The plate-to-rod transition in trabecular bone loss is elusive

Changes in trabecular micro-architecture are key to our understanding of osteoporosis. Previous work focusing on structure model index (SMI) measurements have concluded that disease progression entails a shift from plates to rods in trabecular bone, but SMI is heavily biased by bone volume fraction. As an alternative to SMI, Ellipsoid Factor (EF) has been proposed as a continuous measure of local trabecular shape between plate-like and rod-like extremes. We investigated the relationship between EF distributions, SMI and bone volume fraction of the trabecular geometry in a murine model of disease osteoporosis as well as from human vertebrae of differing bone volume fraction. We observed a moderate shift in EF median (at later disease stages in mouse tibia) and EF mode (in the vertebral samples with low bone volume fraction) towards a more rod-like geometry, but not in EF maximum and minimum. These results support the notion that the plate to rod transition does not coincide with the onset of bone loss and is considerably more moderate, when it does occur, than SMI suggests. A variety of local shapes not straightforward to categorise as rod or plate exist in all our trabecular bone samples.

1. Introduction

The metabolic bone disease osteoporosis is a major health concern associated with high mortality rates and considerable economic costs [1,2], likely to be exacerbated by the increase in the proportion of elderly

© 2014 The Authors. Published by the Royal Society under the terms of the Creative Commons Attribution License <http://creativecommons.org/licenses/by/4.0/>, which permits unrestricted use, provided the original author and source are credited.

2 people in future demographics. In this disease, imbalance between osteoblastic (bone-forming)
3 and osteoclastic (bone-resorbing) cell activity is thought to lead to lower bone turnover and
4 relatively higher resorption than formation, and thus to a lower amount of bone [3]. Lower bone
5 mass causes reduced mechanical competence and increased fracture risk with age [4].

6 The large amount of bone surface relative to bone volume in trabecular bone (compared to
7 cortical bone) may make it particularly sensitive to shifts in the bone remodelling balance [5].
8 Beyond the loss of bone volume fraction in the trabecular bone compartment, changes in tissue
9 morphology may contribute to the deterioration of bone quality of osteoporotic patients. Because
10 such osteoporosis-related changes to the trabecular bone micro-architecture form a link between
11 the bone (re)modelling balance at a tissue level and the mechanical performance of the bone
12 organ, they are key to our understanding of the disease.

13 Prominent amongst parameters considered when evaluating tissue-level morphological
14 changes is *structure model index* (SMI) [6]. SMI was designed to estimate how rod- or plate-like
15 a trabecular geometry is [7]. Evaluation of SMI across a number of data sets from human patients
16 and animal models suggests that trabecular geometry transitions from being more plate-like to
17 more rod-like as osteoporosis severity increases ("plate-to-rod transition") [8–12]. However, it is
18 well known that SMI correlates strongly with bone volume fraction, rendering the comparison
19 of SMI values between samples of vastly different bone volume fraction (such as osteoporotic
20 samples versus healthy control samples) dubious. Furthermore, the concept of SMI is based on
21 relative changes in surface area in response to a small dilation, and relies on the fact that dilating
22 a convex shape (such as a sphere (SMI=4), a cylinder (SMI=3), or a infinite plane (SMI=1) always
23 creates a larger surface area. This is not the case in trabecular bone, because parts of the trabecular
24 bone surface are concave and become smaller when the volume is expanded [13].

25 Ellipsoid Factor (EF) has been proposed as an alternative method to measure the plate-to-rod
26 transition in trabecular bone [14]. EF has since been used within and beyond bone biology (e.g.
27 bone surgical implant testing [15] and the characterisation of the trabecular bone phenotype of
28 genetic dwarfism [16], of the primate mandible [17], of the human tibia [18], and of animal models
29 of osteoarthritis [19], but also studies of fuel cell performance [20,21]). Apart from the original
30 critique of SMI [13], as far as we know, there have been no further reports of EF in osteoporotic
31 samples in the literature.

32 In this study, we expand on our two previous studies on the use of EF and the putative
33 plate-to-rod transition in osteoporosis [13,14]. Specifically, we present new EF data on trabecular
34 bone from an animal model of disuse osteoporosis as well as from human second lumbar (L2)
35 vertebral bodies from women of varying age and bone volume fraction. The aim of the study is to
36 investigate the association between variables describing the trabecular architecture (EF and SMI)
37 and bone health. Our EF data relies on an updated and validated implementation of EF (details
38 in Supplementary Material (a)) available freely as part of the latest BoneJ, a collection of ImageJ
39 plug-ins intended for skeletal biology [22].

40 2. Methods

41 (a) EF algorithm

42 The EF algorithm was first reported in a previous study [14] and is explained here again due to
43 its fundamental relevance to the present study.

EF is a scalar value assigned to each foreground pixel in the three-dimensional binary image
stack of interest. The EF of each pixel depends on the maximal ellipsoid that contains the pixel
and that is contained in the image foreground. Denoting the axis lengths of the maximal ellipsoid
as a, b and c (with $a \leq b \leq c$), EF of each pixel is calculated as a difference of sorted axis ratios

$$EF = \frac{a}{b} - \frac{b}{c}$$

44 EF is confined between -1 and 1, with -1 being very plate-like, and 1 very rod-like.

45 Ellipsoid Factor is calculated by fitting locally maximal ellipsoids into the image foreground,
46 then iterating over the foreground pixels to find the largest ellipsoid in which each pixel is
47 contained. Note that the locally maximal ellipsoid is generally non-unique (Supplementary
48 Material ii).

49 (i) Ellipsoid fitting

50 First, points where a small sphere can start to grow ("seed points") are determined. Two
51 strategies for finding seed points exist. The first is called distance-ridge based seeding. It involves
52 subtracting the results of a morphological opening and a closing operations on the distance
53 transform of the input image from each other. The second is a topology-preserving skeletonisation
54 [23]. Distance-ridge based seeding is computationally more efficient than skeletonisation in
55 practice, but it may miss thin features that skeletonisation preserves well and may overestimate
56 the number of seed points needed to fit ellipsoids to a plate.

57 After being seeded, each spherical ellipsoid grows uniformly by one user-defined increment at
58 a time until a number of surface points equal to the user-defined "contact sensitivity" parameter
59 hit the trabecular bone boundary (a background pixel). Surface points are chosen from a random
60 uniform distribution on the ellipsoid surface.

