Running head: Plastid gene expression is necessary to activate chloroplast quality control.

Significance summary: Reactive oxygen species such as singlet oxygen accumulate in the chloroplast and signal to induce chloroplast degradation, cell death, and changes in nuclear gene expression. We have identified two proteins involved in plastid gene expression that are required to transmit these signals, PPR30 and mTERF9, suggesting that plastid gene expression is necessary to activate chloroplast quality control pathways.

Key words: chloroplast, reactive oxygen species, singlet oxygen, cellular degradation, transcription, photosynthesis

Summary:

Chloroplasts constantly experience photo-oxidative stress while performing photosynthesis. This is particularly true under abiotic stresses that lead to the accumulation of reactive oxygen species (ROS). While ROS leads to the oxidation of DNA, proteins, and lipids, it can also act as a signal to induce chloroplast degradation, cell death, and nuclear gene expression. Although the mechanisms behind ROS signaling from chloroplasts remain mostly unknown, several genetic systems have been devised in the model plant *Arabidopsis* to understand their signaling properties. One system uses the *plastid ferrochelatase two* (*fc2*) mutant that conditionally accumulates the ROS singlet oxygen ($^1O_2$) leading to chloroplast degradation and eventually cell death. Here we have mapped three mutations that suppress chloroplast degradation in the *fc2* mutant and demonstrate that they affect two independent loci (*PPR30* and *mTERF9*) encoding chloroplast proteins predicted to be involved in post-transcriptional gene expression. Mutations in either gene were shown to lead to broadly reduced chloroplast gene expression, impaired chloroplast development, and reduced chloroplast stress signaling. $^1O_2$ levels were uncoupled to chloroplast degradation, however, suggesting that these mutations also affect ROS signaling pathways. In the wild type background, *ppr30* and *mTERF9* mutants were also observed to be less susceptible to cell death induced by excess light stress. Together these results suggest that plastid gene expression (or the expression of specific plastid genes) is a necessary prerequisite for chloroplasts to activate $^1O_2$ signaling pathways to induce chloroplast degradation and/or cell death.

Introduction

Chloroplasts (differentiated plastids that perform photosynthesis) are required for the photoautotrophic lifestyle of plants, and by extension, most of life on the planet. While photosynthesis in these organelles is an essential process for most plants, it is also a problematic one. Photosynthesis itself involves highly reactive chemistry that leads to the formation of reactive oxygen species (ROS) such as singlet oxygen ($^1O_2$) at photosystem II (PSII) and superoxide and hydrogen peroxide (H_2O_2) at photosystem I (PSI) (Asada 2006). Although a certain amount of ROS can be produced even under ideal conditions, many common environmental stresses (e.g., excess light (Triantaphylides *et al.* 2008), drought (Chan *et al.* 2016), salinity (Suo *et al.* 2017), and pathogen attack (Lu and Yao 2018)) can drastically increase ROS production in the chloroplast.

Although chloroplasts still maintain small genomes containing ~100 genes encoding proteins, rRNA's, and tRNA's, the remaining ~3,000 proteins in chloroplasts are encoded in the nucleus (van Wijk and Baginsky 2011). Thus, chloroplasts need to be in constant communication with the rest of the cell to control their own proteome, ROS accumulation, and ROS damage under dynamic environments. This communication is achieved, in part, by the ROS themselves. Although ROS can lead to oxidative damage of proteins, lipids, and metabolites, they can also act as signaling molecules leading to chloroplast degradation, cell death, or changes in nuclear gene expression (Foyer 2018). Therefore, it appears chloroplast ROS can play two roles; as a stress signal to prepare a cell for oxidative damage and as information about the changing external environment to allow the cell (and plant) make the necessary biochemical and physiological changes to maintain efficient photosynthesis and to survive.

Exactly how ROS made in the chloroplast can have specific signaling abilities is still unclear. In *Arabidopsis*, it is known that $^1O_2$ can signal independently of other chloroplast ROS such as H_2O_2 (op den Camp *et al.* 2003) and that $^1O_2$ has the ability to initiate cellular degradation and nuclear gene reprogramming (Ramel *et al.* 2013, Wagner *et al.* 2004, Woodson 2019). These studies have mostly involved $^1O_2$ accumulating mutants of *Arabidopsis* such as *plastid ferrochelatase II* (*fc2*), which conditionally accumulates the photosensitizer tetrapyrrole intermediate protoporphyrin IX (Proto) at dawn under diurnal light cycling conditions (Woodson *et al.* 2015). This accumulation of Proto in the light leads to a burst of chloroplast $^1O_2$ that initiates chloroplast degradation and eventual cell death. A large forward genetic screen for suppressors of the *fc2* cell death phenotype identified 24 *ferrochelatase two suppressors* (*fts*) mutants affecting 17 loci. Some of these mutations could reverse the *fc2* chloroplast degradation phenotype without affecting $^1O_2$ accumulation. This suggested that such cellular degradation was not due to the toxicity of $^1O_2$, but rather a genetic signal. One such mutant, *pub4-6* (*a.k.a. fts29*), was demonstrated to affect Plant U-Box 4, a cytoplasmic ubiquitin E3 ligase. This led to a model whereby cellular ubiquitination machinery is involved in targeting damaged chloroplasts for turnover (Woodson 2016). Such a chloroplast quality control mechanism may permit a cell to maintain a healthy population of chloroplasts under stressful conditions.

How $^1O_2$ is able to initiate such a signal remains unknown. Due to its extremely short half-life (0.5–1 ms in cells (Ogilby 2010)), $^1O_2$ is unlikely to travel further than a few hundred nanometers while chloroplasts are usually 5-10 microns across. Thus, the $^1O_2$ produced within a single chloroplast is unlikely to exit and must generate secondary signals, possibly in the form of oxidized proteins, lipids, or metabolites. Executor 1 (EX1) (Wagner *et al.* 2004), a previously described chloroplast $^1O_2$ signaling protein involved in transmitting retrograde signals to the nucleus to modulate gene expression, does not appear to be involved in chloroplast quality control; *ex1* mutations do not effect chloroplast degradation in *fc2* mutants (Woodson *et al.* 2015). Therefore, to further understand the chloroplast quality control pathway and to identify additional genes involved, we have returned to the genetic *fc2-1* suppressor screen.

To bulk map the original *fts* mutations, the *fts* mutants were backcrossed to the *fc2-1* parent and the F2 plants exhibiting an *fts* phenotype were pooled for genomic DNA isolation, followed by library preparation, and next generation sequencing (Woodson *et al.* 2015). Shore-mapping analysis was used to identify the EMS-generated SNPs in these lines in addition to their proximity to the causative allele (Schneeberger *et al.* 2009). This resulted in the rough-mapping of each mutation to a 1-3 mb region and the identity of the 10-30 SNPs in those regions. In this study, we continued with the analysis of three additional *fts* mutant lines, and demonstrate that they contain mutant alleles of *PPR30* (*fts3* and *fts38*) (a member of the pentatricopeptide repeat (PPR) containing protein family) or *mTERF9* (*fts32*) (a member of the "mitochondrial" transcription termination factor (mTERF) protein family).

