

16

17 **Abstract**

18

19 Arachnids are important components of cave ecosystems and display many examples of
20 troglomorphisms, such as blindness, depigmentation, and elongate appendages. Little is
21 known about how the eyes of arachnids are specified genetically, let alone the mechanisms
22 for eye reduction and loss in troglomorphic arachnids. Additionally, paralogy of Retinal
23 Determination Gene Network (RDGN) homologs in spiders has convoluted functional
24 inferences extrapolated from single-copy homologs in pancrustacean models. Here, we
25 investigated a sister species pair of Israeli cave whip spiders (Arachnopulmonata,
26 Amblypygi, *Charinus*) of which one species has reduced eyes. We generated the first
27 embryonic transcriptomes for Amblypygi, and discovered that several RDGN homologs
28 exhibit duplications. We show that paralogy of RDGN homologs is systemic across
29 arachnopulmonates (arachnid orders that bear book lungs), rather than being a spider-specific
30 phenomenon. A differential gene expression (DGE) analysis comparing the expression of
31 RDGN genes in field-collected embryos of both species identified candidate RDGN genes
32 involved in the formation and reduction of eyes in whip spiders. To ground bioinformatic
33 inference of expression patterns with functional experiments, we interrogated the function of
34 three candidate RDGN genes identified from DGE in a spider, using RNAi in the spider
35 *Parasteatoda tepidariorum*. We provide functional evidence that one of these paralogs, *sine*
36 *oculis/Six1 A (soA)*, is necessary for the development of all arachnid eye types. Our results
37 support the conservation of at least one RDGN component across Arthropoda and establish a
38 framework for investigating the role of gene duplications in arachnid eye diversity.

43 Introduction

44

45 Cave habitats offer apt systems for investigating the genetic basis of morphological
46 convergence because communities of these habitats are similarly shaped by environmental
47 pressures, such as absence of light and diminished primary productivity (Howarth, 1993;
48 Juan, Guzik, Jaume, & Cooper, 2010). Troglobites, species exclusive to cave environments
49 and adapted to life in the dark, exhibit a suite of characteristics common to cave systems
50 around the world, such as reduction or complete loss of eyes, depigmentation, elongation of
51 appendages and sensory structures, and decreased metabolic activity (Jemec, Škufca,
52 Prevorčnik, Fišer, & Zidar, 2017; Protas & Jeffery, 2012; Riddle et al., 2018). Previous work
53 has shown that troglomorphism can evolve over short time spans (<50 kyr) despite gene flow
54 (Bradic, Teotónio, & Borowsky, 2013; Coghill, Darrin Hulseley, Chaves-Campos, García de
55 Leon, & Johnson, 2014; Herman et al., 2018) and that parallel evolution of troglomorphic
56 traits (e.g., depigmentation; eye loss) in independent populations can involve the same
57 genetic locus (Protas et al., 2005; Protas, Trontelj, & Patel, 2011; Re et al., 2018).

58 Troglomorphism and troglobitic fauna have been analyzed across numerous taxonomic
59 groups with respect to systematics and population genetics. However, one component of the
60 troglobitic fauna that remains poorly understood is cave arachnids. Most orders of Arachnida
61 are prone to nocturnal life history and some orders broadly exhibit troglomorphy; in fact,
62 troglobitic species are known from all the extant terrestrial arachnid orders except Solifugae
63 and Uropygi (Cruz-López, Proud, & Pérez-González, 2016; Esposito et al., 2015; Harvey,
64 2002; 2007; Hedin & Thomas, 2010; Mammola, Mazzuca, Pantini, Isaia, & Arnedo, 2017;
65 Miranda, Aharon, Gavish-Regev, Giupponi, & Wizen, 2016; Santibáñez López, Francke, &
66 Prendini, 2014; Smrž, Kováč, Mikeš, & Lukešová, 2013). In addition to eye and pigment
67 loss, troglomorphism in arachnids manifests in the form of compensatory elongation of
68 walking legs and palps, appendages which harbor sensory structures in this group
69 (Derkarabetian, Steinmann, & Hedin, 2010; Mammola & Isaia, 2017; Mammola et al.,
70 2018a; Mammola, Cardoso, Ribera, Pavlek, & Isaia, 2018b).

71 Thorough understanding of the developmental genetic basis for the evolution of
72 troglomorphic traits has been largely spearheaded in two model systems: the Mexican cave
73 fish *Astyanax mexicanus* (Bradic et al., 2013; Coghill et al., 2014; Herman et al., 2018;
74 Porter, Dittmar, & Pérez-Losada, 2007; Protas et al., 2005; Protas & Jeffery, 2012) and the
75 cave isopod *Asellus aquaticus* (Jemec et al., 2017; Re et al., 2018; Stahl et al., 2015). Both
76 model systems have more than one hypogean population, can be maintained in laboratories,

77 and are amenable to approaches such as genetic crosses and quantitative trait locus mapping.
78 The advent of short read sequencing technology in tandem with experimental approaches has
79 transformed the potential to triangulate regulatory differences between hypogean
80 (subterranean) and epigeal (surface-dwelling) lineages (Protas et al., 2005; Re et al., 2018;
81 Riddle et al., 2018; Stahl et al., 2015), and to study a broader range of cave taxa.

82 Among arthropods, work on the isopod *A. aquaticus* in particular has made significant
83 advances in the identification of loci regulating pigmentation and size of arthropod eyes
84 (Protas et al., 2011; Re et al., 2018), complementing forward and reverse genetic screening
85 approaches in other pancrustacean models (e.g., *Drosophila melanogaster*, *Tribolium*
86 *castaneum*, and *Gryllus bimaculatus*) (Cagan, 2009; Kumar, 2009; Takagi et al., 2012;
87 ZarinKamar et al., 2011). However, developmental and genetic insights into the evolution of
88 blindness illuminated by *A. aquaticus* and other pancrustacean models are not directly
89 transferable to Arachnida for two reasons. First, the eyes of arachnids are structurally and
90 functionally different from those of pancrustaceans. Typically, the main eyes of adult
91 Pancrustacea (e.g., *A. aquaticus*) are a pair of faceted (or apposition) eyes, which are
92 composed of many subunits of ommatidia. In addition, adult Pancrustacea have small median
93 ocelli (typically three in holometabolous insects), often located medially and at the top of the
94 head.

95 By contrast, extant arachnids lack ommatidia and typically have multiple pairs of eyes
96 arranged along the frontal carapace. All arachnid eyes are simple-lens eyes or ocelli; each eye
97 has a single cuticular lens, below which are a vitreous body and visual cells. The retina is
98 composed of the visual cells and pigment cells. These eyes are divided in two types, namely
99 the principal eyes and the secondary eyes (Foelix, 2011; Land, 1985). Principal and
100 secondary eyes differ in the orientation of their retina (Homann, 1971): the principal eyes are
101 of the everted type, with the visual cells lying distally, and lack a reflective layer; the
102 secondary eyes are inverted, with the light-sensitive rhabdomeres pointing away from
103 incoming light (analogous to vertebrate eyes). All secondary eyes possess a reflective layer of
104 crystalline deposits called a tapetum, which is responsible for the “eye shine” of spiders. The
105 principal eyes are the median eyes (ME, also known as anterior medium eyes). The
106 secondary eyes comprise the anterior lateral eyes (ALE), posterior lateral eyes (PLE), and
107 medium lateral eyes (MLE; also known as posterior medium eyes) (Fig. 1A) (Foelix, 2011;
108 Land, 1985) (nomenclature used here follows Schomburg et al 2015). Certain orders and
109 suborders of arachnids have lost one type of eye altogether, with the homology of eyes

110 clarified by the fossil record and embryology (Foelix, 2011; Garwood, Sharma, Dunlop, &
111 Giribet, 2014; Morehouse, Buschbeck, Zurek, Steck, & Porter, 2017).

112 The second concern in extending the model derived from pancrustaceans is that a subset
113 of Arachnida exhibits an ancient shared genome duplication, resulting in numerous paralogs
114 of developmental patterning genes. Recent phylogenetic and comparative genomic works on
115 Arachnida have shown that Arachnopulmonata (Ballesteros & Sharma, 2019; Ballesteros,
116 Santibáñez López, Kováč, Gavish-Regev, & Sharma, 2019; Sharma, Kaluziak, Pérez-Porro,
117 González, Hormiga, et al., 2014a), the clade of arachnids that bear book lungs (e.g., spiders,
118 scorpions, whip spiders), retain duplicates of many key transcription factors, such as
119 homeobox genes, often in conserved syntenic blocks (Leite et al., 2018; Schwager et al.,
120 2017; Sharma, Santiago, González-Santillán, Monod, & Wheeler, 2015a; Sharma, Schwager,
121 Extavour, & Wheeler, 2014b). Many of the ensuing paralogs exhibit non-overlapping
122 expression patterns and a small number have been shown to have subdivided the ancestral
123 gene function (subfunctionalization) or acquired new functions (neofunctionalization) (Leite
124 et al., 2018; Paese, Leite, Schönauer, McGregor, & Russell, 2018; Turetzek, Pechmann,
125 Schomburg, Schneider, & Prpic, 2015).