61 When the growing ellipsoid hits the trabecular bone boundary for the first time, the vector
62 from the ellipsoid centre to the average contact point is set as the first ellipsoid axis and the
63 ellipsoid is contracted slightly. Growth of the ellipsoid then continues in the plane orthogonal
64 to this first axis, again until the boundary is hit. This initial ellipsoid fitting is following by a
65 series of small random rotations, translations and dilations of the ellipsoid in an attempt to find a
66 larger ellipsoid in the local region. These attempts end if no increase in volume of the ellipsoid is
67 found after a user set maximum number of iterations (default 50, see (b)), or if the total number
68 of attempts exceeds ten times the maximum iteration number. If more than half of the sampling
69 points on the ellipsoid are outside the image boundary it is invalid, removed and ignored in
70 further calculations.

71 (ii) Assign EF to each pixel and averaging over runs

72 Once maximal ellipsoids are found for each seed point, each foreground pixel is assigned the EF
73 value of the largest ellipsoid that contains it, or NaN (not a number) if no ellipsoids contain that
74 pixel. One iteration of fitting ellipsoids and assigning EF to each pixel is termed a *run*.

75 Ellipsoid factor is a stochastic process and therefore results can vary from run to run. The user
76 has the option to average the outputs over several runs to smooth the results. From experience
77 on various real-life examples, we recommend averaging over 6 runs (the "repetitions" input
78 parameter) for the final result generation. This typically reduces the median and maximum EF
79 variation per pixel per run to less than 0.15 and 0.4, respectively (See supplementary material (c)).

80 (iii) EF inputs and outputs

81 Some further mathematical considerations on the shape of the distributions to be expected when
82 calculating a difference of axis ratios can be found in Supplementary Material ((d)).

83 In the present study, we ran Ellipsoid Factor on two data sets, with sample descriptions and
84 statistical analysis detailed in the next two subsections. EF input parameters used for each of
85 these studies are listed in Table 4. For both studies, we measured BV/TV and SMI, calculated
86 descriptive statistics of the EF distribution (median, maximum, and minimum), and plotted EF
87 histograms.

88 (b) Disuse osteoporosis in mouse tibiae

89 X-ray microtomography (XMT) scans (5 μm nominal pixel spacing) of 12 murine tibiae were
90 obtained from an unrelated study [25] (in preparation). The animals had undergone sciatic

Figure 1. Edge cases of possible maximal ellipsoids, their axis ratios, and where a pixel within such an ellipsoid would be registered on the Flinn peak plot. Note that the orange and the red ellipsoid have the same EF, but vastly different Flinn peak point locations. Small black points are the Flinn peak plot data from the trabecular bone of a great spotted kiwi (*Apteryx hastii*) [24]. Ellipsoids with the same EF value, i.e. EF isolines, are represented by the grey, dashed diagonal lines with slope 1 on the Flinn plot.

91 neurectomy to the right hindlimb, inducing one-sided disuse osteoporosis. They were divided
92 into three groups of four mice. Group 1,2, and 3 were euthanised 5, 35, or 65 days after surgery,
93 respectively. Trabecular bone from the proximal metaphysis was segmented by drawing around
94 the trabecular-cortical boundary using the software CTan (Bruker, Belgium).

95 The segmented images were denoised using a 3D median filter and thresholded at a pixel value
96 of 75 (Figure 2). The thresholding value was selected visually as sensible on one sample and kept
97 consistent across samples. As the EF distributions were uni-modal and not normal in all cases, the
98 EF median, maximum and minimum were taken as representative values for each specimen. SMI
99 values were computed for each sample (using Hildebrand and Rüegsegger's method [7] with

100 volume resampling 2 and mesh smoothing 0.5), and bone volume fraction measurements were
101 taken from the raw data of an unrelated study [25] (in press).

102 For each group, paired t-tests comparing EF median, SMI and bone volume fraction between
103 control and disuse leg were performed using the R software [26]. We performed Pearson's
104 product-moment correlation tests for association between EF median and bone volume fraction,
105 and between SMI and bone volume fraction for each group. The R scripts used for this purpose
106 can be found in an online repository [27] under /R/paired-mouse-disuse-test.R.

Figure 2. The right knee of one of the mouse samples rendered from a binary image. Red arrowhead points to the trabecular bone in the region of interest for this study. View is cranio-caudal with an oblique tilt towards proximal.

107 (c) Ellipsoid Factor in human vertebrae of varying trabecular bone volume 108 fraction

109 To investigate the association of SMI and EF with human bone health, we imaged sagittal sections
110 of 22 vertebrae from women of varying age (24-88 years old) using XMT (30 μm pixel spacing).
111 Pixels with a linear attenuation coefficient of more than 0.7 cm^{-1} were classified as bone, others
112 as background. Cuboidal regions of interest containing trabecular bone, aligned with the image
113 axes, were chosen manually. The vertebrae were originally collected and prepared for imaging
114 with scanning electron microscopy in a previous study [28]. This data set was interesting to the
115 present study for two reasons. Firstly, these are the first EF numbers obtained on healthy and
116 osteoporotic samples from humans. Secondly, they constitute a challenge for choosing reasonable
117 EF input parameters because they are close to the resolution limit at which we can expect EF
118 to fit the local shape well (trabecular thickness is approximately 5-8 pixels in these images). We
119 additionally report mean and maximum trabecular thickness (Tb.Th [mm]) in these samples.

120 The age distribution of our vertebral samples was non-normal, as it was skewed to the left
121 by the prevalence of older samples (Shapiro-Wilk test $p < 0.05$). We therefore performed a non-
122 parametric test of association of age with bone volume fraction. All other variables of interest (EF
123 Median, EF Maximum, EF Mode, EF Minimum, SMI, SMI+, SMI-, mean Tr. Th., maximum Tr. Th)
124 could be assumed to follow a normal distribution (Shapiro-Wilk test $p > 0.05$). As a consequence,
125 we used Pearson's r as a measure of association between these variables and bone volume fraction
126 in our statistical tests. All statistical analysis of the vertebral samples was based on a custom script
127 (available at [27] under R/histo-EF-stats-vertebrae-final.R) using the R programming
128 language [26].