Both PPR and mTERF proteins are predicted to be involved in post-transcriptional gene expression. Although the chloroplast genome normally contains fewer than 100 genes encoding proteins, rRNA's, and tRNA's, their expression is essential for chloroplast development and photosynthesis (Yu *et al.* 2014). Chloroplasts encode one of their three RNA polymerases, the plastid encoded RNA polymerase (PEP), but gene expression is primarily controlled by nuclear-encoded factors influencing post-transcriptional regulation (Barkan and Goldschmidt-Clermont 2000).

Here, we demonstrate that PPR30 and mTERF9 are chloroplast nucleoid-localized proteins and their absence leads to broadly impaired plastid gene expression and chloroplast development.

Furthermore, mutations in *PPR30* and *mTERF9* block $^1O_2$ signals that regulate chloroplast degradation, cell death, and retrograde signaling to the nucleus. Together our results suggest that chloroplast gene expression is a necessary prerequisite in transmitting the $^1O_2$ signal to initiate chloroplast quality control pathways.

Results

<u>Mapping of three *fts* alleles; *fts3*, *fts32*, and *fts38*.</u>

Previously, eight *fts* alleles were mapped and shown to represent four loci involved in chloroplast quality control (Woodson *et al.* 2015). To find additional components in this pathway, we chose three more *fts* mutants for further study (Table S1). As shown in Fig. 1a, while *fc2-1* mutants fail to green in 6h light/18h dark diurnal cycling conditions, *fc2-1 fts3*, *fc2-1 fts32*, and *fc2-1 fts38* survive. Under these conditions, cell death was suppressed in the double mutants as illustrated by reduced trypan blue staining (Fig. 1b). Like many of the other *fts* mutants isolated (Woodson *et al.* 2015), these three mutants also accumulated significantly less chlorophyll than the *fc2-1* parent in constant light conditions (Fig. 1c) and had pale phenotypes (Fig. 1a).

To determine if chloroplasts in these lines are signaling due to photo-oxidative stress, the expression of six marker genes for damaged chloroplasts (Woodson *et al.* 2015), chloroplast $^1O_2$ (op den Camp *et al.* 2003), and general stress (Baruah *et al.* 2009) were monitored in these lines by RT-qPCR. We harvested four day old seedlings one hour after subjective dawn, which is when such stress genes are maximally activated in *fc2-1* mutants (Woodson *et al.* 2015). In 6h light/18h dark diurnal cycling conditions, expression of all six genes were significantly increased in *fc2-1* seedlings compared to wt (Fig. 1d). In the double mutants, however, no single gene was significantly induced compared to wt. Next, we monitored the expression of the same genes in permissive constant light conditions when *fc2-1* mutants do not experience wholesale chloroplast degradation and cell death (Fig. 1e). Under these conditions, four of these marker genes were significantly repressed in *fc2-1 fts32* and *fts2-1 fts38* compared to *fc2-1*. Together, these results indicate that there was no initiation of a stress signal from chloroplasts in these double mutant lines.

Together, the phenotypes of these three suppressors were similar to the previously mapped *fts4/37*, *fts1*, and *fts8/16/24/30* mutations that are mutant alleles of *ppi1, ppi2*, and *chlH*, respectively (Woodson *et al.* 2015). PPI1 and PPI2 are plastid outer envelope-localized protein importers, while CHLH is an essential component of the Proto Mg-chelatase complex at the first committed step of the chlorophyll branch of the chloroplast-localized tetrapyrrole biosynthesis pathway. To investigate the possibility that *fts3*, *fts32*, and *fts38* also contained mutations affecting plastid protein import and/or tetrapyrrole synthesis, we used our sequencing data to determine if any of the ~1,000 SNP's in each line was in the coding sequence of a gene involved in either process. Our cross-referencing of genes involved in tetrapyrrole biosynthesis (Tanaka *et al.* 2011) or plastid protein import (Jarvis and Lopez-Juez 2013) failed to find any putative mutant alleles in the three *fts* mutant lines. As such, we concluded that these three mutants may be affecting a different process related to chloroplast quality control.

The causative mutations in *fts3* and *fts38* had been mapped to the same region on the north arm of chromosome three (6.2-9.2 mb) suggesting that they may contain mutant alleles of the same gene (Woodson *et al.* 2015). A comparison of genes with SNPs in their coding regions identified *AT3g23020* as the only gene mutated in both *fts3* and *fts38* (Fig. 2a). *AT3g23020* is predicted to encode PPR30, belonging to the PPR family of organelle proteins that bind specific RNA

transcripts and can regulate their expression by influencing stability, translation, splicing, and editing (Barkan and Small 2014). *fts3* and *ft38* have mutations leading to the amino acid substitutions D765N and G821R, respectively. A protein alignment suggests that these residues are conserved among dicots, while D765 and G821R reside within PPR motif 16 or just outside PPR motif 17, respectively (Fig. 2b). Interestingly, null mutations in *AT3g23020* have been observed to be embryo lethal, suggesting that *AT3g23020* encodes an essential gene (Savage *et al.* 2013). Therefore, it is possible that *fts3* and *fts38* encode weak loss-of-function alleles.

To confirm if *fts3* and *fts38* are allelic, we performed crosses between the two lines and tested the *fts* phenotype of the resulting F1 generation. In agreement with *fts3* and *fts38* being allelic, F1 seedlings from the cross were similar to both *fc2-1 fts3* and *fc2-1 fts38* and survived 6h light/18h dark diurnal cycling conditions (Fig. 2c). On the other hand, *fc2-1 fts3* or *fc2-1 fts38* backcrossed to *fc2-1* resulted in F1 seedlings with an *fc2-1* phenotype (seedlings failed to green in 6h light/18h dark diurnal cycling conditions) confirming that both mutations are recessive. A genomic fragment containing the *AT3g23020* coding sequence and promoter was cloned into a binary vector and transformed into *fc2-1 fts3* and *fc2-1 fts38*. In the T3 generation of both lines, this wt copy of *AT3g23020 r*estored the parent *fc2-1* phenotype (the seedlings failed to green in 6h light/18h dark diurnal cycling conditions (Fig. 2d) and cell death was observed through trypan blue staining (Figs. 2e, S1a and b)). Together, these results clearly indicate that the mutations in *AT3g23020* were responsible for the *fts* phenotypes of *fc2-1 fts3* and *fc2-1 fts38*.