126 While comparatively little is known about the genetics of arachnid eye development, gene
127 expression surveys of insect retinal determination gene network (RDGN) homologs of two
128 spiders (*Cupiennius salei* and *Parasteatoda tepidariorum*) have shown that this phenomenon
129 extends to the formation of spider eyes as well (Samadi, Schmid, & Eriksson, 2015;
130 Schomburg et al., 2015). Different paralog pairs (orthologs of *Pax6*, *Six1*, *Six3*, *eyes absent*,
131 *atonal*, *dachshund* and *orthodenticle*) exhibit non-overlapping expression boundaries in the
132 developing eye fields, resulting in different combinations of transcription factor expression in
133 the eye pairs (Samadi et al., 2015; Schomburg et al., 2015). While these expression patterns
134 offer a potentially elegant solution to the differentiation of spider eye pairs, only a few
135 studies with the spider *P. tepidariorum* have attempted to experimentally test the role of these
136 genes in the formation of arachnid eyes. *Ptep-orthodenticle-1* maternal RNA interference
137 (RNAi) knockdown results in a range of anterior defects, including complete loss of the head,
138 which precluded assessment of a role in the formation of the eyes (Pechmann, McGregor,
139 Schwager, Feitosa, & Damen, 2009). *Ptep-dac2* RNAi knockdown results in appendage
140 segment defects, but no eye patterning defects were reported by the authors (Turetzek et al.,
141 2015). More recently, a functional interrogation of *Ptep-Six3* paralogs, focused on labrum
142 development, reported no discernible morphological phenotype, despite a lower hatching rate
143 than controls and disruption of a downstream target with a labral expression domain

144 (Schacht, Schomburg, & Bucher, 2020). Thus, gene expression patterns of duplicated RDGN
145 paralogs have never been linked to eye-related phenotypic outcomes in any
146 arachnospulmonate model. Similarly, the functions of the single-copy orthologs of RDGN
147 genes in groups like mites (Grbić et al., 2007; Telford & Thomas, 1998), ticks (Santos et al.,
148 2013), and harvestmen (Garwood et al., 2014; Sharma, Schwager, Giribet, Jockusch, &
149 Extavour, 2013; Sharma, Tarazona, Lopez, Schwager, Cohn, Wheeler, et al., 2015b) are
150 entirely unexplored, in one case because an otherwise tractable arachnid species lacks eyes
151 altogether (the mite *Archegozetes longisetosus* (Barnett & Thomas, 2012; 2013a; 2013b;
152 Telford & Thomas, 1998).

153 Investigating the evolution of eye loss in arachnids thus has the potential to elucidate
154 simultaneously (1) the morphogenesis of a poorly understood subset of metazoan eyes
155 (Foelix, 2011; Morehouse et al., 2017), (2) developmental mechanisms underlying a
156 convergent trait (i.e., eye loss in caves) in phylogenetically distant arthropod groups (Protas
157 & Jeffery, 2012; Re et al., 2018), (3) shared programs in eye development common to
158 Arthropoda (through comparisons with pancrustacean datasets) (Cagan, 2009; Stahl et al.,
159 2015; Takagi et al., 2012; ZarinKamar et al., 2011), and (4) the role of ancient gene
160 duplicates in establishing the diversity of eyes in arachnospulmonates (Leite et al., 2018;
161 Samadi et al., 2015; Schomburg et al., 2015).

162 As first steps toward these goals, we first developed transcriptomic resources for a sister
163 species pair of cave-dwelling *Charinus* whip spiders, wherein one species exhibits typical eye
164 morphology and the other highly reduced eyes (a troglobitic condition). We applied a
165 differential gene expression (DGE) analysis to these datasets to investigate whether candidate
166 RDGN genes with known expression patterns in model spider species (*C. salei*, *P.*
167 *tepidariorum*) exhibit differential expression in non-spider arachnospulmonates, as a function
168 of both eye condition and developmental stage. To link bioinformatic inference of expression
169 patterns with functional outcomes, we interrogated the function of three candidate RDGN
170 genes identified from DGE in a model arachnospulmonate, using RNAi in the spider *P.*
171 *tepidariorum*, which exhibits the same number and types of eyes as whip spiders. We provide
172 functional evidence that one of these candidates, *sine oculis/Six1*, is necessary for the
173 development of all spider eye types.

174

175 **Results**

176

177 *Charinus ioanniticus* and *Charinus israelensis* embryonic transcriptomes

178

179 As an empirical case of closely related, non-spider arachnoplumonate sister species pair
180 that constitutes one epigeal and one troglobitic species, we selected the whip spider species
181 *Charinus ioanniticus* and *C. israelensis* (Fig. 1 B–C). Whip spiders, arachnoplumonates of
182 the order Amblypygi, are commonly found in cave habitats ranging from rain forests,
183 savannahs and deserts (Weygoldt, 2000). The recently described troglobitic species *Charinus*
184 *israelensis* (reduced-eyes) occurs in close proximity to its congener *Charinus ioanniticus*
185 (normal-eyes) in caves in the Galilee, northern Israel (Miranda et al. 2016). Given that the
186 formation of Levantine cave refuges is considerably recent, *C. israelensis* and *C. ioanniticus*
187 are likely sister species with a small time of divergence, an inference supported by their
188 similar morphology (Miranda et al 2016). We collected ovigerous females from both species
189 in caves in Israel and extracted RNA from embryos (SI Appendix, Table S1). Embryos of
190 whip-spiders (*Phrynus marginemaculatus*) achieve a deutembryo stage around 20–25 days
191 after egg laying (dAEL), a stage where most external features of the embryo, such as
192 tagmosis and appendages are fully formed, but not the eyes (Weygoldt, 1975). The
193 deutembryo hatches from the egg membrane inside the broodsac carried by the mother, but
194 remains in this stage relatively unchanged for around 70 days. The eyes begin to form around
195 50 dAEL, but the eye spots become externally visible and pigmented only close to hatching
196 (90 dAEL) (Weygoldt, 1975).

197 For *de novo* assembly of the embryonic transcriptomes of *C. ioanniticus* and *C.*
198 *israelensis*, we extracted RNA from all embryonic deutembryo stages collected in the field
199 (see Supplementary Information; table 1 for localities and sample explanations). Assemblies
200 include two deutembryo stages before eyespot formation and one deutembryo stage bearing
201 eyespots for *C. ioanniticus*; and two early deutembryo stages for *C. israelensis* (SI Appendix,
202 Fig. S1).

203 The assembly of *C. ioanniticus* reads resulted in 219,797 transcripts composed of
204 143,282,365 bp with and N50 of 1122 bp (more than 50% of transcripts are 1122 bp or
205 longer) (SI Appendix, Table S2). Universal single copy ortholog benchmarking with BUSCO
206 v3.0 (Waterhouse et al., 2017) indicated 93.8% completeness, with 5.7% of BUSCO genes
207 exhibiting duplication.

208 The assembly *C. israelensis* resulted in a higher number of transcripts: 663,281
209 transcripts composed of 230,044,656 bp and with N50 of 1045 bp. The BUSCO analysis
210 shows 95.2% completeness, which is similar to the value for *C. ioanniticus* assembly.

211

212 RDGN gene duplication in *Charinus* whip spiders

213

214 Amblypygi is inferred to be nested stably in Arachnoplumonata, the clade of arachnids
215 that bear book lungs (Ballesteros & Sharma, 2019; Giribet, 2018; Lozano-Fernandez et al.,
216 2019; Rota-Stabelli et al., 2010; Sharma, Kaluziak, Pérez-Porro, González, Hormiga, et al.,
217 2014a). Recent evidence suggests that the common ancestor of arachnoplumonates has
218 undergone a whole- or partial-genome duplication affecting large gene families, such as
219 homeobox genes (Leite et al., 2018; Schwager et al., 2017; Sharma, Santiago, González-
220 Santillán, Monod, & Wheeler, 2015a). The stable phylogenetic position of Amblypygi in
221 Arachnoplumonata predicts that genes in RDGN that are duplicated in spiders, should also be
222 duplicated in *Charinus* whip spiders. To test this hypothesis, we performed phylogenetically-
223 informed orthology searches on the newly assembled embryonic transcriptomes of both
224 *Charinus* species, and conducted phylogenetic analysis with orthologs across selected
225 arthropod species. We discovered that homologs of *atonal*, *Pax6*, *dachshund*, *sine oculis*
226 (*Six1*), *Optix* (*Six3*), and *orthodenticle* are duplicated in *Charinus*, whereas *eyegone* and *eyes*
227 *absent* occur as single-copy orthologs (these latter two also occurring single-copy in spiders)
228 (Fig. 2).

