance, which could explain its distinctive subcellular localization (Nielsen and Thordal-Christensen, 2012; 2013). Interestingly, in *Marchantia*, MpSYP12A locates to the plasma membrane and seems vital for cell plate formation whereas MpSYP12B locates to a type of oil body unique to liverworts (Kanazawa et al., 2016; 2020). This indicates yet another functional specialization of the SYP12 clade similar to what has occurred in *Arabidopsis*.

We suggest that MpSYP12A and SYP122 represent the original SYP12 clade functionality in land plants, which provides a highly conserved and effective broad-spectrum immunity towards filamentous pathogens. Before plant terrestrialization, the land was already colonized by filamentous fungi that were able to degrade cell walls and to utilize living or dead plant tissue as a nutrient source (Chang et al., 2015). Recent findings suggest that even before terrestrialization, plants used nucleotide-binding leucine-rich repeat receptors (NLRs) to activate their defense responses (Gao et al., 2018). Activation of plant NLRs leads to a fast, programmed cell death response, which does not provide immunity against fungi living on dead or dying plant tissue (Wang et al., 2019a; Wang et al., 2019b; Horsefield et al., 2019; Wan et al., 2019). Instead, the papilla/encasement defense structures would have conferred an effective defensive barrier against attack by the early saprophytic filamentous fungi already present on the land. Moreover, it is generally accepted that plant colonization of the land was aided by, or dependent on, mycorrhiza-like fungi (Pirozynskjk et al., 1975; Redecker et al., 2000; Heckman et al., 2001). These mutualistic interactions are thought to have resulted from ancestral land plants being able to 'tame' early saprophytic filamentous fungi (Chang et al., 2015; Berbee et al., 2017). In this context, hyphal encasement may have provided a tool for plants to restrict and manipulate the intracellular growth of these fungi. We envisage that the SYP12 syntaxins enabled early land plants to regulate fungal entry and colonization, and that over time this lead to the mutually beneficial interactions that facilitated terrestrialization.

Adapted filamentous pathogens are able to overcome pre-invasive immunity in their respective host-plants, but not in other plant species. Our finding that plants could rely on a common membrane trafficking pathway to block pathogen entry should lead to new insights into how successful

pathogens defeat this immunity by means of effector proteins (Jones et al., 2016). A future goal will

be to identify the membrane trafficking targets of such effectors and to exchange those between hosts

and non-hosts to generate a pre-invasive immunity that pathogens cannot overcome.

Acknowledgments

We would like to thank Takashi Ueda for providing *Marchantia polymorpha* lines and cDNA clones of MpSYPs (Kanazawa et al., 2016). Also to Bent Jørgen Nielsen and Christina Dixelius for providing *Phytophthora infestans*. We are grateful to Christine Strullu-Derrien for fruitful

discussions on the evolution of plant-fungus interactions and to Hans Thordal-Christensen, Stefan Wenkel, Sebastian Marquardt, Morten Petersen and Pierre-Marc Delaux for useful comments on the manuscript. **Funding:** This project was supported by grants from Villum Foundation (M.E.N, VKR023502), Independent Research Fund Denmark, Technical and Production Sciences (M.E.N., 6111-00524B) and Agence Nationale de la Recherche (R.J.O., ANR-17-CAPS-0004-01). **Author contributions**: M.E.N. and R.J.O. designed the experiments; H.M.R., M.L. and M.E.N. conducted and analyzed the experiments; M.E.N. prepared the manuscript with contributions from all authors. **Competing interests:** The authors declare no competing interests. **Data and materials availability:** All materials are available on request.

Materials and Methods

<u>Plant, fungal and oomycete growth</u>

Plants of *Arabidopsis thaliana* and *Marchantia polymorpha* (Tak-1) were grown at 21°C, with 8 h of light at 125 micro Einstein $s^{-1}m^{-2}$ per day. All mutant plant lines were reported previously (Collins et al., 2003; Assaad et al., 2004; Zhang et al., 2008; Rodriguez-Furlan et al., 2016). The barley powdery mildew fungus, *Bgh* (*B. graminis* f.sp. *hordei*, isolate C15) and Arabidopsis powdery mildew, *G. orontii*, were propagated on barley and *Arabidopsis*, respectively. *C. destructivum* isolate LARS 709 and *C. higginsianum* isolate IMI 349063A was cultured on Mathur's medium containing glucose (2.8 g), $MgSO_4$-$7H_2O$ (1.22 g), KH_2PO_4 (2.72 g), Oxoid Mycological peptone (2.18 g) and agar (30 g) in 1 liter of deionised water at 25 °C in the dark. The *P. infestans* (field isolate 2017-DK-31-03 and SW1_A1) was cultured on rye sucrose (2%) agar supplemented with β-sitosterol (50mg/L), Pimaricin (10mg/L) and Ampicillin (100mg/L) at 18 °C in the dark (Tzelepis et al., 2020).