As *fts3* and *fts38* may affect gene expression in the chloroplast, we scanned the mapped region of *fc2-1 fts32* (chromosome five 22.2mb – 24.9mb) for mutations in genes encoding chloroplast proteins. In this region, we found that *At5g55580/mTERF9* contained a mutation leading to a premature stop codon at residue R368 (Fig. 2f). *mTERF9* has previously been shown to encode a chloroplast-localized mTERF protein that is involved in chloroplast gene expression (Robles *et al.* 2015). To determine if this mutation was responsible for the *fts32* phenotype, we took two approaches. First, we transformed *fc2-1 fts32* mutant plants with a *35S::mTERF9-YFP* construct that produces a wt mTERF9 protein with a C-terminal YFP tag. This construct was able to fully complement the *fts32* phenotype leading to cell death (Figs. 2e, S1a and b) and the failure to green under 6h light/18h dark diurnal cycling conditions (Fig. 2d). At the same time, we obtained a second allele of *mTERF9* containing a T-DNA in its fourth intron leading to a loss-of-function phenotype (Fig. 2f) (Robles *et al.* 2015). This allele was crossed into the *fc2-1* background and tested for an *fts* phenotype. As expected, this allele phenocopied the *fts32* mutation and *fc2-1 mterf9* was able to green under 6h light/18h dark diurnal cycling conditions and avoid cell death (Figs. 2d and e, S1a and b). Together, these results confirm that the *mTERF9* nonsense mutation in *fc2-1 fts32* is the causal mutation leading to suppression of chloroplast degradation.

AT3g23020 and mTERF9 are localized to chloroplasts

To determine the subcellular localization of PPR30 and mTERF9, we transiently produced these proteins with C-terminal YFP tags in *Nicotine benthamiana* leaves and monitored YFP localization using a laser scanning confocal microscope. As shown in Fig. S2, PPR30-YFP and mTERF9-YFP clearly overlapped with chlorophyll autofluorecence in the leaf mesophyll cells indicating that these two proteins are localized to chloroplasts. This result confirmed an earlier report that mTERF9 is exclusively localized to chloroplasts and not mitochondria (Babiychuk *et al.* 2011). Interestingly, with both constructs, a speckle-like pattern of YFP signal was also observed in these chloroplasts. Such a pattern indicates a localization to chromatin-dense nucleoid

complexes within these organelles and is consistent with a role in gene expression (Yagi and Shiina 2014).

fc2-1 fts32 and *fc2-1 fts38* mutants have delayed chloroplast development

Because the *fts3/38* and *fts32* mutations lead to reduced chlorophyll accumulation in the *fc2-1* background (Fig. 1c), we hypothesized that these mutants may have impaired chloroplast function or development. One hallmark of such defects is the down-regulation of photosynthesis associated nuclear genes (PhANGs) by retrograde signals from developing chloroplasts (Chan *et al.* 2015). Using RT-qPCR, we monitored the expression of four PhANGs (*LHCB1.2*, *LHCB1.2*, *CA1*, and *RBCS2b*) in 4-day-old seedlings grown in constant light. Consistent with these lines having delayed chloroplast development, the expression of at least two PhANGs were significantly down-regulated compared to *fc2-1* in each of the three double mutants. In the case of *fc2-1 fts38*, all four genes were significantly repressed (Fig 3a).

Next, we attempted to visualize the ultrastructure of cotyledon mesophyll chloroplasts. Four day old seedlings grown in both constant light and 6h light/18h dark diurnal cycling conditions were fixed and imaged by transmission electron microscopy (TEM). As was expected from the phenotypes, *fc2-1* chloroplasts were degraded under 6h/day light diurnal cycling conditions (Fig. 3b). Such chloroplasts have poorly defined envelopes, a loss of organized thylakoid structures, and large plastoglobules (Woodson *et al.* 2015). Conversely, chloroplasts in *fc2-1 fts32*, *fc2-1 fts38*, and wt were intact. Interestingly, under constant light conditions, *fc2-1 fts32* and *fc2-1 fts38* chloroplasts were also irregularly shaped, contained fewer internal membranes, were significantly smaller, and constituted a smaller portion of the cell compared to wt and *fc2-1* (Figs. 3c and S3). Unlike wt chloroplasts, a short-day length did not appear to reduce chloroplast size or development in *fc2-1 fts32* and *fc2-1 fts38* mutants. Together, these results indicate that mutations in *mTERF9* and *PPR30* lead to chloroplasts that avoid degradation, are insensitive to light shifts, but are impaired in their development.

fts3, *fts32*, and *fts38* are defective in plastid gene expression

As PPR30 and mTERF9 are chloroplast-localized proteins with predicted roles in gene expression, we tested if the *fc2-1 fts3*, *fc2-1 fts32*, or *fc2-1 fts38* mutants have altered levels of plastid-encoded transcripts. RT-qPCR analysis was used to assess the steady state levels of seven transcripts primarily transcribed by the plastid-encoded polymerase (PEP) (*spa, psbB, psaJ, rbcL, trnEY*), the nuclear-encoded polymerase (NEP) (*rpoB*), or both (*clpP*) (Yagi and Shiina 2014). Unlike the other protein-encoding genes, *trnEY* is a polycistronic transcript encoding the tRNA species for glutamate and tyrosine. Glutamyl-tRNA is of special interest, as it is the starting precursor to tetrapyrrole (and chlorophyll) biosynthesis in addition to protein synthesis (Tanaka *et al.* 2011). Compared to *fc2-1*, the levels of two or four PEP transcripts were significantly reduced in *fc2-1 fts3* and *fc2-1 fts32*, respectively (Fig. 4). In the case of *fc2-1 fts38,* all five transcripts were significantly reduced including *trnEY*. Unlike the PEP transcripts, the NEP transcripts were unresponsive or increased in the double mutants compared to *fc2-1*. Together, these results suggest that the *fts3/38* and *fts32* mutations lead to a broad defect in PEP-directed gene expression.

fts3, *fts32*, and *fts38* have different effects on tetrapyrrole synthesis and singlet oxygen levels.

In *fc2-1* mutants, $^1O_2$ production is the result of the accumulation of Proto or other free tetrapyrroles (Scharfenberg *et al.* 2015, Woodson *et al.* 2015). Because tetrapyrrole synthesis is dependent on transcript abundance of *trnE*, we hypothesized that the *fts3/38* or *fts32* mutants were

indirectly reducing tetrapyrrole synthesis through reduced expression of *trnE*. To this end, we tested the ability of the mutant lines to synthesize 5-aminolevulinic acid (ALA), the first committed step of the pathway. In six day-old seedlings grown in constant light, only the *fc2-1 fts38* mutant had reduced ALA synthesis compared to *fc2-1* suggesting that early steps in tetrapyrrole synthesis had been impaired in this mutant (Fig. 5a). To determine if later steps of tetrapyrrole synthesis may be affected in these mutants, we next measured the accumulation of protochlorophyllide (Pchlide) in etiolated (dark grown) seedlings. As previously shown (Scharfenberg *et al.* 2015, Woodson *et al.* 2015), the *fc2-1* mutant accumulated ~2.5-fold more Pchlide than wt (Fig. 5b). However, all three *fts* mutations reduced Pchlide back down to wt levels, suggesting that later steps of tetrapyrrole synthesis are inhibited by the *fts3* and *fts32* mutations.