229 *atonal*: The *atonal* gene tree showed poor resolution (SI Appendix, Fig. S2), hampering
230 unambiguous assignment of the whip spider genes to *atonal* copies previously annotated in
231 spiders (Samadi et al., 2015; Schwager et al., 2017). *D. melanogaster* copies of *atonal* and
232 *amos* clustered together forming a clade with other pancrustacean and myriapod sequences,
233 suggesting these paralogs are restricted to Mandibulata. The fruit fly *cousin of atonal* (*cato*)
234 formed a clade including the *Cupiennius salei* sequence of *atonalB* whereas the second copy
235 of *C. salei*, *atonaLA*, is found in an independent clade with only arachnid sequences. It is in
236 this later clade that the only sequences of *Charinus* related to *atonal* are found, in turn
237 forming two separate clades with clear amino acid differences between these copies (SI
238 Appendix, Dataset S1; *atonal* alignment). Herein, these copies are labeled *atonaLA* (*atoA*) and
239 *atonaLB* (*atoB*). Note that the reference genomic sequences, annotated as “*atonal like*
240 *homolog 8 like*” (Ptep XP 0159181091), is found orthologous to the gene *net* in *D.*
241 *melanogaster*.

242 *Pax6*: In *D. melanogaster*, there are two paralogous copies of the vertebrate *Pax6*, *eyeless*
243 and *twin of eyeless*. This duplication seems to be shared across all arthropods and both *Pax6*
244 copies have been characterized in spiders (Samadi et al., 2015; Schomburg et al., 2015). The
245 gene tree of *Pax6* homologues clearly identified a clade for *toy* including chelicerate and

246 mandibulate copies, but no *Charinus* sequences are found in this clade (SI Appendix, Fig.
247 S3). The sister clade (*eyeless*) consists only of pancrustacean sequences whereas the
248 chelicerate copies, previously annotated as *eyeless* orthologs, are found in a separate clade.
249 Among these, two distinct genes, herein dubbed *Pax6A* and *Pax6B*, are present in both
250 *Charinus* species. Sequence similarity searches (blastp) of both *Pax6A* and *Pax6B* against the
251 genome of *Drosophila melanogaster* points to *Dmel-toy* as the best hit, followed by *Dmel-ey*.
252 Therefore, although the homology of these copies with *Dmel-ey/toy* is evident, it is not trivial
253 to assign these to either of these genes or if these represent taxon-restricted duplicates of
254 *eyeless*.

255 *eyegone/twin of eyegone*: These members of the Pax gene family are paralogous in *D.*
256 *melanogaster* but occur as single copy in arachnids. Single copy orthologs of *eyg/toe* are
257 present in the two target Amblypygi species (SI Appendix, Fig. S3).

258 *dachshund*: Spiders and scorpions have two paralogous copies of *dachshund* (Nolan,
259 Santibáñez López, & Sharma, 2020; Turetzek et al., 2015). Two copies are present in the
260 transcriptomes of both *Charinus* species and are here termed *dacA* and *dacB* (SI Appendix,
261 Fig. S4). The *C. israelensis dacB* is assembled in two different gene fragments that overlap
262 by three amino acids (SI Appendix, Fig. S4; see *dachshund* alignment in SI Appendix
263 Dataset S1). The *C. ioanniticus dacA* copy is also assembled as two different gene fragments
264 with little sequence overlap but being part of the *dacA* clade (SI Appendix, Fig. S4).

265 *eyes absent*: This single-copy orthologs are found in arthropods and arachnids alike
266 and is represented in both *Charinus* species. The association of transcript to this gene is
267 unambiguous for both amblypid species (SI Appendix, Fig. S5).

268 *orthodenticle*: As with spiders, there are two copies homologous to *Dmel-otd* in
269 *Charinus*. The resolution of the gene tree is poor and does not allow uncontroversial
270 association to spider orthologs (SI Appendix, Fig. S6). *Charinus* copies are termed *otdA* and
271 *otdB*.

272 *Optix*: There are two very similar copies of *Optix* in *C. israelensis* and one in *C.*
273 *ioanniticus* (SI Appendix, Fig. S7). The *C. ioanniticus* copy is termed *OptixA*. The two copies
274 of *C. israelensis* show very conserved amino acid sequences but clear nucleotide differences.
275 Although the gene tree with the reference genome shows them more closely allied to one of
276 the spider paralogous copies of *Optix* (Ptep NP 00130752.1), a reduced analysis including
277 *Cupiennius salei* and *P. tepidariorum* copies, suggests that the *Charinus* copies are
278 independent duplications. Here the two whip spider copies are dubbed *OptixA* and *OptixB* but
279 they should not be considered orthologous to the spider *OptixA/B*.

280 *sine oculis*: Two copies of *sine oculis* are found in *C. israelensis* and one in *C.*
281 *ioanniticus*. Both copies are nested in a clade with *Ptep-soA* (SI Appendix, Fig. S8). These
282 are herein dubbed as *soA* and *soB* given that orthology with either spider copy is unclear.
283
284 RDGN genes in whip spider eye formation: comparing early and late stages of *C. ioanniticus*
285

286 The expression of paralog pairs of *Pax6*, *sine oculis*, *Optix*, *eyes absent*, *atonal*,
287 *dachshund* and *orthodenticle* in the developing eyes of the spiders (Samadi et al., 2015;
288 Schomburg et al., 2015), and the occurrence of the same paralogs in *Charinus* whip spiders,
289 suggest that these genes may also be involved in the formation of eyes in whip spiders. We
290 investigated this idea by comparing the expression levels of these RDGN genes in the stages
291 before eye-spot formation versus a stage after eye-spot formation in the eye-bearing whip
292 spider *Charinus ioanniticus* (henceforth “Comparison 1”; Fig. 3A).

293 We mapped reads of both treatments to the reference transcriptome of *C. ioanniticus*
294 using the quasi-alignment software Salmon v. 1.1.0 (Patro, Duggal, Love, Irizarry, &
295 Kingsford, 2017) and conducted a differential gene expression analysis of Comparison 1
296 using DESeq2 v 1.24.0 (Love, Huber, & Anders, 2014) (SI Appendix, Fig. S9). These
297 comparisons showed that *Cioa-dacA*, *Cioa-otdA*, *Cioa-eya* and *Cioa-soA* are significantly
298 over-expressed ($p_{\text{adj}} < 0.05$) in the eyespot stage in comparison with the stage before eyespot
299 formation (Fig. 3A). While we cannot rule out that the differences in gene expression are due
300 to other developmental differences between the two stages sequenced, these results
301 highlighted these four RDGN genes as promising candidates involved in the formation of
302 eyes in whip spiders.

303
304 RDGN genes in whip spider eye reduction: comparing *C. ioanniticus* and *C. israelensis*
305

306 Blindness in adults of the model cave fish *Astyanax mexicanus* is a result of an embryonic
307 process in which the rudimentary eye of the embryo is induced to degenerate by signals
308 emitted from the lens tissue (Jeffery, 2009). Both early and late expression of RDGN genes,
309 such as *Pax6*, are responsible for the reduction of eyes in fish from cave populations
310 (Jeffery, 2009; Strickler, Yamamoto, & Jeffery, 2001). Likewise, in the isopod crustacean
311 *Asellus aquaticus* cave blindness has a strong genetic component and mechanisms of eye
312 reduction also act at embryonic stages (Mojaddidi, Fernandez, Erickson, & Protas, 2018;
313 Protas et al., 2011). The embryonic development of the reduced-eyes whip spider *C.*

314 *israelensis* has not been explored to date, but we expect that reduction of eyes results from
315 changes in embryonic gene expression during the deutembryo stage (Weygoldt, 1975). We
316 investigated this possibility by quantifying the relative gene expression of RDGN genes in
317 comparable embryonic stages of *C. israelensis* (reduced eyes) and *C. ioanniticus* (normal
318 eyes) embryos before eye-spot formation (SI Appendix Table S1; Figure S1). Using the DGE
319 approach from Comparison 1, we conducted a heterospecific analysis using as the reference
320 either the *C. israelensis* transcriptome (henceforth “Comparison 2.1”) or the *C. ioanniticus*
321 transcriptome (henceforth “Comparison 2.2”).