Parameter name	Description	Default values
Number of sampling vectors	Number of sampling directions used to search for contacts with the boundary.	100
Sampling increment	Increment for vector searching in pixel units.	1/2.3
Skeleton points per ellipsoid	Number of skeleton points per ellipsoid. Sets the granularity of the ellipsoid fields.	10
Contact sensitivity	Number of sampling vectors in contact with surface required to be classified as a collision.	1
Maximum iterations	Maximum fitting iterations to try improving ellipsoid fit before stopping.	50
Maximum drift	Maximum distance ellipsoid may drift from seed point. Defaults to unit pixel diagonal length	1
Repetitions	Number of separate runs over which to average EF value	1
Seed points (distance ridge)	Seed ellipsoids based on the foreground distance ridge	yes
Seed points (topology-preserving)	Seed ellipsoids based on topology-preserving skeletonisation	no
Show secondary images	Display secondary images (volume, semi-axes, axis ratios, Flinn Plot).	no
Show convergence data	Display convergence data for 2 runs or more.	no

Table 1. List of EF input parameter names, brief descriptions and default values, as listed in the ellipsoid factor documentation. We suggest users to record and publish their values for these parameters as well as the BoneJ version used to enhance the reproducibility of their experiment (See Table 4 for some examples). Note that although the defaults for "skeleton points/ellipsoid" and "repetitions" are 10 and 1 respectively, these values represent "good" values to get a quick overview on an example image. Once ready to run on an entire data set, we recommend setting these to 1 and 6, respectively (See Supplementary Material (c)).

Min EF	Minimum of sample EF distribution.
Max EF	Maximum of sample EF distribution.
Median EF	Median of sample EF distribution.
Filling percentage	Percentage of foreground filled by at least one valid ellipsoid.
Number of ellipsoids found	Total number of valid ellipsoids fitted into trabecular foreground.
Median change n	Median change in EF value from run (n-1) to run (n). This indicates how well the EF algorithm converged.
Maximum change n	Maximum change in EF value from run (n-1) to run (n). This indicates how well the EF algorithm converged.

Table 2. Values written by EF into the ImageJ results table. Median change n and Maximum change n values are only shown if the "Show convergence data" input box is ticked and EF is averaged over at least 2 runs.

EF image	Image containing EF values for foreground pixels
Seed image	Binary image with ellipsoid seed points in foreground
Volume image	Image containing the volume of the locally maximal ellipsoid
ID image	Image containing the index in sorted ellipsoid list
a image	shortest semi-axis of locally maximal ellipsoids
b image	intermediate semi-axis of locally maximal ellipsoids
c image	longest semi-axis of locally maximal ellipsoids
a/b image	a/b semi-axis ratio image
b/c image	b/c semi-axis ratio image
Flinn peak plot	Plot of semi-axis ratios of locally maximal ellipsoids (y-axis: a/b, x-axis: b/c)
Flinn plot	Plot of semi-axis ratios of all (not necessarily maximal) ellipsoids fitted

Table 3. EF primary (above line) and secondary (below line) output images, with brief descriptions.

study subject	mouse tibiae	human vertebrae
description in Methods	(b)	(c)
number of vectors	100	100
sampling increment	1/2.3	0.1/2.3
seed points per ellipsoid	1	1
contact sensitivity	1	5
maximum iterations	50	50
maximum drift	1	1
number of runs	6	6
average of largest n	1	1
seed points (distance ridge)	yes	yes
seed points (topo.-preserv.)	yes	yes

Table 4. EF input parameters used for the two case studies presented in this article.

129 3. Results

130 All distributions of EF observed in images of bone were uni-modal, as seen in the histograms of
131 Figures 3 and 12. As described earlier, we used the median, maximum and minimum (and the
132 mode, for the vertebrae) of the distribution as a representative value to describe the distributions
133 of local shape in these images for statistical analysis.