Next, we tested if reduced tetrapyrrole synthesis or plastid gene expression was affecting $^1O_2$ production. The fluorescent $^1O_2$ marker dye SOSG was infiltrated into four day-old seedlings grown under 6h light/18h dark diurnal cycling conditions and seedlings were monitored for fluorescence and the presence of $^1O_2$ two hours after dawn (when $^1O_2$ can be visualized in *fc2-1* seedlings (Woodson *et al.* 2015)). As expected, *fc2-1* mutants accumulated significantly higher levels of $^1O_2$ than wt (Figs. 5c and d). Surprisingly, both *fc2-1 fts3* and *fc2-1 fts32* retained high levels of $^1O_2$ similar to *fc2-1*, while *fc2-1 fts38* had reduced $^1O_2$ production similar to wt. Together these results suggest that *fts3* and *fts32* have uncoupled $^1O_2$ production and chloroplast degradation.

fts3, fts32, and *fts38* increase resistance to excess light.

The previous results suggested that *fc2-1 fts3* and *fc2-1 fts32* still produce a significant amount of $^1O_2$, but their chloroplasts do not suffer photo-oxidative damage and/or signal for chloroplast degradation. To further test the possibility that these mutants are resistant to $^1O_2$, we outcrossed the double mutants to wt plants to isolate *fts3*, *fts32*, and *fts38* in wt backgrounds allowing us to test chloroplast stress in the absence of the *fc2-1* mutation. Plants were first grown for three weeks under mild light conditions of 100 μmol m^{-2} sec^{-1} white light (16h light/day) at 21°C. Individual leaves were then floated on liquid media and shifted to 650 μmol m^{-2} sec^{-1} white light at 4°C. The combination of excess light and low temperatures has previously been shown to lead to $^1O_2$–induced cell death (Kim *et al.* 2012a, Meskauskiene *et al.* 2009, Triantaphylides *et al.* 2008). Over the course of 50h, leaves were stained for cell death with trypan blue. While wt leaves began to experience cell death after 18 hours, *fts3, fts38, fts32,* and *mTERF9* plants all suffered significantly less $^1O_2$–induced cell death up through 50 hours of excess light (Figs. 6a and b). Exposing leaves to 4°C in dim light for a similar period of time did not induce cell death (except in *mTERF9*, which exhibited a mild (but statistically significant) increase in trypan blue staining), suggesting that cell death in this experiment was largely dependent on photo-oxidative damage caused by excess light (Figs. S4a and b).

sig2, sig6, and gun1 do not lead to *fts* phenotypes

The conclusion that *fts3, fts32,* and *fts38* may lead to $^1O_2$ resistance by reducing plastid gene expression suggests that any mutation negatively affecting plastid gene expression could also suppress *fc2-1* phenotypes in diurnal cycling light. One well-characterized mutation that leads to broadly impaired plastid gene expression is *sigma factor 2* (*sig2*) (Hanaoka *et al.* 2003, Woodson *et al.* 2013), which is defective in a sigma factor subunit of the PEP complex and has reduced expression of *psaJ, psaA, psaB, psbD, psbN* (Woodson *et al.* 2013) and tRNAs (trnE-UUC and trnV-UAC) (Hanaoka *et al.* 2003). It does not appear that *sig2* mutants were isolated in our original

screen (Woodson *et al.* 2015). Of the remaining unmapped mutations, only *fts2*, *fts13*, and *fts40* were mapped near the location of *SIG2* (*At1g08540*). However, no mutation was found within ~26 kb of *SIG2* in these three mutants. Therefore, to test the possibility that *sig2* mutations may also lead to resistance to $^1O_2$, we attempted to generate *fc2-1 sig2-2* double mutants by crossing. However, plants homozygous for both mutations were unable to be recovered on soil as they bleached and died before flowering. Therefore, we used a line that was homozygous for *sig2-2* and segregating for the *fc2-1* T-DNA allele. As shown in Fig. 7a, the *fc2-1* cell death phenotype was observed to be segregating in this background in a 1:3 ratio (X^2 value = 0.214, p value 0.643, n = 224 seedlings) when seedlings were grown under 6h light / 18h dark diurnal cycling conditions. This ratio consistent with these dead seedlings being *fc2 sig2-2* double mutants. Trypan blue staining confirmed these phenotypes and showed that the *fc2-1 sig2-2* mutants experienced more cell death than wt or *fc2-1 fts3* (Fig. 7b and c). Therefore, contrary to the other plastid gene expression mutants, the *sig2* mutation did not allow greening in diurnal light cycling conditions or suppress cell death (Figs. 7a, b, and c).

Like PPR30, GUN1 is another chloroplast-localized PPR protein that has been implicated in chloroplast stress and signaling (Koussevitzky *et al.* 2007). When chloroplast development has been blocked, *gun1* mutants can also have reduced chloroplast gene expression (Woodson *et al.* 2013). As such, we tested the possibility that *gun1* mutants may also suppress the *fc2-1* phenotype. A *fc2-1 gun1-9* double mutant was generated by crossing and then grown in 24h or 6h light/18h dark diurnal cycling conditions. Instead of suppressing the *fc2-1* phenotype, *gun1-9* appeared to enhance it; *fc2-1 gun1-9* seedlings were much paler than *fc2-1* mutants in 24h light conditions and appeared to suffer more photo-oxidative damage in 6h light / 18h dark diurnal cycling conditions as shown by reduced chlorophyll accumulation (Figs. 7d and e). As recent reports have suggested that GUN1 may be involved in tetrapyrrole synthesis, we measured the levels of Pchlide in five day-old etiolated seedlings (Fig. 7f). Surprisingly, *fc2-1 gun1-9* mutants had significantly elevated Pchlide compared to *fc2-1*. Together these results suggest that by increasing tetrapyrrole synthesis, *gun1-9* mutants may also increase the sensitivity of *fc2-1* to diurnal cycling light.

Discussion

During photosynthesis, chloroplasts constantly experience stress in the form of ROS, which has the ability to cause extensive oxidative damage to the organelle and the cell. Although it is known that such ROS can lead to signals that control chloroplast degradation, cell death, and nuclear gene expression, how ROS initiates these signals and how these signals are propagated remains unclear. This is due, in part, to the complexity of different ROS being produced under natural stress conditions (e.g., excess light, drought) that likely lead to multiple signaling networks being activated in a single cell (Chan *et al.* 2015, Woodson 2019). However, the use of *Arabidopsis* mutants that specifically produce only one ROS in the chloroplast, has allowed for the study of these pathways in isolation. The study of one such mutant, *fc2-1*, has revealed a $^1O_2$ pathway that leads to the degradation of severely damaged chloroplasts. The purpose of such a chloroplast quality control pathway may be to ensure a healthy population of photosynthesizing chloroplasts in a given cell. Although it is hypothesized that $^1O_2$ accumulation leads to the ubiquitination of chloroplast envelope proteins to "mark" a chloroplast for degradation, how this signal is initiated within the chloroplast is still not known.