<u>Infection studies</u>

Spores from *Bgh* and *G.orontii* were blown evenly onto the leaves of 4-week-old *Arabidopsis* plants and kept at 21°C. For *Colletotrichum*, spores were harvested in water from a 7-10 day old culture. Spores were adjusted to a final concentration of 5 x 10^5 or 1 x 10^6 spores ml^{-1} and sprayed evenly onto the leaves of 5-week-old *Arabidopsis* plants. Following inoculation, the plants were sealed inside plastic bags and kept at 21°C. Zoospores of *P. infestans* were released from sporangia by addition of cold water and incubation at 4°C for 90 min. The zoospore suspension was diluted to 5 x 10^5 or 1 x

10^6 spores/ml and added to the abaxial side of attached leaves from 4-week-old *Arabidopsis* plants.

The leaves were kept in a closed Petri dish on water-soaked filter paper at 21°C.

For scoring penetration success, leaf material was Trypan blue–stained at 24 h post inoculation for

Bgh or *P. infestans*, and 72 h post inoculation for *C. destructivum* (Keogh et al., 1980). For each leaf

a minimum of 50 interactions were counted. Penetration was determined by the presence of a

developing IPS inside epidermal cells using light microscopy. To avoid the possibility that cells

undergoing programmed cell death would be restricted in their encasement response to IPS, these

cells were excluded from our observations based on Trypan blue staining. Callose staining was

performed using 0.01% Aniline blue in 1 M glycine [adjusted to pH 9.5 using NaOH] and visualized

by UV epifluorescence. All experiments were repeated a least three times with similar results. Data

from the individual studies described above represent discrete variables since it was recorded whether

or not a certain event had taken place (e.g., whether or not a spore caused penetration). Consequently,

these data were analysed by logistic regression, assuming a binomial distribution (corrected for over-

dispersion when present) (Collet, 1991). Hypotheses were rejected at $P<0.001$. All data were analysed

by PC-SAS (release 9.4; SAS Institute, Cary, NC).

<u>Constructs</u>

Open reading frames (ORFs) of PEN1 and SYP122 were amplified by PCR from cDNA and the

amplified products were subcloned into pDONR221 (Invitrogen). Along with pENTR clones

containing MpSYP12A and MpSYP12B (Kanazawa et al., 2016), PEN1 and SYP122 were cloned

into pUBIN-GFP, and PEN1 also in pB7WGR2, (Karimi et al., 2002; Grefen et al., 2010) destination

vectors according to the manufacturer's instructions. For cloning, the following primers were used:

attB1-for   GGGGACAAGTTTGTACAAAAAAGCAGGCTAC

attB2-rev   GGGGACCACTTTGTACAAGAAAGCTGGGTC

B1-PEN1-for   AAAAAGCAGGCTACATGAACGATTTGTTTTCC

B2-PEN1-rev   AGAAAGCTGGGTCTCAACGCAATAGACGCCTTGC

B1-SYP122-for   AAAAAGCAGGCTACATGAACGATCTTCTCTCC

B2-SYP122-rev   AGAAAGCTGGGTCTTAGCGTAGTAGCCGCCG

<u>Fluorescent protein and callose detection using confocal microscopy</u>

Samples were examined using a 63× water immersion lens mounted on a Leica CLSM TCS SP5 confocal microscope. For detection and localization of the fluorophores and stains, GFP were excited at 488 nm and detected between 500 and 520 nm. Aniline blue-stained callose was excited at 405 nm and detected between 435 nm and 485 nm. Imaging data were collected at the Center for Advanced Bioimaging (CAB) Denmark, University of Copenhagen. Projections of serial confocal sections, image overlays, and contrast enhancement were performed using image processing software (GIMP 2).

Figure 1

Figure 1. PEN1/SYP122 are required for papilla and encasement responses to *Bgh*. (A, B) Spontaneous callose depositions in leaves of 3 week old plants. (C-G) Accumulation of callose in response to *Bgh* attack at appressoria (arrows) and primary germ tube (arrowheads) in (C-D) non-penetrated cells and (E-G) and cells following a successful penetration. Open arrows point to the developing IPS. (G) Same as F, but optical section taken below the point of entry. * marks cells with cell death response. Bars = 20 µm.

Figure 2

Figure 2. PEN1/SYP122 are required for accumulation of TET8-GFP in response to *Bgh*. (A-D) Localization of TET8-GFP in (A, C) resting epidermal cells and in (B, D) response to *Bgh* attack (arrows) and initiation of the IPS (dotted line). Bars = 10 µm.