134 (a) Disuse osteoporosis in mouse tibiae

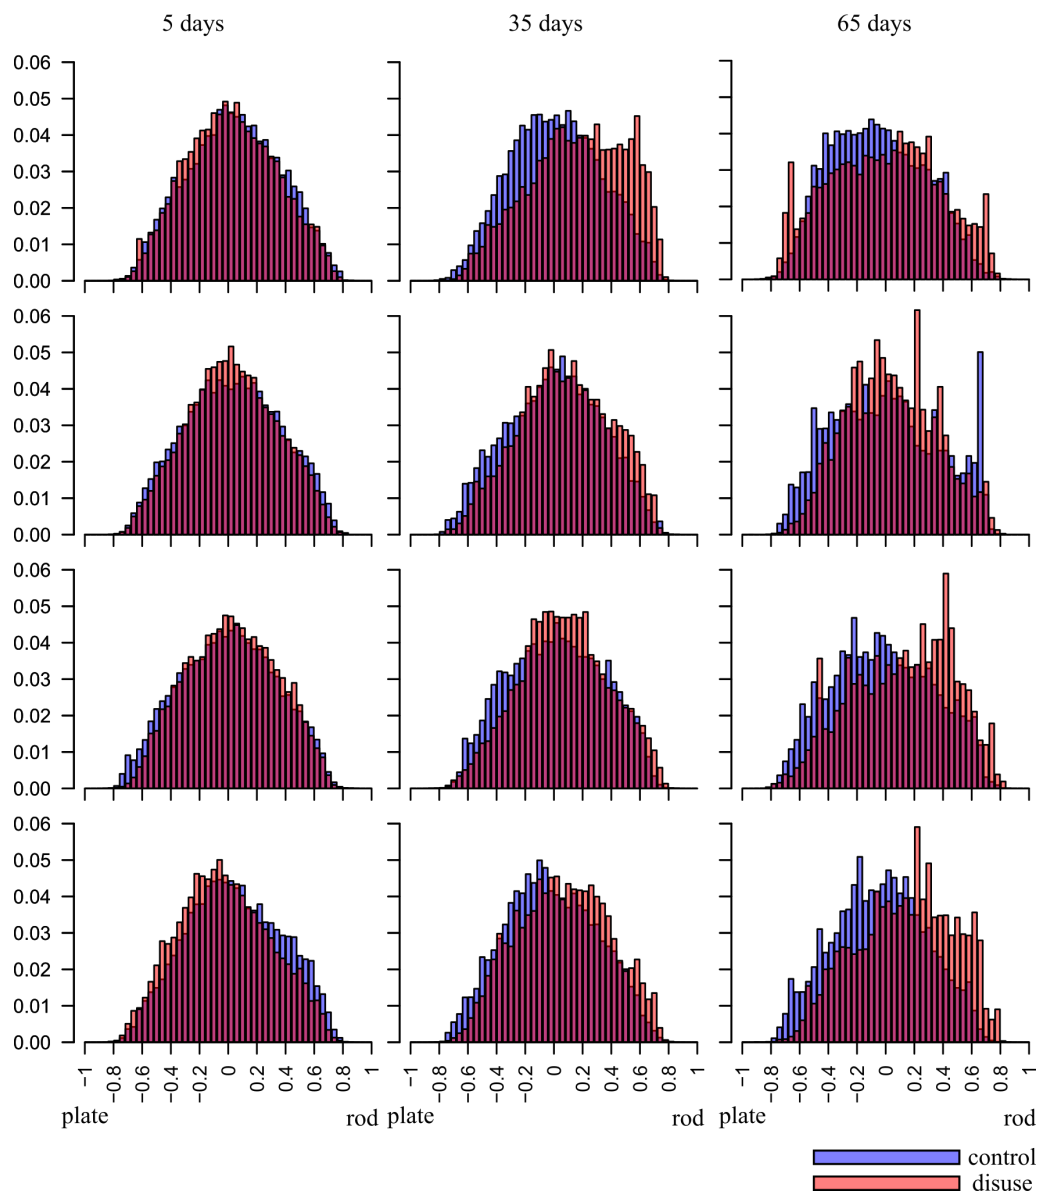

Figure 3. EF frequency histograms for each mouse, at 5 (left column), 35 (central column) and 65 (right column) days post-surgery. Large parts of the control (blue) and disuse (red) histograms overlap. Paired t-tests on EF median suggest a subtle plate-to-rod-transition at 35 and 65 days, but no plate-to-rod transition despite significant bone loss at 5 days.

135 Paired one-sided t-tests ($n=4$) showed BV/TV and SMI values were significantly different
136 between disuse and control limbs at the 5% level between control and disuse groups at all time
137 points (Figures 5 and 6). Minimum and maximum EF were not statistically associated with disease
138 state ($p > 0.05$) at any time point (Figure 7). There was no link between EF median and disuse at 5
139 days (paired one-sided t-test, $p > 0.05$) and 35 days (difference not normally distributed (Shapiro-
140 Wilk $p < 0.05$), paired one-sided Wilcoxon rank sum test, $p = 0.06$), but there was a statistical
141 difference at 65 days ($p < 0.05$). Unlike SMI, these measurements suggest therefore the presence
142 of a small shift of about EF 0.1 occurred only after a large amount of bone had already been
143 lost. Over all time points, bone volume fraction explained considerably less of the variance in
144 EF (Pearson's $r^2 = 0.25$, $p < 0.05$) than SMI (Pearson's $r^2 = -0.81$, $p < 0.001$, Figure 8). The R-
145 script used to perform this analysis can be found under `/R/mouse-smi-tests.R` in [27]. EF
146 images and histograms for our murine samples can be seen in Figures 4 and 3, respectively. EF
147 filling percentage was higher than 90% for all our murine samples, although significantly differed
148 between disuse and control at all time points (Paired t-test, $p < 0.05$).

149 (b) Ellipsoid Factor in human vertebrae of varying trabecular bone volume 150 fraction

151 Filling percentages ranged from 74% to 97% and median change in EF between the two final runs
152 ranged from 0.1 to 0.17 (Figure 9). Correlation tests showed that there was no association ($p >$
153 0.05) between bone volume fraction and any of the three convergence variables median change,
154 maximum change and filling percentage, indicating that the EF algorithm did not preferentially
155 fill the trabecular bone more completely or in a more stable way in samples with relatively low or
156 high bone volume fraction. This was evidence for a satisfactory convergence of the EF algorithm,
157 albeit not as complete as in the murine samples.

158 There was a negative association between BV/TV and age (Spearman's $\rho = -0.58$, $p = 0.004$),
159 but not between BV/TV and mean or maximum trabecular thickness ($p > 0.05$). SMI, SMI+ and
160 SMI- were strongly and significantly associated with bone volume fraction: Values for Pearson's
161 r were -0.69 , -0.65 , and -0.73 , respectively, while p -values were all < 0.005 (Figure 10). SMI
162 ranged from 1.36 to 3.11.

163 Median, maximum and minimum EF were not associated with bone volume fraction ($p > 0.05$,
164 Figure 11), and there was a mild negative association between bone volume fraction and EF modal
165 value ($r = -0.45$, $p = 0.03$). Histograms of the EF distribution were occasionally skewed in either
166 direction across all values for bone volume fraction (Figure 12). Sometimes similar EF values
167 clustered in one region of the vertebra, while in other cases, a range of EF values could be found
168 in all anatomical regions considered. Figure 13 shows EF images for 20 of the 22 vertebrae we
169 analysed.