322 Both analyses are anchored on the premise that a hybrid mapping between the sister
323 species is possible given the recent divergence between them. The mapping rate of the *C.*
324 *ioanniticus* reads was similar regardless of the reference species, (96.74% and 96.59%
325 respectively for *C. ioanniticus* and *C. israelensis*). In the case of the reads from *C. israelensis*
326 embryos, mapping rate to the conspecific (96.8%) transcriptome was higher than when
327 mapping against *C. ioanniticus* (82.45%). The similar mapping rate of *C. ioanniticus* reads
328 suggests that the two whip spiders are sufficiently closely related to generate interspecific
329 comparisons of gene expression. Comparisons 2.1 and 2.2 yielded similar results with respect
330 to the direction of differentially expressed RDGN genes (Fig. 3B–C). In comparison 2.1,
331 *Pax6A*, *OptixA* and *OptixB* are significantly over-expressed in the normal-eyes species, with
332 expression levels at least 4 times higher than in the reduced-eyes species ($\log_2FC > 2$; $p_{adj} <$
333 0.05) (Fig. 3B; SI Appendix, Fig. S10). In comparison 2.2, *Pax6A* and *OptixA* are also over-
334 expressed in *C. ioanniticus* ($p_{adj} < 0.05$), and so is *eyes absent* ($p_{adj} < 0.05$; Fig. 3C). In
335 comparison 2.2, *orthodenticle-B* appears under-expressed in the normal-eyes species ($p_{adj} <$
336 0.05 (Fig. 3C; SI Appendix, Fig. S11). We note that the magnitude of \log_2FC and
337 significance values differed considerably between analysis. Nonetheless, *Pax6A* and *OptixA*
338 were consistently over expressed in the normal-eyes species, highlighting these two genes as
339 promising candidates involved in the reduction of eyes in *Charinus israelensis*.

340

341 *sine oculis* is necessary for principal and secondary eye development in a model
342 arachnoplumate

343

344 Our bioinformatic analysis in the whip spider system suggested that *eyes absent* and
345 paralogs of *sine oculis*, *orthodenticle*, and *dachshund* may be involved in the normal
346 formation of eyes in *C. ioanniticus* (Comparison 1). We also found evidence that *Pax6* and a
347 paralog of *Optix* may be involved in the reduction of eyes in the cave whip spider *C.*

348 *israelensis*. To link bioinformatic reconstructions of gene expression with functional
349 outcomes, we interrogated the function of RDGN genes using parental RNA interference
350 (RNAi) in the spider *Parasteatoda tepidariorum*. We selected *Ptep-soA* (*Ptep-so1 sensu*
351 Schomburg et al. 2015), *Ptep-otdB* (*Ptep-otd2 sensu* Schomburg et al. 2015) and *Ptep-OptixB*
352 (*Ptep Six3.2 sensu* Schomburg et al. 2015). In *P. tepidariorum*, these genes are known to be
353 expressed in all eye types, in the median eyes only, and in the lateral eyes, respectively (Fig.
354 1D) (Schomburg et al., 2015).

355 Early expression of *Ptep-soA* is detected in lateral domains of the head lobes (stage 10)
356 corresponding to the principal and secondary eyes, and continues until the pre-hatching stage
357 14 (Schomburg et al., 2015). Expression of *Ptep-soA* on wild type stage 14.1 embryos is
358 bilaterally symmetrical on all eyes and uniformly strong (Fig. 4A–B). By stage 14.2, it
359 remains strong on the principal eyes but it is stronger at the periphery of the secondary eye
360 spots (Fig. 4A, C).

361 *P. tepidariorum* hatchlings, or postembryos, initially have no externally visible lenses and
362 pigment. The red pigment and lenses of all eyes, and the reflective tapetum of the lateral
363 eyes, become progressively recognizable in the 48 hours (at 26°C) until the animal molts into
364 the first instar with fully formed eyes (SI Appendix, Video S1) (see also Mittmann & Wolff,
365 2012). We fixed embryos from *Ptep-soA* dsRNA-injected and dH₂O-injected treatments
366 between 24h-48h, which encompasses stages where the eyes of postembryos are already
367 recognizable until the first instar.

368 Negative control experiments (dH₂O-injected females) yielded postembryos with eye
369 morphology indistinguishable from wild type animals: the median eyes (ME; principal eyes)
370 have an inferior semi-lunar ring of red pigment and lack the tapetum; and all pairs of lateral
371 eyes (secondary eyes) have the canoe-shaped tapetum type (Foelix, 2011; Land, 1985), which
372 is split in the middle and surrounded by red pigment (Fig. 5A; panel 1). We observed
373 misshaped tapeta on the lateral eyes of some postembryos on the earlier side of the
374 developmental spectrum of fixed animals, but that was never observed on postembryos close
375 to molting or first instars (SI Appendix, Fig. S12). It is unclear if this reflects a natural
376 variation of early developing tapetum or an artifact of sample preparation.

377 Embryos from *Ptep-soA* dsRNA-injected females are also able to hatch into postembryos
378 and continue molting to adulthood (SI Appendix, Video S2). However, a subset of the
379 embryos of dsRNA-injected treatment (9.5%; n=195/2049) exhibits a spectrum of eye defects
380 that was not observed on the controls (Fig. 5A–B; SI Appendix, Fig. S13). The defects
381 occurred on all eyes, namely median eyes (ME), anterior lateral eyes (ALE), posterior lateral

382 eyes (PLE), and medium lateral eyes (MLE) (Fig. 5A). Affected medium eyes have reduced
383 pigmentation or complete absence (Fig. 5A, panels 2–6), while lateral eyes also exhibited
384 defects of the tapetum or complete absence of the eye (Fig. 5A, panels 4–6).

385 We selected a subset of the knockdown postembryos initially scored as having any eye
386 defect (n=48) for quantifying the degree of effect per eye type, and the proportion of
387 symmetrical and mosaic eye phenotypes in our sample. Medium eyes are affected in almost
388 all cases (97%), whereas the three lateral eye types were similarly lowly affected (MLE:
389 14%; PLE: 8%; ALE: 10%) (Fig. 5C; SI Appendix, Fig. S12; detailed scoring criteria in
390 Material and Methods). The majority of defective eyes are mosaics, meaning that a given eye
391 pair is affected only on one side of the animal (Fig. 5C; SI Appendix, Fig. S12).

392 Parental RNAi against *Ptep-soA* did not completely abolish its expression, as detected by
393 in situ hybridization (Fig. 4D; see Material and Methods). Nevertheless, we detected
394 asymmetrical reduction of *Ptep-soA* expression on single eyes of a subset of stage 14
395 embryos (n=6/16; Fig. 4D), which closely correlates with the predominance of mosaic
396 phenotypes observed in late postembryos (Fig. 5C).

397 Parental RNAi experiments using the same protocol targeting *Ptep-otdB* and *Ptep-OptixB*
398 did not result in any detectable phenotypic effects on the eyes of embryos from dsRNA-
399 injected treatment (two and six females injected, respectively; counts not shown). These
400 results accord with a recent study that knocked down both *Optix* paralogs *P. tepidariorum*
401 and did not recover eye defects (Schacht et al., 2020)

402

403 Discussion

404

405 Paralogy of RDGN members in arachnoplumonates

406

407 Amblypygi have a critical placement within arachnid phylogeny, as they are part of a trio
408 of arachnid orders (collectively, the Pedipalpi, comprised of Amblypygi, Thelyphonida, and
409 Schizomida), which in turn is the sister group to spiders. Whereas the eyes of spiders have
410 greatly diversified in structure, function, and degree of visual acuity (particularly the eyes of
411 hunting and jumping spiders), the arrangement and number of eyes in Amblypygi likely
412 reflects the ancestral condition across Tetrapulmonata (= spiders + Pedipalpi), consisting of
413 three pairs of simple lateral ocelli and a pair of median ocelli; a similar condition is observed
414 in basally branching spider groups like Mesothelae and Mygalomorphae, as well as
415 Thelyphonida (vinegaroons). However, while developmental genetic datasets and diverse

416 genomic resources are available for spiders and scorpions (Oda & Akiyama-Oda, 2020;
417 Posnien et al., 2014; Schwager et al., 2017; Sharma, Schwager, Extavour, & Wheeler,
418 2014b), the developmental biology of the other three arachnopulmonate orders has been
419 virtually unexplored in the past four decades beyond a single work describing the
420 embryology of one North American amblypygid species (Weygoldt, 1975). To address this
421 gap, we focused our investigation on a sister species pair of cave whip spiders and generated
422 the first embryonic transcriptomes for this order. These datasets are immediately amenable to
423 testing the incidence of RDGN duplicates previously known only from two spiders (Samadi
424 et al., 2015; Schomburg et al., 2015) and their putative effects in patterning eyes across
425 Arachnopulmonata broadly.