To address this and to identify such signaling factors, we have mapped three additional *fts* mutations that suppress the *fc2-1* cell death phenotype under diurnal light cycling conditions. Two

of these alleles (*fts3* (*fts30-1*) and *fts38* (*fts30-2*)) have point mutations in *At3g20320* (*FTS30*), which encodes a chloroplast-localized PPR protein. The PPR proteins are a greatly expanded group of proteins in land plants, with most species having over 400 members (Small and Peeters 2000). In most cases these proteins are targeted to organelles (both plastids and mitochondria) where they play a role in almost every step of gene expression including transcription, RNA stabilization, RNA cleavage, RNA splicing, RNA editing, and translation (Barkan and Small 2014). PPR30 specifically belongs to the P type PPR protein that contains the archetypal 35 amino acid P motif (Small and Peeters 2000). This class of protein is usually involved in the stabilization of specific RNA's, but it can also promote cleavage, translation, and in rare cases, editing (Doniwa *et al.* 2010). The exact role of PPR30 is still unknown, but here we show that *ppr30* mutations reduce the accumulation of several PEP-dependent transcripts and lead to impaired chloroplast development. However, a previous report has shown that null alleles of *PPR30* are embryo lethal (Savage *et al.* 2013) suggesting a role beyond photosynthesis. Therefore, PPR30 may be involved in the more general process of plastid translation (possibly through the expression of an rRNA transcript), thus affecting PEP formation indirectly. Consistent with this hypothesis, the maize ortholog of PPR30 shows the strongest expression near the base of the maize leaf, suggesting it has a role in the build-up of plastid gene expression machinery in the very early stages of chloroplast development (Li *et al.* 2010).

Another PPR protein known to have an important role in chloroplast signaling is GUN1, which is necessary for the coordination of photosynthetic gene expression between the chloroplast and nuclear genomes (Koussevitzky *et al.* 2007). Interestingly, GUN1 may be an unusual case as it has not yet been shown to target a specific RNA transcript (Pesaresi and Kim 2019). Instead, GUN1 has been proposed to bind to several different proteins in the chloroplast including import-related chaperone cpHSC70-1 (Wu *et al.* 2019), the MORF2 editing protein (Zhao *et al.* 2019), and Plastid Ferrochelatase 1 (FC1) (Shimizu *et al.* 2019). Here we establish that *gun1* clearly does not suppress *fc2* or lead to an *fts* phenotype. Instead, *fc2-1 gun1* mutants appear to suffer enhanced photo-damage. This appears to be due to an increase of tetrapyrrole synthesis in this mutant and is consistent with a recent report demonstrating that GUN1 plays a role in tetrapyrrole metabolism by directly binding to tetrapyrroles such as Proto and by stimulating FC1 activity (Shimizu *et al.* 2019). As such, by modulating tetrapyrrole synthesis or by sequestering Proto, GUN1 may play an indirect role in $^1O_2$ signaling from the chloroplast.

A third mutant, *fts32*, was shown to affect the function of mTERF9 by introducing a premature stop codon in its coding sequence. Like PPR proteins, mTERF's are a large family of proteins with roles in organellar gene expression and have been shown to affect the expression of specific genes through transcriptional termination and RNA processing (Kleine 2012). Here we demonstrate that mTERF9 localizes to chloroplast nucleoids, which is in agreement with a previous proteomic study that aimed to define the nucleoid proteome (Majeran *et al.* 2012). Also like PPR30, loss of mTERF9 using the *fts32* allele leads to a broad reduction of PEP-dependent gene expression and impaired chloroplast development. Robles *et al.* (2015) also reported the null mTERF9 T-DNA line has reduced *psbA* and *psbD* transcript levels and changes in chloroplast ultrastructure. Unlike PPR30, however, mTERF9 is dispensable for growth as a null T-DNA line (Robles *et al.* 2015) is viable without any supplemental carbon source. This may suggest that mTERF9 directs the expression of a different component in the chloroplast or is a partially redundant protein. However, the target gene of mTERF9 is still unknown.

The commonality behind these mutants is that they all broadly reduce PEP-dependent gene expression in the chloroplast. As such, how can the reduction of plastid gene expression lead to an

fts phenotype and suppress chloroplast degradation in the *fc2-1* mutant? We tested the possibility that these mutants were reducing available transcripts of *trnE*, which would limit the synthesis of tetrapyrroles and thus, $^1O_2$. However, only *fc2-1 fts38* had a mild reduction of *trnE* transcripts and ALA synthesis suggesting that this was not the common factor among the mutants. Furthermore, only in *fc2-1 fts38* mutants was $^1O_2$ reduced to wt levels, while $^1O_2$ levels were not significantly different in *fc2-1 fts3 or fc2-1 fts32* compared to *fc2-1*. Therefore, in the *fts3* and *fts32* (and possibly *fts38*) mutants, chloroplast degradation and cell death has been uncoupled with $^1O_2$. This is reminiscent of the mutants *soldat8* (Coll *et al.* 2009) and *soldat10* (Meskauskiene *et al.* 2009), that have mutations in *SIGMA6* and *mTERF1*, respectively. Both were found as suppressors of $^1O_2$-induced cell death in the *fluorescent in blue* light (*flu*) mutant that over-accumulates the photosensitizer tetrapyrrole Pchlide in the dark. Their mode of suppression, however, appears to involve disrupting chloroplast homeostasis and promoting a constitutive stress response in the nucleus through retrograde signals. Our RT-qPCR analysis of stress-related transcripts in *fc2-1 fts3*, *fc2-1 fts38*, and *fc2-1 fts32* showed that such transcripts are clearly not upregulated under permissive constant light conditions. Furthermore, unlike the *soldat* mutants, $^1O_2$-marker genes were also not upregulated under stress conditions (diurnal cycling light in this report) suggesting that chloroplast retrograde signals are blocked by the *ppr30* and *mterf9* mutations. Together this suggests that *fts3*, *fts32*, and (possibly) *fts38* are blocking the ability of $^1O_2$ to signal outside the chloroplast. While the short half-life (~1 usec (Ogilby 2010)) of $^1O_2$ makes it an unlikely signaling molecule, it is possible that an oxidation product (a chloroplast lipid, protein, or metabolite) may be the true signal for such a cascade. Such a hypothetical chloroplast metabolite may then be less abundant in the *fts3/38/32* mutants due to decreased gene expression and delayed chloroplast development.