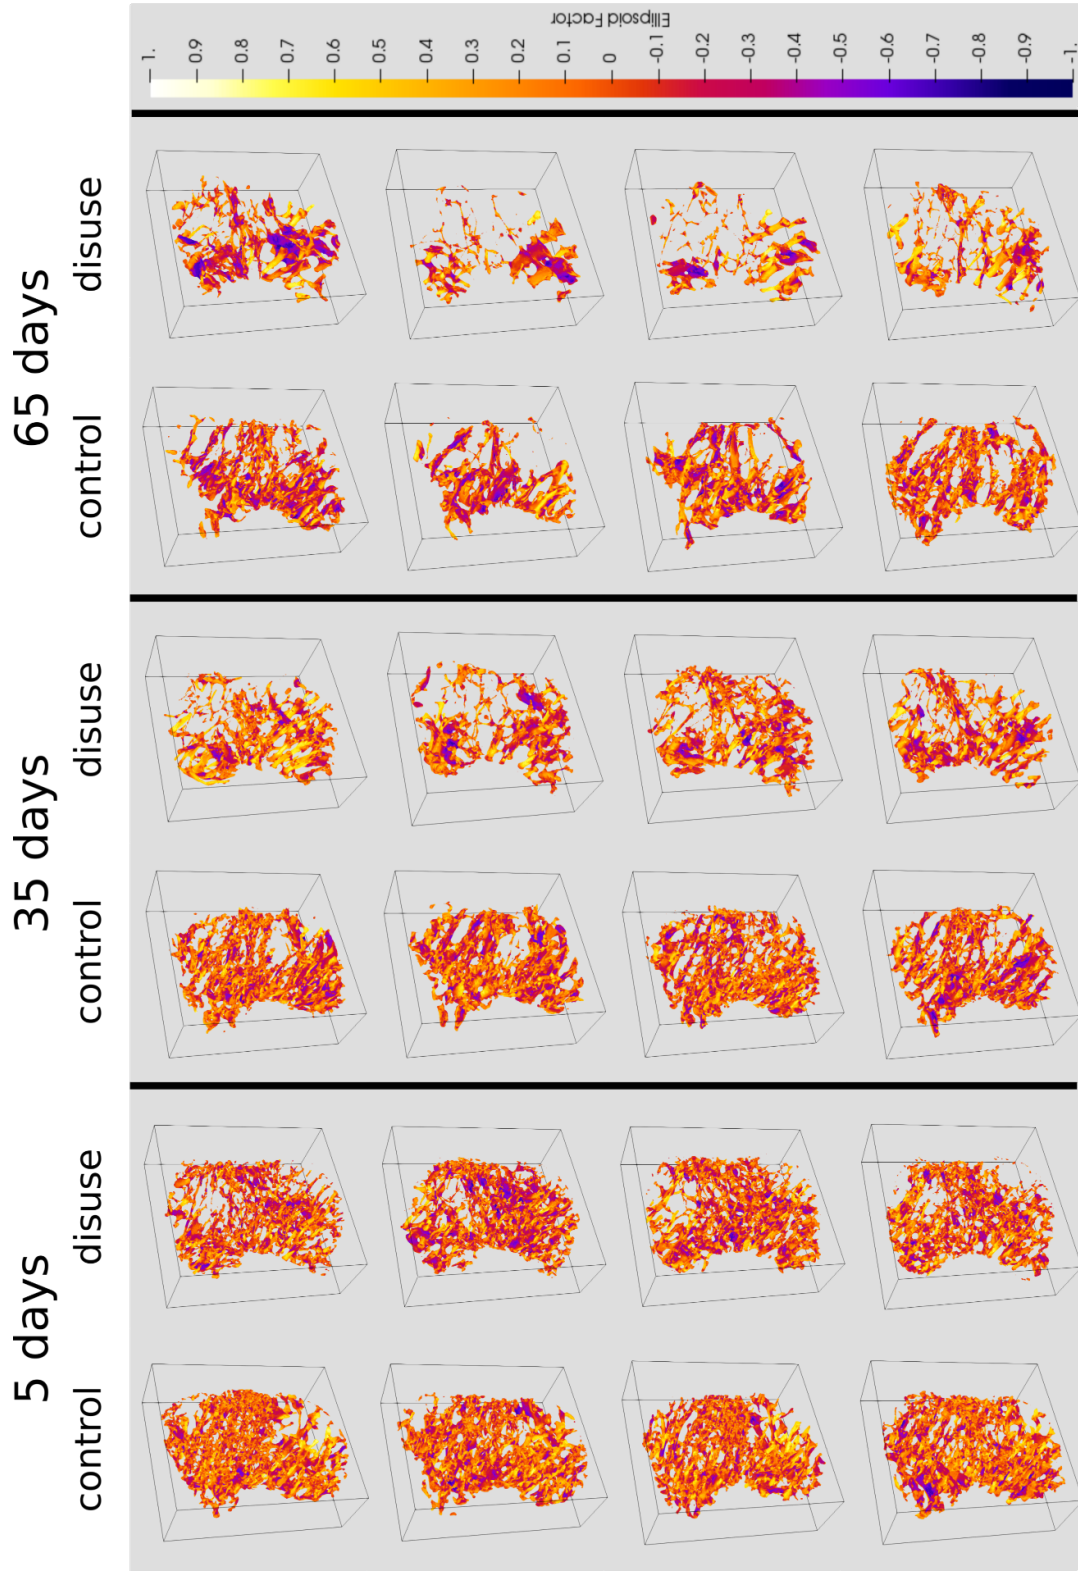

Figure 4. EF renders for each mouse limb over the three time points. The positive Y-direction is towards posterior and the positive z-directions is towards proximal. The X-direction is towards lateral for the control limbs, and towards medial for the disuse limbs. Bone loss appears to start medially.

Figure 5. Scatter plots of SMI for each time point of either mouse limb. SMI is significantly different between control and disuse limb at all time points ($p < 0.05$).

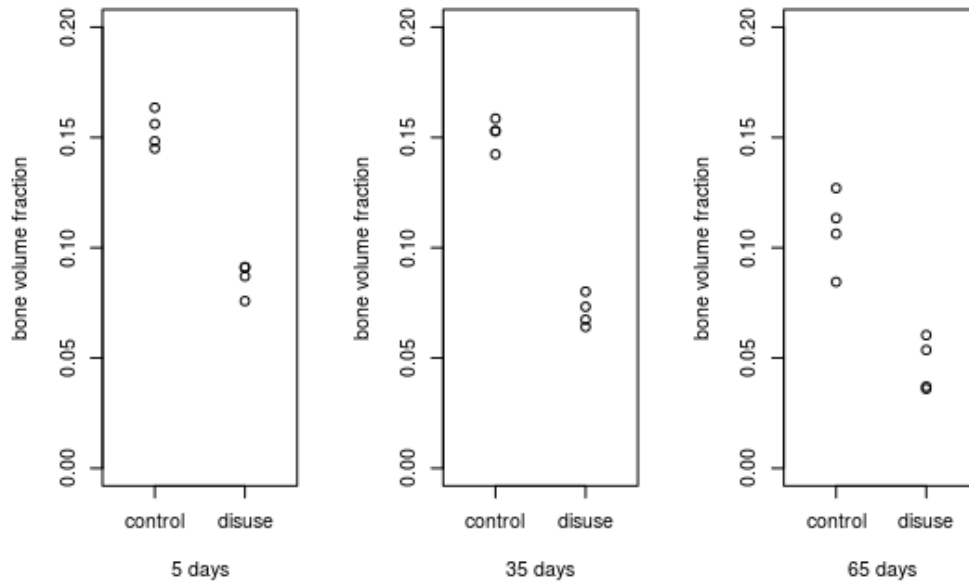

Figure 6. Scatter plots of bone volume fraction for each time point of either mouse limb. Bone volume fraction is significantly different between control and disuse limb at all time points ($p < 0.05$).

Figure 7. Scatter plots of EF median (white), maximum (yellow) and minimum (blue) for each time point of either mouse limb. EF median is significantly different ($p = 0.05$) between disuse and healthy limbs only at the two later time points.

Figure 8. SMI value plotted against bone volume fraction in murine trabecular bone samples. Bone volume fraction and SMI values are strongly correlated (Pearson's moment-product correlation $r = -0.9$, $p < 0.001$).