426 The inference of a partial or whole genome duplication (WGD) in the most recent
427 common ancestor of Arachnopulmonata is supported by the systemic duplications of
428 transcription factors and synteny detected in the genomes of the scorpion *Centruroides*
429 *sculpturatus*, and the spider *Parasteatoda tepidariorum*, as well as homeobox gene
430 duplications detected in the genome of the scorpion *Mesobuthus martensii* and transcriptome
431 of the spider *Pholcus phalangioides* (Leite et al., 2018; Schwager et al., 2017). Additional
432 evidence comes from shared expression patterns of leg gap gene paralogs in a spider and a
433 scorpion (Nolan et al., 2020). Embryonic transcriptomes are particularly helpful in the
434 absence of genomes, as several duplicated genes, such as some homeobox genes, are only
435 expressed during early stages of development (Leite et al., 2018; Sharma, Santiago,
436 González-Santillán, Monod, & Wheeler, 2015a; Sharma, Schwager, Extavour, & Wheeler,
437 2014b). Our analysis of *Charinus* embryonic transcriptomes shows that RDGN gene
438 duplicates observed in spiders also occur in whip spiders, supporting the hypothesis that these
439 paralogous copies originated from a shared WGD event in the common ancestor of
440 Arachnopulmonata.

441 The conservation of some transcription factors patterning eyes is widespread in the
442 Metazoan tree of life (Vopalensky & Kozmik, 2009). In the model fruit fly *D. melanogaster*,
443 the homeobox Pax6 homolog, *eyeless*, was the first transcription factor identified as a “master
444 gene”, necessary for compound eye formation and capable of inducing ectopic eye formation
445 (Gehring & Ikeo, 1999; Kumar, 2009). The Pax6 protein is essential for eye formation across
446 several metazoan taxa, which has fomented ample debate about the deep homology of gene
447 regulatory networks in patterning structurally disparate eyes (Carroll, 2008; Shubin, Tabin, &
448 Carroll, 2009; Vopalensky & Kozmik, 2009). In the case of *sine oculis* (Six1/2), orthologs
449 are found across metazoans (Bebenek, Gates, Morris, Hartenstein, & Jacobs, 2004; Byrne et

450 al., 2017; Rivera et al., 2013). Evidence that *sine oculis* is required for the eye patterning in
451 other bilaterians comes from expression pattern in the developing eyes of the annelid
452 *Platynereis dumerilii* (Arendt, Tessmar, Medeiros de Campos-Baptista, Dorresteijn, &
453 Wittbrodt, 2002), and functional experiments in the planarian *Girardia tigrina* (Pineda et al.,
454 2000). Therefore, studies interrogating the genetic bases of eye formation in chelicerate
455 models have the potential to clarify which components of the eye gene regulatory network of
456 Arthropoda evolved in the MRCA of the phylum, and which reflect deep homologies with
457 other metazoan genes.

458

459 A conserved role for a *sine oculis* homolog in patterning arachnospulmonate eyes

460

461 The eyes of arthropods are diverse in number, arrangement, structure and function
462 (Paulus, 1979). Both types of eyes observed in Arthropoda, the faceted eyes (compound) and
463 single-lens eyes (ocelli), achieve complexity and visual acuity in various ways. To mention
464 two extremes, in Mandibulata the compound eyes of mantis shrimps (Stomatopoda) achieve a
465 unique type of color vision and movements by using 12 different photoreceptive types and
466 flexible eye-stalks (Daly, How, Partridge, & Roberts, 2018; Marshall, Cronin, & Kleinlogel,
467 2007; Thoen, How, Chiou, & Marshall, 2014). In Arachnida, the simple-lens median eyes of
468 some jumping spiders (Salticidae) have exceptional visual acuity in relation to their eye size,
469 achieve trichromatic vision through spectral filtering, and can move their retina using
470 specialized muscles (Harland, Li, & Jackson, 2012; Land, 1985; Zurek et al., 2015).

471 Comparative anatomy suggests that the common ancestor of Arthropoda had both lateral
472 compound eyes and median ocelli that then became independently modified in the arthropod
473 subphyla (Morehouse et al., 2017; Paulus, 1979). While in situ hybridization data for selected
474 RDGN genes across arthropods generally support the hypotheses of eye homology,
475 comparative developmental datasets remain phylogenetically sparse outside of Pancrustacea
476 (Samadi et al., 2015; Schomburg et al., 2015)

477 We therefore applied a bioinformatic approach in a study system that lacked any genomic
478 resources (Amblypygi) to assess whether RDGN homologs are transcriptionally active during
479 the formation of eyes in the eye-bearing *C. ioanniticus* (Comparison 1), as well as those that
480 may be putatively involved in eye loss in its troglobitic sister species (Comparison 2). As first
481 steps toward understanding how arachnid eyes are patterned, our experiments demonstrated
482 that *soA*, a *sine oculis* paralog identified as differentially expressed during the formation of
483 eyes in *C. ioanniticus*, is necessary for patterning all eyes of a model arachnid system with

484 the same eye configuration (*Parasteatoda tepidariorum*). Thus, we provide the first
485 functional evidence that part of the RDGN is evolutionarily conserved in the most recent
486 common ancestor (MRCA) of insects and arachnids, and by extension, across Arthropoda.

487 The advantage of such a bioinformatic approach is that it can potentially narrow the range
488 of candidate genes for functional screens, due to the inherent challenges imposed by paralogy
489 when assessing gene function. Eye reduction in the cave fish *Astyanax mexicanus* has been
490 shown to involve differential expression of genes known to be involved in eye patterning in
491 model organisms, such as *hedgehog* and *Pax6* (*eyeless/toy*) (Jeffery, 2009; Protas & Jeffery,
492 2012). In addition, other “non-traditional” candidates have been identified, such as *hsp90*
493 (Jeffery, 2009). Likewise, evidence from quantitative trait loci mapping in cave populations
494 of the troglobitic crustacean *Asellus aquaticus* shows that eye loss phenotype is correlated
495 with loci that are not part of the RDGN (Protas et al., 2011; Protas & Jeffery, 2012). The
496 results of the DGE analysis in whip spiders underscore the potential of a DGE approach to
497 triangulate targets among candidate genes in non-model species more broadly. Future efforts
498 in the *Charinus* system should focus on dissecting individual eye and limb primordia of
499 embryos of both species, in order to identify candidate genes putatively involved in the
500 reduction of each eye type, as well as compensatory elongation of the sensory legs of the
501 troglobitic species, toward downstream functional investigation.

502

503 Do gene duplications play a role in the functional diversification of arachnoplumonate eyes?

504

505 A challenge in studying arachnoplumonate models to understand ancestral modes of eye
506 patterning in Arthropoda is the occurrence of RDGN duplicates in this lineage. Our orthology
507 searches and phylogenetic analysis showed that the evolutionary history of genes is not
508 always resolved using standard phylogenetic methods, as short alignable regions and/or
509 uncertainty of multiple sequence alignments can result in ambiguous gene trees. One way to
510 circumvent this limitation is by analyzing expression patterns via in situ hybridization
511 between paralogs in different arachnids in order to determine which patterns are
512 plesiomorphic (Leite et al., 2018; Nolan et al., 2020; Turetzek et al., 2015). Nonetheless, the
513 possibility of subfunctionalization and neofunctionalization may also complicate such
514 inferences because discerning one process from the other is analytically challenging (Sandve,
515 Rohlf, & Hvidsten, 2018).