Rose Bengal (a photo sensitizer dye that leads to $^1O_2$ production) has previously been shown initiate cell death in *Arabidopsis* cell cultures, but only those with mature chloroplasts (Gutierrez *et al.* 2014). Along with the work reported here, these results demonstrate a strong link between the developmental stage of a chloroplast (or plastid) and its ability to respond to $^1O_2$. However, it does not appear that generally reducing plastid gene expression and development is always sufficient to lead to an *fts* phenotype and block $^1O_2$ signaling. The *sig2* mutation has previously been shown to lead to a broad reduction of plastid transcription, translation, and tetrapyrrole synthesis (Hanaoka *et al.* 2003, Woodson *et al.* 2013). However, the *sig2* mutation is not able to suppress the *fc2-1* phenotype as cell death was still observed in *fc2-1 sig2-2* mutants under diurnal cycling light conditions (Figs. 7 a, b, and c). As such, this result suggests that *fts3/fts38/fts32* mutations are blocking the accumulation of a specific component(s) of the mature chloroplast that must be both produced and in place for chloroplasts to respond to $^1O_2$ accumulation. Such a switch may allow developing seedlings and leaves to establish mature photosynthesizing chloroplasts before they employ any chloroplast quality control pathways.

The role of such a pathway appears to be independent of the *fc2-1* mutation. When the *fts3, fts38,* and *fts32* mutants were outcrossed to wt, they exhibited delayed photo-bleaching and cell death under a combination of moderate excess light and cold temperatures. Such stress has previously been shown to cause chloroplast $^1O_2$ accumulation followed by cell death (Kim *et al.* 2012a, Meskauskiene *et al.* 2009, Triantaphylides *et al.* 2008). Therefore, the regulation of chloroplast gene expression may be one natural mechanism that allows plants to modulate growth and stress under dynamic and harsh environments. Interestingly, organellar gene expression has previously been implicated in the ability of plants to respond to environmental abiotic stress as evidenced by various *mTERF* mutants (Leister *et al.* 2017). *mTERF9* mutants have also been

shown to have increased resistance to osmotic stress from salt and mannitol treatments (Robles *et al.* 2015). Loss of two other chloroplast-localized mTERF proteins, mTERF1 (Meskauskiene *et al.* 2009) and mTERF5 (Robles *et al.* 2012), lead to resistance to chloroplast $^1O_2$, and osmotic stress, respectively. Finally, mutants lacking the mitochondrial localized mTERF4 (Quesada *et al.* 2011) and mTEF18 (Kim *et al.* 2012b) have increased and decreased tolerance to heat, respectively. Although the transcripts regulated by these mTERFs are unknown, these reports suggest that plastid gene expression and stress are intimately linked in complex ways.

Conclusions

      The work presented here has demonstrated that full chloroplast gene expression, or the expression of a specific set of genes, is a prerequisite for initiating $^1O_2$ signals from stressed chloroplasts. Future work will undoubtedly focus on identifying the specific targets of PPR30, mTERF9, and other proteins involved in post-transcriptional chloroplast gene expression. A deeper understanding of these proteins' targets and their relation to stress should offer unique tools to engineer plants with specific responses to environmental stresses. Such knowledge of the control of photosynthesis and growth will aid our quest for abundant and inexpensive sources of food and fuel in the coming century.

Experimental Procedures

Biological material, growth conditions, and treatments

      In this study, the wt line used in all experiments and to generate all transgenic constructs was *Arabidopsis thaliana* ecotype *Columbia* (Col-0). Table S2 lists the mutant lines used. Sequence data for the T-DNA lines came from the GABI (Kleinboelting *et al.* 2012), WiscDsLox (Woody *et al.* 2007), SAIL (Sessions *et al.* 2002), and SALK (The Salk Institute Genomic Analysis Laboratory) (Alonso *et al.* 2003) collections; *fc2-1* (GABI_766H08) (Woodson *et al.* 2011), *mterf9* (WiscDsLox474E07) (Robles *et al.* 2015), and *sig2-2* (Salk_045706) (Woodson *et al.* 2013) were described previously. Crossing was used to generate double mutant lines, which were confirmed by PCR-based markers listed in table S3.

      Seeds were surface sterilized using 30% liquid bleach (v:v) with 0.04% Triton X-100 (v:v) for ten minutes. Seeds were pelleted at room temperature in a microfuge for 30 seconds at 2,000 x g. The seeds were then washed four times in sterile water and finally resuspended in 0.1% micropropagation type-1 agar powder (Caisson Laboratories). The seed suspension was then plated on Linsmaier and Skoog medium pH 5.7 (Caisson Laboratories North Logan, UT) with 0.6% micropropagation type-1 agar powder. A 3-4 day cold treatment of 4°C in the dark was used to stratify seeds before transferring them to constant light or diurnal light/dark cycling conditions of approximately ~80 µmol m^{-2} sec^{-1} white light at 22°C. For Pchlide measurement studies, germination was induced with only two hours of light exposure before the plates were wrapped in three layers of aluminum foil and incubated in the dark at 22°C. Seedlings were allowed to germinate and then harvested under dim green light for Pchlide extraction. For inducing excess light stress in adult plants, seedlings were grown on plates for 7 days in constant light conditions and then transferred to soil where they grew in 16h light/8h dark diurnal cycling light (~90-100 µmol m^{-2} sec^{-1} white light at 22°C) conditions. After 21 days in total, plants were moved under a LED panel (Hettich, Beverly, MA) and exposed to constant excess (650 µmol m^{-2} sec^{-1}) or dim (6 µmol m^{-2} sec^{-1}) white light at 4°C. For transient expression experiments, *Nicotiana benthamiana* was grown under 16h light/8h dark diurnal cycling light conditions of ~100 µmol m^{-2} sec^{-1} white

light at 22°C. Photosynthetically active radiation was measured using a LI-250A light meter with a LI-190R-BNC-2 Quantum Sensor (LiCOR). All bacteria (*E. coli* and *Agrobacterium tumefaciens* strains) were grown in liquid Miller nutrient broth or solid medium containing 1.5% agar (w/v). Cells were grown at 37°C (*E. coli*) or 28°C (*A. tumefaciens*) with the appropriate antibiotics and liquid medium was shaken at 225 rpm.

Construction of complementation vectors

DNA fragments were amplified from wt *Arabidopsis* genomic DNA template using the Phusion enzyme (Finnzymes Espoo, Finland). These DNA fragments were gel-purified using the QIAquick Gel Extraction Kit (Qiagen) and cloned into the Gateway compatible vector pENTR-D/TOPO (Invitrogen) according to the manufacturer's instructions. All primers and vectors are listed in tables S3 and S4, respectively.