Figure 9. EF convergence parameters (Filling percentage, maximum and median EF change between two final runs) plotted against bone volume fraction for our human vertebral samples. There were no statistical associations between the variables, showing that all samples were equally likely to have a high filling percentage, independent of volume fraction.

Figure 10. Two left images: bone volume fraction was correlated with age in our samples (Spearman's $\rho = -0.58$, $p = 0.004$) and SMI, SMI+ and SMI- (Pearson's $r = -0.69$, -0.65 , and -0.73 , respectively; $p < 0.005$). Two right images: mean and maximum Tr Th did not correlate with bone volume fraction ($p > 0.05$).

Figure 11. EF distribution parameters plotted against bone volume fraction in our vertebral samples. Only the mode of the distribution was mildly associated with bone volume fraction; Median, maximum and minimum were not.

Figure 12. EF histograms of the vertebrae studied, sorted from top-left to bottom-right by bone volume fraction. EF histograms are all unimodal, and some skew in either direction. The mode, but not the median, of the EF distribution was associated with bone volume fraction. Samples 49 and 12 not shown.

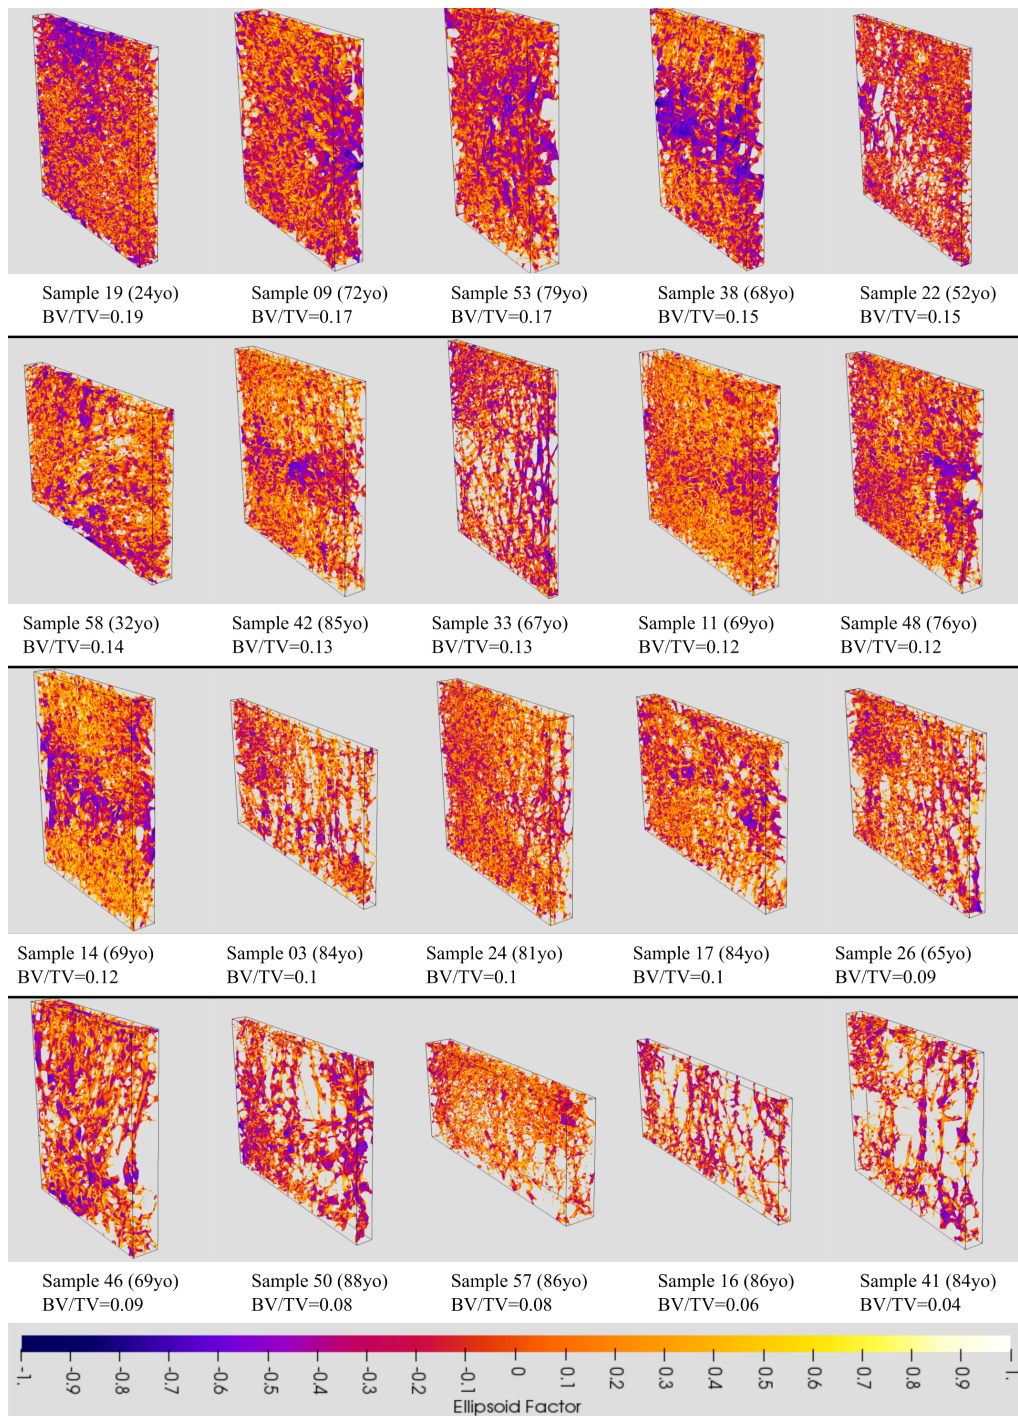

Figure 13. EF image renders of the vertebrae studied, sorted from top-left to bottom-right by bone volume fraction. Yellow pixels indicate a more rod-like, and blue pixels a more plate-like local shape, with orange indicating a shape on a continuum between plates and rods. All samples display a range of EF values. In some samples, pixels of similar EF value seem to cluster in the same region (e.g sample 42), while in others there seems to be a mix of EF values in all regions (e.g. sample 33). Samples 49 and 12 not shown.