Figure 3

Figure 3: PEN1/SYP122 are required for papilla responses towards *Bgh*. (A-B, D-E) Accumulation of callose (A-B) or H$_2$O$_2$ (D-E) in response to *Bgh* attack (arrows) at non-penetrated attack sites. Bars = 10 µm. (C, F) Frequency of papillae in response to *Bgh* in non-penetrated cells as detected by staining for callose (C) or H$_2$O$_2$ (F). (C, F) All values are mean ±SD (n = 5 leaves per genotype). Different letters indicate significantly different values at P ≤ 0.001 estimated using logistic regression.

Figure 4

Figure 4: PEN1/SYP122 are required for encasement responses towards *Bgh*.
(A-B, D) Accumulation of callose (A-B) or H_2O_2 (D) in response to *Bgh* attack (arrows)
at penetrated attack sites. Open arrows point to the developing IPS. Bars = 10 μm.
(C, E) Frequency of encasements in response to *Bgh* in penetrated cells as detected
by staining for callose (C) or H_2O_2 (E). (F) Frequency of penetrations by *Bgh*. (C, E-F)
All values are mean ±SD (n = 5 leaves per genotype). Different letters indicate
significantly different values at P ≤ 0.001 estimated using logistic regression.

Figure 5

Figure 5: PEN1/SYP122 are required for pre-invasive immunity towards *C. destructivum.* (A,B and D,E) Accumulation of callose in response to *C. destructivum* attack (arrows) at (A and B) non-penetrated and (D and E) penetrated attack sites. Open arrows point to the developing IPS. Bars = 10 μm. (C) Frequency of papillae in response to *C. destructivum* in non-penetrated cells. (F) Frequency of penetrations by *C. destructivum.* (C, F) All values are mean ±SD (n = 4 leaves per genotype). Different letters indicate significantly different values at P ≤ 0.001 estimated using logistic regression.

Figure 6

Figure 6: PEN1/SYP122 are required for pre-invasive immunity towards *P. infestans*. (A-B, D-E) Accumulation of callose in response to *P. infestans* attack (arrows) at (A and B) non-penetrated and (D and E) penetrated attack sites. Open arrows point to the developing IPS. Bars = 10 μm. (C) Frequency of papillae in response to *P. infestans* in non-penetrated cells. (F) Frequency of penetrations by *P. infestans*. (C, F) All values are mean ±SD (n = 4 leaves per genotype). Different letters indicate significantly different values at P ≤ 0.001 estimated using logistic regression.

Figure 7

Figure 7. Responses in *Marchantia polymorpha* to filamentous pathogens. (A-B) Accumulation of callose in *Marchantia* in response to attack (arrows) by (A) *P. infestans* or (B) *C. destructivum* in non-penetrated cells. Note that the frequency of *P. infestans* spores that attack a host-cell is very low. (C-F) mCitrine signal of MpSYPs in response to attack (arrows) by *C. destructivum* in non-penetrated cells. We did not observe any successful penetrations in *Marchantia* by *C. destructivum*. Bars=10 μm.

Figure 8

Figure 8: *Marchantia* **syntaxins rescue papilla and encasement responses in**
Arabidopsis. (A, B) Accumulation of callose in response to attack (arrow) by *Bgh* in
(A) non-penetrated- and (B) penetrated cells. Open arrow points to the developing
IPS. (C, D) Localization of MpSYP12A and PEN1 in response to attack (arrows) by
Bgh in (C) non-penetrated- and (D) penetrated cells. Bars = 10 µm. (E ,F) Frequency
of penetration by (E) *Bgh* and (F) *P. infestans*. All values are mean ±SD (n = 4 leaves
per genotype). Different letters indicate significantly different values at P ≤ 0.001
estimated using logistic regression.

Figure 9

Fig. 9. Simplified model of syntaxin mediated secretion. The bulk secretion of proteins that follow a conventional secretory pathway through the *trans*-Golgi Network (TGN), are delivered to the plasma membrane (PM) using mainly SYP132. In response to attack by filamentous pathogens, papillary cargo is received at the PM by PEN1 or SYP122 and secreted in between the plant cell wall (CW) and the PM. Pre-invasive immunity against powdery mildew fungi requires a second function of PEN1. This function occurs at the TGN and enables for a recycling of cargo that facilitates a fast papilla response. Formation of the general papilla and the encasement relies on a pathway that does not require PEN1. The components of this second pathway are still unsolved, but could include the TGN as part of a specialization of the conventional secretory pathway.