516 Genetic compensation of gene paralogs is another confounding variable, which can be
517 accounted for by experimental advances in model organisms (e.g., Shull et al., 2020). We

518 note that the overall penetrance in this experiment is low (9.5%) when compared to some
519 studies in *P. tepidariorum* (e.g., Khadjeh et al 2012; >59% in *Ptep-Antp* RNAi). Wide
520 variance in penetrance has been reported by several research groups in this system, with
521 phenotypic effects varying broadly even within individual experiments (e.g., Fig. 5 of
522 Akiyama-Oda & Oda, 2006; Fig. S5 of Schwager, Pechmann, Feitosa, McGregor, & Damen,
523 2009). Furthermore, some genes have empirically proven intractable to misexpression by
524 RNAi in *P. tepidariorum*, with one case suggesting functional redundancy of posterior Hox
525 genes to be the cause (Khadjeh et al., 2012). Double knockdown experiments have been
526 shown to exhibit poor penetrance (0-1.5%) in *P. tepidariorum* as well (Fig. S3 of Khadjeh et
527 al. 2012; Fig. S1 of Setton et al., 2017), and to our knowledge, no triple knockdown has ever
528 been achieved. While we cannot rule out functional redundancy with other RDGN paralogs
529 in the present study, the low penetrance we observed may also be partly attributable to our
530 conservative phenotyping strategy (see Material and Methods), which did not assess a
531 possible delay in eye formation and emphasized dramatic defects in eye morphology for
532 scoring.

533 The occurrence of RDGN gene duplications in Arachnoplumonata, in tandem with
534 improving functional genetic toolkits in *P. tepidariorum* (e.g., Pechmann, 2016), offers a
535 unique opportunity of studying the role of sub- and neofunctionalization in the development
536 of their eyes, and a possible role of this process in the diversification of number, position and
537 structure of the eyes in an ancient group of arthropods (Harland et al., 2012; Land, 1985;
538 Morehouse et al., 2017; Paulus, 1979; Zurek et al., 2015). The genomes of mites, ticks, and
539 harvestmen (Grbić et al., 2011; Hoy et al., 2016) (Gulia-Nuss et al., 2016) reveal that
540 apulmonate arachnid orders have not undergone genome duplication events as seen in
541 Arachnoplumonata (Schwager et al., 2017), or horseshoe crabs (Kenny et al., 2015; Nossa et
542 al., 2014; Zhou et al., 2020). Future comparative studies focused on understanding the
543 ancestral role of chelicerate RDGN genes should additionally prioritize single-copy orthologs
544 in emerging model systems independent of the arachnoplumonate gene expansion, such as
545 the harvestman *Phalangium opilio* (Sharma et al., 2013; Sharma, Schwager, Extavour, &
546 Giribet, 2012).

547

548 **Materials and Methods**

549

550 Animal collection

551

552 Three ovigerous females of the normal-eyes species, *Charinus ioanniticus* (ISR021-2;
553 ISR021-3; ISR021-4), and two egg-carrying females of the reduced-eyes species, *Charinus*
554 *israelensis* (ISR051-4; ISR051-6), were hand collected in caves in Israel in August 2018
555 (Supplementary Information; Table 1). Females were sacrificed and the brood sacs
556 containing the embryos were dissected under phosphate saline buffer (PBS). For each female,
557 a subset of the embryos (5 to 13 individuals) was fixed in RNAlater solution after poking a
558 whole into the egg membrane with fine forceps, while the remaining embryos of the clutch
559 were fixed in a 4% formaldehyde/PBS solution to serve as vouchers (SI Appendix, Table S1).
560 Adult animals and embryos of *Parasteatoda tepidariorum* were obtained from the colony at
561 UW-Madison, US.

562

563 Transcriptome assembly for *Charinus* whip spiders

564

565 RNAlater-fixed embryos were transferred to 1.5mL tubes filled with TRIZOL
566 (Invitrogen) after two months, and subject to RNA extraction. Total RNA extracted from
567 each sample of the embryos of *C. ioanniticus* (three samples) and *C. israelensis* (two
568 samples) (SI Appendix, Table S1) was submitted for library preparation at the Biotechnology
569 Center of the University of Wisconsin-Madison. Each sample was sequenced in triplicate in
570 an Illumina High-Seq platform using paired-end 100 bp-long read strategy at the same
571 facility. Read quality was assessed with FastQC (Babraham Bioinformatics). Paired-end
572 reads for *C. ioanniticus* (ISR021) and *C. israelensis* (ISR051) were compiled and *de novo*
573 assembled using Trinity v.3.3 (Grabherr et al., 2011) enabling Trimmomatic v.0.36 to remove
574 adapters and low-quality reads (Bolger, Lohse, & Usadel, 2014). Transcriptome quality was
575 assessed with the Trinity package script '*TrinityStats.pl*' and BUSCO v.3 (Waterhouse et al.,
576 2017). For BUSCO, we used the 'Arthropoda' database and analyzed the transcriptomes
577 filtered for the longest isoform per Trinity gene.

578

579 RNA sequencing for differential gene expression

580

581 The total RNA extraction of each sample of *C. ioanniticus* and *C. israelensis* embryos
582 was sequenced in triplicate in an Illumina High-Seq platform using a single-end 100 bp-long
583 read strategy in the same facility as described above. For *C. ioanniticus* (normal-eyes), we
584 sequenced two biological replicates of embryos at an early embryonic stage, before eye-spot
585 formation (ISR021-2, ISR021-3), and one sample of late embryos, after eye-spot formation

586 (ISR021-4); For *C. israelensis* (reduced-eyes), we sequenced embryos at an early embryonic
587 stage (ISR051-6; ISR051-4) comparable to the early stage in *C. ioanniticus* (ISR021-2,
588 ISR021-3), as inferred by the elongated lateral profile of the body and marked furrows on the
589 opisthosomal segments (SI Appendix, Fig. S1).

590

591 Differential gene expression analysis in *Charinus* and identification of eye gene orthologs

592

593 Orthologs of *Drosophila melanogaster* *eyeless* and *twin of eyeless* (*Pax6A*, *Pax6B*), *sine*
594 *oculis* (*soA*, *soB*), *orthodenticle* (*otdA*, *otdB*), *Optix* (*Six3.1*, *Six3.2*), *dachshund* (*dacA*, *dacB*),
595 and *eyes absent* (*eya*) had been previously isolated in *Parasteatoda tepidariorum*
596 (Schomburg et al., 2015, and references therein). We used as reference sequences the
597 complete predicted transcripts for these genes from *P. tepidariorum* genome (Schwager et al.,
598 2017), *Cupiennius salei* (Samadi et al., 2015) (for *atonal* and *Pax6*), and *D. melanogaster*,
599 including also *atonal* and *eyegone* from the latter species. The sequences were aligned with
600 MAFFT (v7.407) (Kato & Standley, 2013) and the resulting alignment used to build hidden
601 Markov model profiles for each gene (hmmbuild, from the hmmer suite v.3.3) (Finn et al.,
602 2015). Matches to these profiles were found using hmmsearch in the reference transcriptomes
603 of *C. ioanniticus* and *C. israelensis* as well as in the genomes of representative arthropods
604 including *D. melanogaster* (GCA 000001215.4), *Tribolium castaneum* (GCA 000002335.3),
605 *Daphnia magna* (GCA 003990815.1), *Strigamia maritima* (GCA 000239455.1),
606 *Dinotrombium tinctorium* (GCA 003675995.1), *Ixodes scapularis* (GCA 002892825.2),
607 *Tetranychus urticae* (GCA 000239435.1), *Limulus polyphemus* (GCA 000517525.1),
608 *Tachypleus tridentatus* (GCA 004210375.1), *Centruroides sculpturatus* (GCA 000671375.2),
609 *Parasteatoda tepidariorum* (GCA 000365465.2) and *Trichonephila clavipes* (GCA
610 002102615.1). These species were selected from a pool relatively recent genome assembly
611 resources and well curated reference genomes.

612 Homologous sequences (those with hmmer expectation value, $e < 10^{-10}$) to the genes of
613 interest were then compiled into individual gene FASTA files, combined with the reference
614 sequences used for the homology search, aligned (MAFFT), trimmed of gap rich regions
615 (trimAL v.1.2, -gappyout) (Capella-Gutiérrez, Silla-Martínez, & Gabaldón, 2009) and used
616 for maximum likelihood gene tree estimation (IQTREE v.1.6.8, -mset
617 LG,WAG,JTT,DCMUT -bb 1000) (Nguyen, Schmidt, Haeseler, & Minh, 2015). The
618 association of transcripts in the *Charinus* species with the genes of interest is based on the
619 gene phylogeny and was followed by inspection of the coding sequences to distinguish

620 splicing variants from other gene copies. Alignments and the list of *Charinus* sequences is
621 available in SI Appendix Dataset S1. These gene transcript association was then used for the
622 transcript to gene map required for the DGE analysis.