170 4. Discussion

171 We measured Ellipsoid Factor distributions in trabecular bone from healthy and unloaded mouse
172 tibiae and from human vertebrae. Only on some occasions, EF supported the presence of a
173 small shift towards a more rod-like geometry linked with decreases in bone volume fraction.
174 SMI, on the other hand, suggested the presence of a drastic plate to rod transition whenever a
175 difference in bone volume fraction was found. EF distributions in the samples from both species
176 we investigated in the present study were consistently uni-modal.

177 In the murine samples, bone loss happened shortly after surgery in one condyle, but EF
178 median changed only later during disease progression. This suggests that local shape changes
179 in the trabecular bone may be delayed with respect to the initial loss of bone. The strong
180 interdependence between SMI and bone volume fraction is misleading in this case, as it support
181 an immediate change in local trabecular shape that culminates into a geometry that is more
182 convex than a perfect rod ($SMI > 3$) at the latest time point. Minimum and maximum EF values
183 are not different in healthy and osteoporotic murine samples, underlining that very plate- and
184 very rod-like structures co-exist in all samples.

185 Similarly, in the human vertebra samples, only the mode of the distribution correlated with
186 bone volume fraction, highlighting that any changes in local shape linked to a decrease in bone
187 volume fraction are subtle. Considerable variability in local shape can be seen in the EF images
188 of the vertebral samples. Some of the samples agree with the results of a descriptive anatomical
189 study of human 4th lumbar vertebral bodies, which characterised the trabecular geometry as
190 central plates and braces surrounded cranially and caudally by a honeycomb of rods [29].

191 In this study, we further presented some recommendations for suitable default parameters for
192 EF (Table 1), based on the convergence behaviour of EF reported in Supplementary Material (c).

193 (a) What is the mechanical relevance of plates and rods in cancellous 194 bone?

195 Modelling cancellous bone as a cellular solid gave rise to the idea that plates and rods contribute
196 to mechanical performance. Theoretical, idealised models of open-cell and closed-cell porous
197 solids predicted a dependence of the stiffness and strength on the square and the cube of the
198 characteristic length r , respectively. In a seminal study for the concept of rods and plates in
199 trabecular bone, Gibson analysed previous data from this perspective and showed that these
200 models were consistent with a transition from open-cell to closed-cell mechanical behaviour at
201 a bone volume fraction of 0.2 [30]. This is further evidence that attempting to measure rods and
202 plates in trabecular bone is not independent of the amount of bone present (contrary to what was
203 stated in the original SMI study [7]). The bone volume fraction in our samples was below 20%,
204 where the influence of concave surface and negative SMI are less than in samples with greater
205 BV/TV [13], so it would be interesting to compare EF in samples with bone volume fraction
206 above and below this value in the future.

207 The mechanical environment has a strong effect on bone size and shape at an organ and tissue
208 level (e.g. [31–33], for a review, see [34]), but Frost's mechanostat may not be the main driver of
209 trabecular adaptation within the life of an individual [5]. Across species, trabecular bone micro-
210 structure scales as a function of animal size and is likely to behave differently in small animals
211 compared to large animals [35]).

212 Changes in local shape may indicate preferential osteoclastic resorption and/or osteoblastic
213 formation in certain areas of bone. Qualitative descriptions based on scanning electron
214 micrographs of human lumbar vertebrae suggest defective and or slowed bone formation
215 and mineralisation, as well as decoupling of resorption and formation as characteristic of the
216 osteoporotic trabecular geometry at a length scale below the one investigated in the present
217 study [36]. Resorption cavities in human fourth lumbar vertebrae may occur most often near
218 trabecular nodes, with the next most common location plate-like trabeculae [37]. The study gives

219 no details on how plates, rods, nodes and "fenestrations" are characterised. It would be interesting
220 to correlate SMI and EF results with such observational studies in the future.

221 (b) Measures of local shape beyond SMI and EF

222 Individual trabecula segmentation (ITS) has been proposed as a method to classify the local shape
223 of trabecular bone as rods and plates [38]. ITS is based on a decomposition of the trabecular
224 geometry into surfaces and curves [39], with subsequent assignment of all foreground pixels to
225 one of these surfaces and curves based on a measure of vicinity and orientation [40]. ITS has been
226 measured in biopsies of hip replacement patients with inter-trochanteric fractures [41]. Compared
227 to cadaveric controls, these fracture patients had lower ITS plate bone volume fraction, but equal
228 ITS rod bone volume fraction, as well as lower stiffness moduli and lower overall bone volume
229 fraction (BV/TV). We find it interesting that ITS-measured plate volume fraction correlates with
230 stiffness in these studies. However, we note that ITS-measured axial volume fraction is also (often
231 more strongly) correlated to stiffness than plate volume fraction. It is clear that, at equal bone
232 volume fraction, bone that is less aligned to the direction in which stiffness is measured will
233 behave in a more compliant manner than bone that is more strongly aligned to this direction [42].
234 We therefore suggest that, in the ITS studies, the driving factor for these observations may not
235 be a change in local plate/rod shape, but rather a change in local alignment to the axes in which
236 stiffness is measured. It would be interesting to compare ITS and EF results in the future.

237 Another method that decomposes trabecular bone into rods and plates was developed but
238 validated only on piece-wise convex objects [43]. Applying it to human vertebral samples
239 suggested that three parameters of micro-architecture (two relating to the supposed rod elements)
240 explained 90% of bone stiffness, the same amount of variation in sample stiffness explained by
241 apparent bone volume fraction alone [44]. However, all three of these parameters had a significant
242 and strong correlation with bone volume fraction, and this study therefore does not constitute
243 evidence for geometrical changes in the trabecular compartment driving mechanical properties
244 beyond the loss of material. Fatigue failure of trabecular bone may further be related to elements
245 oriented transversely to the main loading direction, which have little effect on stiffness and
246 strength [45].

247 (c) Limitations and Future work

248 Ellipsoid Factor is a useful addition to the many geometrical and topological quantities that are
249 routinely measured in trabecular bone, some of which depend on each other, as we have shown
250 here. Ellipsoid Factor is at least designed to be a priori independent of bone volume fraction, the
251 most important descriptor of trabecular bone mechanical properties [42,46]. The lengths of the
252 ellipsoid semi-axes a, b, c as half-thickness, half-width, and half-length trabecular variables could
253 be seen as an extension to measuring trabecular thickness alone.