DNA fragments were then transferred to either pEARLEYGATE101 (35S overexpression promoter plus C-terminal HA and YFP tags (Earley *et al.* 2006)) or pGBGWY (no promoter (Zhong *et al.* 2008)) to overexpress tagged YFP-HA proteins or to express native proteins with the native promoter, respectively. DNA fragments were then transferred to these vectors using LR clonase (Invitrogen) according to manufacturer's instructions. The completed vectors were then transformed into the *A. tumefaciens* strain GV301, which was subsequently used to transform *Arabidopsis* via the floral dip method. T_1 plants were selected for their ability to grow on Basta-soaked soil and propagated to the next generation. T_2 lines were monitored for single insertions (segregating 3:1 for Basta resistance:sensitivity) and propagated to the next generation. Finally, homozygous lines were selected in the T_3 generation based on 100% Basta-resistance

RNA extraction and Real-time quantitative PCR

The RNeasy Plant Mini Kit (Qiagen) was used to extract total RNA from whole seedlings. Next, cDNA was synthesized using the Maxima first strand cDNA synthesis kit for RT-qPCR with DNase (Thermo Scientific) following the manufacturer's instructions. Real-time PCR was performed using the SYBR Green Master Mix (BioRad) with the SYBR Green fluorophore and a CFX Connect Real Time PCR Detection System (Biorad). The following 2-step thermal profile was used in all RT-qPCR: 95 °C for 3 min, 40 cycles of 95 °C for 10s and 60 °C for 30s. *Actin2* expression was used as a standard to normalize all gene expression data. Table S3 lists the primers used.

Chlorophyll measurements

Total chlorophyll was extracted from whole seedlings with 80% acetone and measured as previously described (Woodson *et al.* 2015). Levels were calculated spectrophotometrically according to (Hendry and Grime 1993).

Protochlorophyllide measurements

Pchlide was extracted from whole seedlings with 80% acetone and measured by fluorescence using an adapted protocol (Shin *et al.* 2009) as previously described (Woodson *et al.* 2015).

ALA measurements

ALA accumulation was measured as previously described (Woodson *et al.* 2015) using an adaptation of a previously described protocol (Czarnecki *et al.* 2011).

Monitoring Singlet oxygen accumulation

To measure $^1O_2$ accumulation in cotyledon mesophyll cells, we used a previously described method (Woodson *et al.* 2015) with minor alterations. Seedlings were grown on plates in 6h light/18h dark diurnal cycling light conditions. At the end of day 3, seedlings were transferred to 1.5 ml centrifuge tubes containing 250 μl of ½-strength Linsmaier liquid media and subsequently wrapped in foil and incubated in the dark at 22°C overnight. 60 min prior to dawn on the fourth day, 50 μM of 1.5 mM Singlet Oxygen Sensor Green (SOSG, Molecular Probes) and 0.1% Tween 20 (v/v) was added to the medium under dim light (final [250 μM]. Seedlings were vacuum infiltrated for 30 min and placed back in the dark. After 30 additional minutes, seedlings were exposed to light (dawn number four) for two hours. Seedlings were then washed twice with 1 ml of ½-strength Linsmaier and then imaged using a Zeiss Axiozoom 16 fluorescent stereo microscope equipped with a Hamamatsu Flash 4.0 camera and a GFP fluorescence filter. At least ten seedlings from each genotype were monitored and average fluorescence per mm^2 was quantified using ImageJ.

Trypan Blue staining

Trypan blue staining was used to assess cell death in leaves and cotyledons using a previously described method (Woodson *et al.* 2015). To quantify cell death, trypan blue intensity was measured with ImageJ using at least six seedlings from each genotype.

In vivo protein localization

Expression constructs were transiently expressed in *N. benthamiana* leaves prior to imaging. To transform *N. benthamiana* leaves, dense 5 ml *A. tumefaciens* cultures harboring the appropriate vector were pelleted (2 minutes at 10,000 x g) and resuspended in 1 ml infiltration buffer (10 mM MES pH 5.6, 10 mM MgCl$_2$). The optical density of the culture was adjusted to OD600 = 0.8, and 1.5 μl of Acetosyringone (100 mM stock in 100% DMSO) was added per 1 ml infiltration buffer. Cultures were incubated in the dark at room temperature for two hours before being infiltrated into leaves using a blunt end syringe. Tobacco plants were then grown normally and imaged three days later. Leaves were imaged using a Leica SP/2 inverted laser scanning confocal microscope. Image analysis was performed using the Leica SP/2 software package and the ImageJ (Schneider *et al.* 2012) bundle (Wright Cell Imaging facility).

Electron Microscopy

Four day old seedlings were removed from LS plates and plunged into a solution of 2.5% glutaraldehyde and 2% formaldehyde (v:v) in 0.133 M Sorensen's buffer (pH 7.4). Primary fixation was carried out under vacuum for approximately 18 hours. Seedlings were then washed three times with Sorenson's buffer (10 minutes per wash) before being transferred to the secondary fixation solution of 1% osmium tetroxide and 1.5% potassium ferrocyanide in buffer for 90 minutes. Seedlings were then rinsed three times in ddH$_2$0 (10 minutes per rinse) before *enbloc* staining in 2% uranyl acetate for 2 hours, followed again by three rinses in ddH$_2$0. All fixations were carried out at room temperature. Seedlings were dehydrated in an ascending ethanol series (20%, 40%...) and infiltrated in 25% increments with Spurr's resin (Spurr 1969). Infiltrated seedlings were placed in flat silicone molds with fresh Spurr's resin before polymerization at 60°C for 24 hours. Selected seedlings were sectioned on a Reichert UCT ultramicrotome (Leica

Microsystems Inc., Bannockburn, IL), collected on copper grids, and imaged with a FEI Tecnai Spirit Transmission Electron Microscope at 100kV (ThermoFisher, Waltham, MA).

Chloroplast area and chloroplast compartment size (% chloroplast area/total cell area) were analyzed using ImageJ. Average chloroplast size was calculated on a per cell basis. For chloroplast compartment ratios, the sum of all chloroplast areas was divided by the total cell area. Only intact and fully imaged cells were used for these calculations. Measurements were collected from at least three cells in three different seedlings in each genotype and growth condition.

Statistical analyses

All reported statistical analyses (one-way ANOVA and post-tests (Tukey-Kramer and Dunnett's multiple comparisons)) were performed using GraphPad Prism software.

Acknowledgements

We thank Dr. Alice Barkan (U. Oregon) for useful discussions about PPR30. The authors acknowledge the Division of Chemical Sciences, Geosciences, and Biosciences, Office of Basic Energy Sciences of the U.S. Department of Energy grants DE-SC0019573 and DE-FG02-04ER15540 awarded to J.D.W. and J.C., respectively.