623

624 Read mapping, transcript abundance quantification

625

626 For the *in-silico* analysis of gene expression, single-end raw reads were first trimmed
627 using the software Trimmomatic v. 0.35 (Bolger et al., 2014). For the intra-specific analysis
628 of early (before eyespot) and late (eyespot) embryos of *C. ioanniticus* (Comparison 1), the
629 trimmed reads were quantified in the embryonic transcriptome of *C. ioanniticus*. For the
630 intra-specific comparison of early embryos of *C. ioanniticus* and *C. israelensis*, two
631 reciprocal analysis were conducted: reads from both species mapped onto *C. israelensis*
632 transcriptome as the reference (Comparison 2.1); and reads from both species mapped onto
633 *C. ioanniticus* transcriptome (Comparison 2.2).

634 Transcript abundance was quantified using the software Salmon v. 1.1.0 (Patro et al.,
635 2017), enabling ‘*-validateMapping*’ flag. Analysis of differential gene expression was
636 conducted with the software DESeq2 v 1.24.0 (Love et al., 2014) following a pipeline with
637 the R package *tximport* v.1.12.3 (Soneson, Love, & Robinson, 2015). The exact procedures
638 are documented in the custom R script (SI Appendix, Dataset S2)

639

640 Parental RNA interference, in situ hybridization, and imaging in *Parasteatoda tepidariorum*

641

642 Total RNA from a range of embryonic stages of *P. tepidariorum* was extracted with
643 TRIZOL (Invitrogen), and cDNA was synthesized using SuperScriptIII (Invitrogen). Gene
644 fragments for *Ptep-sine oculis A (soA)*, *orthodenticle B (otdB)* and *OptixB* were amplified
645 from cDNA using gene specific primers designed with Primers3Web version 4.1.0
646 (Koressaar & Remm, 2007) and appended with T7 ends. Cloning amplicons were generated
647 using the TOPO TA Cloning Kit with One Shot Top10 chemically competent *Escherichia*
648 *coli* (Invitrogen). Amplicon identities and directionality were assessed with Sanger
649 sequencing. Primer, amplicon sequences and fragment lengths are available in SI Appendix
650 Dataset S3. Double-stranded RNA for *Ptep-soA*, *Ptep-otdB* and *Ptep-OptixB* was synthesized
651 from amplicon on plasmids using MEGAScript T7 transcription kit (Thermo Fischer) with
652 T7/T7T3 primers. Sense and antisense RNA probes for colorimetric in situ hybridization

653 were synthesized from plasmid templates with DIG RNA labeling mix (Roche) and T7/T3
654 RNA polymerase (New England Biolabs) using the manufacturer's instructions.

655 Parental RNA interference (RNAi) followed established protocols for double-stranded
656 RNA (dsRNA) injection in virgin females of *P. tepidariorum* (Oda & Akiyama-Oda, 2020).
657 Each female was injected four times with 2.5 μ L of dsRNA at a concentration of 2 μ g/ μ L, to
658 a total of 20 μ g. For *Ptep-soA*, seven virgin females were injected with dsRNA of a 1048bp
659 cloned fragment (SI Appendix, Fig. S13C) and 3 females were injected with the same volume
660 of dH₂O as a procedural control. Two virgin females were injected with dsRNA for *Ptep-*
661 *otdB*, and six females for *Ptep-OptixB*. All females were mated after the second injection, and
662 were fed approximately every-other day after the last injection. Cocoons were collected until
663 the sixth clutch, approximately one per week.

664 Hatchlings for all cocoons were fixed between 24–48 hours after hatching. Freshly
665 hatched postembryos have almost no external signs of eye lenses and pigments. The selected
666 fixation window encompasses a period in which postembryos have deposited eye pigments
667 until the beginning of the first instar, where eyes are completely formed (SI Appendix, Video
668 S1, S2). Hatchlings were immersed in 25% ethanol/PBST and stored at 4°C. For the *Ptep-soA*
669 RNAi experiment, hatchlings were scored in four classes: (1) wild type, where all eyes were
670 present and bilaterally symmetrical; (2) Eyes defective, where one or more eyes were reduced
671 in size or completely absent; (3) dead/arrested; (4) Undetermined, where embryos were
672 damaged or clearly freshly hatched. A subset of *Ptep-soA* dsRNA-injected embryos from four
673 clutches (n=48) and of three control clutches (n=48) were further inspected in detail to assess
674 the effects on individual eye types. Given that there is a spectrum on the intensity of pigment
675 deposition in the medium eyes (ME), and small asymmetries on the shape of the early
676 developing tapetum of the lateral eyes (LE) in control embryos, the following conservative
677 criteria was adopted: ME were considered affected when asymmetry in pigmentation or lens
678 size was detected. Both ME were only scored as affected when they were both completely
679 missing, in order to rule out embryos were simply delayed in pigment deposition; LE were
680 considered defective only when the tapetum was completely absent (SI Appendix, Fig. S12).
681 Therefore, our coding does not allow detection of a phenotype consisting of delayed
682 pigmentation.

683 For in situ hybridization, a subset of *Ptep-soA* dsRNA-injected embryos at stage 13/14
684 (Mittmann & Wolff, 2012) was fixed in a phase of heptane and 4% formaldehyde for 12–24
685 hours, washed in PBST, gradually dehydrated in methanol and stored at -20°C for at least 3

686 days before downstream procedures, after a modified protocol of Akiyama-Oda and Oda
687 (2003). In situ hybridization followed the protocol of Akiyama-Oda and Oda (2003).

688 Embryos from in situ hybridization were stained with Hoechst nuclear staining and
689 imaged in a Nikon SMZ25 fluorescence stereomicroscope mounted with a DS-Fi2 digital
690 color camera (Nikon Elements software). For postembryos, the prosoma was dissected with
691 fine forceps, gradually immersed in 70% Glycerol/PBS-T and mounted on glass slides.
692 Postembryos were imaged using an Olympus DP70 color camera mounted on an Olympus
693 BX60 epifluorescence compound microscope.

694

695 **Acknowledgements**

696

697 Microscopy was performed at the Newcomb Imaging Center, Department of Botany,
698 University of Wisconsin-Madison. Sequencing was performed at the UW-Madison
699 Biotechnology Center. Access to computing nodes for intensive tasks was provided by the
700 Center for High Throughput Computing (CHTC) and the Bioinformatics Resource Center
701 (BRC) of the University of Wisconsin–Madison. Specimens were collected under permit
702 2018/42037, issued by the Israel National Parks Authority to E.G.R. Fieldwork in Israel was
703 supported by a National Geographic Society Expeditions Council grant no. NGS-271R-18 to
704 J.A.B. This work was supported by National Science Foundation (grant no. IOS-1552610) to
705 P.P.S.

1068 Figure 1: Species used in this study and their eye arrangement. A: Schematic representation
1069 of the eyes of *Charinus* whip spiders (Amblypygi) (upper), and the spider *Parasteatoda*
1070 *tepidariorum* (Araneae; lower). B: Live specimen of *C. ioanniticus* from Khirbet Haruba
1071 cave (Haruva cave). Inset: detail of the median eyes. C: Live specimen of *C. israelensis*
1072 from Mimlach cave. Inset: detail of the reduced median eyes. D: Live specimen of
1073 *Parasteatoda tepidariorum*, and schematic representation of the expression patterns of
1074 paralog pairs of *Ptep-sine oculis* (*soA/soB*), *Ptep-orthodenticle* (*otdA/otdB*), and *Ptep-*
1075 *Optix* (*OptixA/OptixB*) in the eyes. ME: median eyes; ALE: anterior lateral eyes; PLE:
1076 posterior lateral eyes; MLE: median lateral eyes; LE: lateral eyes.