Figure Legends

Figure 1. *fts3, 38, 32* are robust suppressors of the *fc2* cell death phenotype.
fc2-1 fts3, fc2-1 fts38, and fc2-1 fts32 mutants suppress the *fc2-1* cell death phenotype. **A)** *fc2-1 fts3, fc2-1 fts38, and fc2-1 fts32* were isolated based on their ability to survive under diurnal light cycling conditions. Shown are seven-day-old seedlings grown in constant (24h) light or diurnal cycling (6h days / 18h nights) light. **B)** Shown are representative seven-day-old seedlings stained with trypan blue. The deep dark color is indicative of cell death. **C)** Total chlorophyll levels of five-day-old seedlings grown in constant light. Shown are means of biological replicates (n = 3) +/- SD. The chlorophyll statistical analysis was performed by a one-way ANOVA and different

letters above bars indicate significant differences determined by a Tukey-Kramer post-test (p value ≤ 0.05). RT-qPCR analysis of transcripts from 4 day old seedlings grown in **D)** 6 hours of light / 18 hours dark diurnal cycling and **E)** constant light conditions. Seedlings were harvested one hour post subjective dawn. Shown are means of biological replicates (n = 3) +/- SD. The RT-qPCR statistical analyses were performed by a one-way ANOVA followed by Dunnett's multiple comparisons test with the wt (D) or *fc2-1* (E) sample. * and ** indicates an adjusted p value of ≤ 0.05 and ≤ 0.01, respectively. In all bar graphs, closed circles represent individual data points.

Figure 2. Mapping of *fts3*, *fts32*, and *fts38*.
fts3, *38*, and *32* were mapped to two independent loci encoding proteins putatively involved in chloroplast gene expression. **A)** A schematic of the *PPR30* (*At3g23020*) gene in *Arabidopsis*. Shown is the position of the EMS generated *fts3* and *fts38* alleles identified in the *fc2-1* suppressor screen and two previously described T- DNA insertion lines (Savage *et al.* 2013). Predicted PPR motifs 1-18 are indicated under the FTS3 schematic. **B)** Alignment of FTS3 orthologs in various land plants. Numbers on the left hand side indicate amino acid positions. The two amino acids substituted in the *fts3* and *fts38* mutants are indicated with asterisks. **C and D)** Representative images of six-day-old seedlings grown in constant (24h) light or 6h light / 18h dark diurnal cycling conditions. **He)** Shown are representative six-day-old seedlings from **D** stained with trypan blue. The deep dark color is indicative of cell death. **F)** A schematic of the *FTS32/mTERF9* (*At5g55580*) gene in *Arabidopsis*. Shown is the position of the EMS generated *fts32* allele identified in the *fc2-1* suppressor screen. Also shown are the positions of the previously described T- DNA insertion line (Robles *et al.* 2015).

Figure 3. *fc2-1 fts32* and *fc2-1 fts38* have delayed chloroplast development.
A) RT-qPCR analysis of transcripts from 4 day old seedlings grown in constant light. Shown are means of biological replicates (n=3) +/- SD. Statistical analysis was performed by a one-way ANOVA followed by Dunnett's multiple comparisons test with the *fc2-1* sample. * and ** indicate an adjusted p value of ≤ 0.05 and ≤ 0.01, respectively. **B)** Shown are representative TEM micrographs of chloroplasts in cotyledon mesophyll cells of four day-old seedlings grown in 24h constant light or 6h light/18h dark diurnal cycling conditions one hour after subjective dawn. Plastids (P), Nuclei (N), central vacuoles, (CV), lipid bodies (L), plastoglobules (PG), and mitochondria (M) are noted. Scale bars = 500 nm. **C)** Shown are means of the average size (um^2) of chloroplasts in b (+/- SD) (n ≥ 9 cells). Statistical analysis was performed by a one-way ANOVA and different letters above bars indicate significant differences determined by a Tukey-Kramer post-test (p value ≤ 0.05). In all bar graphs, closed circles represent individual data points.

Figure 4. *fc2-1 fts3*, *fc2-1 fts38*, *fc2-1 fts32* mutants have impaired plastid gene expression.
Shown are means (+/- SD) of expression levels of plastid transcripts from 4 day old seedlings grown in constant light as measured by RT-qPCR (n ≥ 2 biological replicates). Closed circles represent individual data points. Statistical analysis was performed by a one-way ANOVA followed by Dunnett's multiple comparisons test with the *fc2-1* sample. * and ** indicate an adjusted p value of ≤ 0.05 and ≤ 0.01, respectively.

Figure 5. *fc2-1 fts3*, *fc2-1 fts38*, *fc2-1 fts32* mutants have impaired tetrapyrrole synthesis.
A) ALA synthesis rates of six-day-old seedlings grown in constant light. Shown are means of biological replicate measurements (n ≥ 3) +/- SD. **B)** Protochlorophyllide levels of five-day-old

seedlings grown in constant dark. Shown are means of biological replicate measurements ($n \geq 3$) +/- SD. **C** and **D)** SOSG fluorescence in four day-old seedlings grown in diurnal cycling light (6 hours light/18h dark). Shown are representative seedlings and means of average intensities of SOSG signal across one cotyledon per seedling ($n \geq 10$) +/- SD. Statistical analysis was performed by a one-way ANOVA and different letters above bars indicate significant differences determined by a Tukey-Kramer post-test (p value ≤ 0.05). In all bar graphs, closed circles represent individual data points

Figure 6. *ppr30* and *mTERF9* mutants are resistant to excess light stress.
Single leaves of *ppr30* and *mTERF9* mutants were exposed to excess light (650 μmol m^{-2} sec^{-1}) and cold temperatures (4°C) for various lengths of time. **A)** Shown are representative images of these leaves stained by trypan blue. The deep blue color is indicative of cell death. **B)** Shown are the means of average intensities of the trypan blue signal/mm^2 across the entire leaf ($n = 6$) +/- SD.

Figure 7. *fts3, 38, 32* mutants have specific defects in gene expression.
sig2 and *gun1* mutations do not suppress the *fc2-1* cell death phenotype under diurnal light cycling conditions. **A)** Shown are six-day-old seedlings grown in constant (24h) light or diurnal cycling (6h days / 18h nights) light. **B)** Shown are representative six-day-old seedlings grown in diurnal cycling conditions and stained with trypan blue. The deep dark color is indicative of cell death. **C)** Quantification of the trypan blue staining (relative intensity/mm^2) (means of nine seedlings +/- SD). **D)** Shown are four-day-old seedlings grown in constant light or diurnal cycling light. **E)** Total chlorophyll levels of same seedlings. Shown are means of biological replicates ($n = 8$, 24h samples; 4, 6h samples) +/- SD. **F)** Pchlide levels of five-day-old seedlings grown in constant dark. Shown are means of biological replicates ($n \geq 4$) +/- SD. Statistical analysis was performed by a one-way ANOVA and different letters above bars indicate significant differences determined by a Tukey-Kramer post-test (p value ≤ 0.05). In all bar graphs, closed circles represent individual data points.