1077

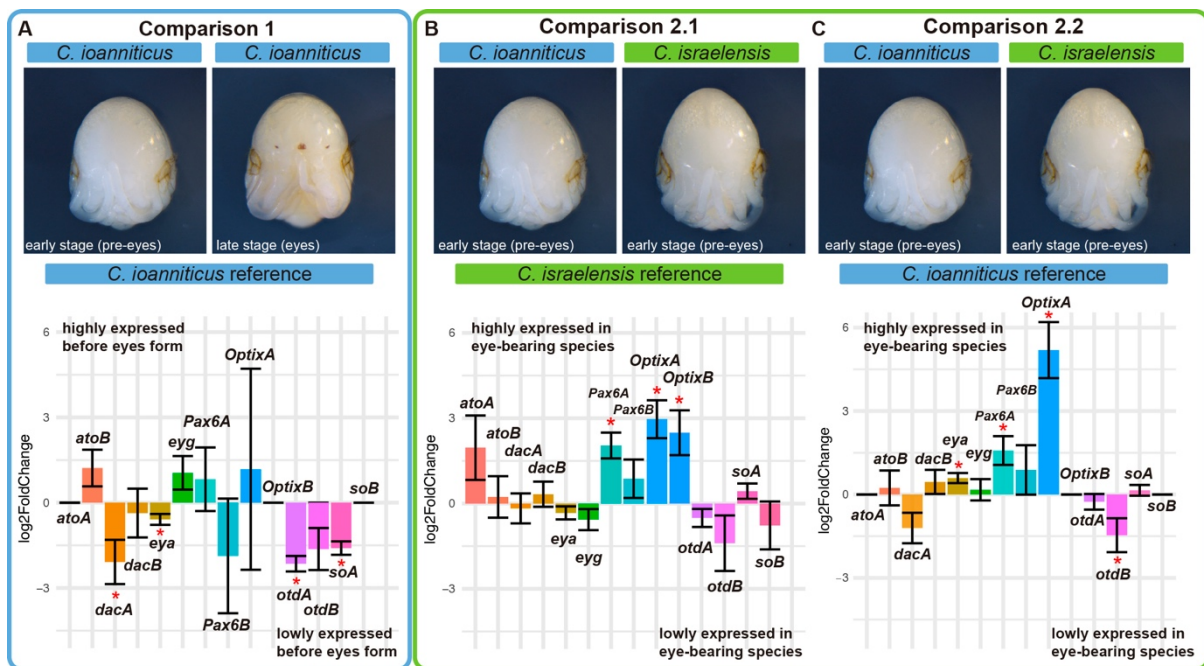

1078 Figure 2: Phylogenetic distribution of Retinal Determination Gene Network (RDGN) genes
 1079 in an insect (*Drosophila melanogaster*), a non-arachnoplumonate arachnid group
 1080 (Acariformes: *Dinothrombium tinctorium*; *Tetranychus urticae*) and Arachnoplumonata
 1081 (spider: *Parasteatoda tepidariorum*; scorpion: *Centruroides sculpturatus*), including
 1082 newly discovered orthologs in *Charinus* whip spiders (Amblypygi). Colored squares
 1083 indicate number of gene copies for each RDGN gene. Dotted squares indicate missing
 1084 data, not gene loss. For comprehensive list of duplicated genes in Arachnoplumonata see
 1085 Schwager et al. (2017) and Leite et al. 2018. Gene trees and alignments for each gene are
 1086 available in SI Appendix Dataset S1.

1087

1088

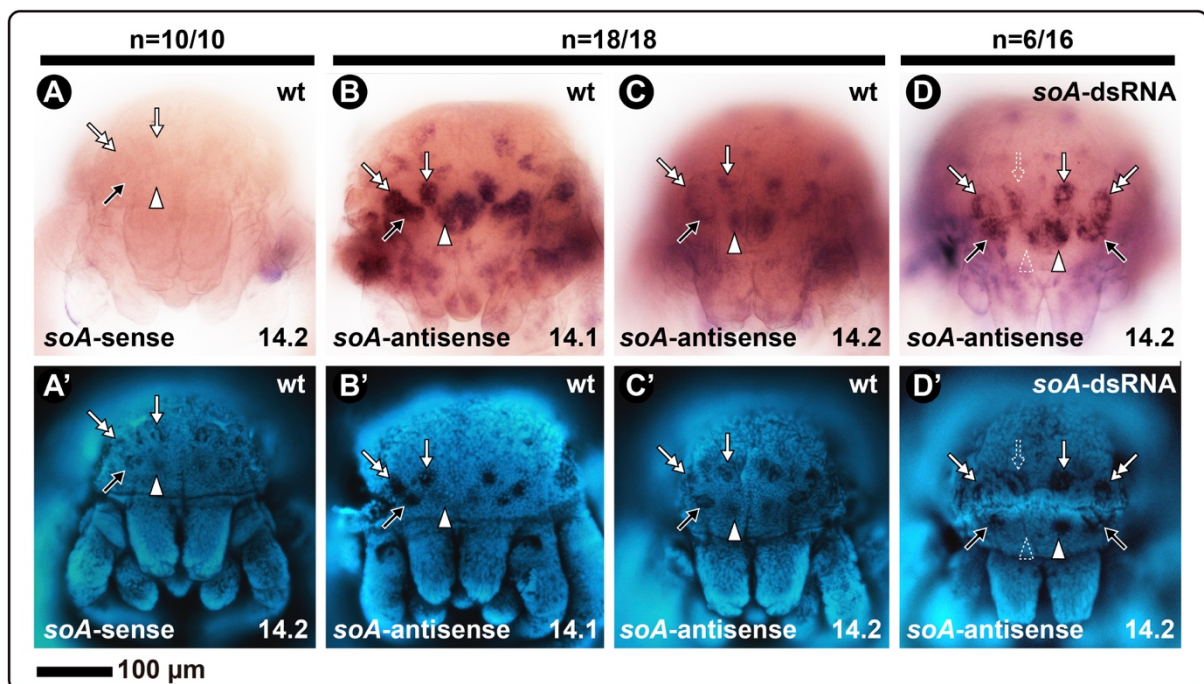

1089 Figure 3: Differential gene expression analysis of Retinal Determination Gene Network
 1090 (RDGN) genes in *Charinus* whip spider deutembryos. Bar graphs display \log_2 fold
 1091 change of selected RDGN genes. Direction of differential gene expression always
 1092 follows sample to the left. A: Comparison 1; Comparison between reads of early (pre-
 1093 eyespot) and late deutembryos (eyespot) of the eye-bearing species *C. ioanniticus*
 1094 mapped onto *C. ioanniticus* transcriptome. B: Comparison 2.1; Comparison between
 1095 reads of early deutembryo of *C. ioanniticus* and early deutembryo of *C. israelensis*
 1096 mapped onto *C. israelensis* transcriptome. C: Comparison 2.2; Comparison between
 1097 reads of early deutembryo of *C. ioanniticus* and early deutembryo of *C. israelensis*
 1098 mapped onto *C. ioanniticus* transcriptome. *atoA/B*: *atonaA/atonaB*; *dacA/B*:
 1099 *dachshundA/B*; *eya*: *eyes absent*; *eyg*: *eyegone*; *otdA/B*: *orthodenticleA/B*; *soA/B*: *sine*
 1100 *oculisA/B*. Asterisks denote genes that were differentially expressed with a $p_{adj} > 0.05$.
 1101 $\log_2FC = 0$ for *atoA*, *OptixB*, and *soB* for Comparison 1 and Comparison 2.2 are due to
 1102 the absence of those paralogs in *C. ioanniticus* reference transcriptome.

1103

1104

1105 Figure 4: In situ hybridization using DIG-labeled riboprobes for *Ptep-soA* in late embryos of
1106 the spider *Parasteatoda tepidariorum*. All embryos in frontal view. A–D: bright field
1107 images. A'–D': Same embryos, in Hoechst staining. A: Sense probe of a stage 14.2
1108 embryo (no signal). B: Antisense probe on a wild type stage 14.1 embryo. C: Antisense
1109 probe on a wild type stage 14.2 embryo. D: Antisense probe on a stage 14.2 embryo from
1110 the *Ptep-soA* dsRNA-injected treatment. *soA*: *sine oculis A*. White arrowhead: median
1111 eye; Black arrow: anterior lateral eye; White arrow: median lateral eye; Double white
1112 arrow: Posterior lateral eye. Dotted arrowhead/arrow indicate asymmetrical expression
1113 and eye defect. Sample sizes are indicated above each treatment.

1114

1115

1116 Figure 5: RNA interference against *Ptep-sine oculis A*. A: Bright field images of the spider
 1117 *Parasteatoda tepidariorum* postembryos resulting from control treatment (dH₂O-
 1118 injected, panel 1) and double stranded RNA (dsRNA) injected treatment (panels 2–6), in
 1119 frontal view. B: Frequencies of each phenotypic class per treatment from the combined
 1120 clutches of all females. See SI Appendix Fig. S13 for counts per clutch. C: Frequencies
 1121 of symmetrical, asymmetrical, and wild type eyes quantified from a subset of 48
 1122 individuals with eye reduction phenotype. See SI Appendix Fig. S12 for figures of all
 1123 specimens and coding, and Material and Methods for the scoring criteria. ME: median
 1124 eyes; ALE: anterior lateral eyes; PLE: posterior lateral eyes; MLE: median lateral eyes.
 1125 Schematics for the different eye types follows the nomenclature in Figure 1.