254 The samples we consider in this paper are cross-sectional, which unfortunately precludes
255 us from following the trabecular architecture of a single individual over time. Ellipsoid Factor,
256 like all other measures of trabecular micro-architecture, requires a sufficient resolution of the
257 individual geometrical features to minimise artefacts such as noise and partial volume effect.
258 Where resolution is insufficient for EF to run on a binarised image, it might be possible to
259 locate the trabecular boundary using fuzzy edge detection (and therefore circumventing the
260 need for precise thresholding), as is done in the tensor scale algorithm [47–49]. The current EF
261 software is designed in such a way as to make an approach based on fuzzy boundary detection
262 straightforward. Very small trabeculae may be routinely missed by XMT altogether, but dealing
263 with this limitation was outside the scope of this study.

264 Ellipsoid Factor is a complex algorithm, with several input parameters that need to be tailored
265 to the application. We believe that this is also an advantage in some ways, as it will force users to
266 better understand the methods they are using. We encourage users to ask questions can be asked
267 on the ImageJ forum (<https://forum.image.sc/>). Despite its complexity, an advantage of EF is that

268 it reduces local shape down to a single number per pixel. Important information on the subtlety
269 of trabecular local shape is lost due to this simplification and users are encouraged to view and
270 interpret the Flinn peak plot because it is a more complete, but more complex, representation of
271 the local shapes present in their sample (Figure 1). The Flinn plot may require more advanced
272 statistics, for 2-D, non-independent response variables, to rigorously compare sampled groups. It
273 might be possible to improve the performance of EF in the future by transferring some parallel
274 computations onto the graphics card [50].

275 Further avenues of future research could investigating how well EF characterises curved
276 trabecular bone, and understanding whether characteristic combinations of axis ratios $\frac{a}{b}$ and $\frac{b}{c}$
277 for an individual or a group exist that are not immediately recognised by looking at the axis ratio
278 difference.

279 5. Conclusion

280 Our investigations suggest that local shape in trabecular bone is not straightforward to
281 decompose into rods and plates, and that a wealth of shapes across the plate-rod continuum exist
282 in any sample. Our data support the presence of a slight tendency of the trabecular geometry to
283 have higher EF in osteoporotic samples, possibly as a consequence of a cell-driven re-organisation
284 that is delayed in respect to the initiation of bone loss. This transition, where it occurs, is
285 considerably more subtle than SMI values suggest.

286 Acknowledgments

287 The authors thank Phil Salmon (Bruker Micro-CT), Andy Pitsillides (RVC) and the wider RVC
288 Skeletal Biology Group for helpful discussions on trabecular bone, as well as Richard Domander
289 (RVC) and Curtis Rueden (University of Wisconsin-Madison) for valuable help and support in
290 working with ImageJ2. We also thank Yu-Mei Chang for advice with statistical analysis, and Eva
291 Herbst for critically reading the manuscript. This research was supported by a BBSRC Project
292 Grant to MD (BB/P006167/1).

293 Author contributions

294 MD had the idea for Ellipsoid Factor and designed the overall project. AAF and MD implemented
295 the ImageJ code. AAF wrote the R and Python scripts, did the statistical analysis, made the figures,
296 and wrote the manuscript draft. RS performed the surgery and dissected the mouse tibiae. BJ
297 imaged the murine samples. SM segmented the trabecular compartment of the mouse tibiae, and
298 measured bone volume fraction in the mouse samples under the guidance of BJ. DM and AB
299 prepared and imaged the human vertebrae. All authors read the manuscript, provided feedback
300 and approved the final version of the manuscript.

301 Competing interests

302 MD was a member of the Editorial Board of Royal Society Open Science at the time of submission
303 and was not involved in the assessment of this submission.

304 Data availability

305 Vertebral XMT scans (https://figshare.com/projects/Assessment_of_Bone_Quality_in_Osteoporosis_-_XMT_and_SEM/76962) and segmented XMT of mouse trabecular bone
306 (https://figshare.com/projects/Segmented_trabecularbone_from_microCT_scans_of_mice_with_one-sided_neurectomy_to_hindlimb/79583) are available on the data
307 sharing repository figshare. Some vertebral scans can additionally be explored as 3d renderings
308 on SketchFab: <https://sketchfab.com/alexjcb/collections/vertebrae-sections>.

313 Ethics

314 The image data were obtained and re-used from unrelated experiments in which animal
315 procedures and human samples were used with appropriate ethical approval. The use of animals
316 in the unrelated study was carried out in accordance with the Animals (Scientific Procedures) Act
317 1986, an Act of Parliament of the United Kingdom, approved by the Royal Veterinary College
318 Ethical Review Committee and the United Kingdom Government Home Office, and followed
319 ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines. Human second lumbar
320 vertebral body samples were obtained via the European Union BIOMED I study "Assessment of
321 Bone Quality in Osteoporosis".

475 (a) Implementation and software design

476 Results presented in this study were obtained with a development version of BoneJ (commit
477 0ce1c5eba). We have verified that the differences obtained with the initial "styloid" release of BoneJ
478 [22] are approximately 0.15 on average, which is what is to be expected from the stochasticity of
479 the EF algorithm.

480 The latest Ellipsoid Factor implementation adheres to the principles of modern ImageJ -
481 ImageJ2 [51], dividing the the execution of the algorithm into small, modular and re-usable
482 part ("ops", in our case: seed-point finding, ellipsoid fitting) combined into a high-level ImageJ
483 plugin ("command", in our case, the Ellipsoid Factor command, part of BoneJ2 [52]). Installation
484 instructions for BoneJ2 can be found at <https://imagej.net/BoneJ2#Installation>.

485 The modularity of the seed point finding allows easy switching between the two existing
486 seed point finding strategies (distance-ridge-based and topology-preserving). Similarly, the
487 modularity of ellipsoid fitting allows future extension to e.g. fuzzy edge detection of trabecular
488 surface points on low-resolution grey scale images (which may be relevant for *in-vivo* HR-
489 pQCT images of human trabecular bone with (comparatively) low resolution [53]; for a related
490 algorithm, see [47,49,54]) or a surface-based ellipsoid fitting strategy [55].

491 The two modules are decoupled from each other, so a change in one will not affect the usability
492 of the other.

493 (b) Sensitivity to max iteration parameter

494 Figure S1 shows that the difference in EF for different values of "max iterations" was small (other
495 input parameters being equal). Numerical experiments showed that for the emu and shrew test
496 images, an ellipsoid that had not improved its volume for approximately 40 iterations was equally
497 likely to not be fitted well than it was to be fitted well. We therefore chose 50 as a reasonable,
498 conservative default value for "max iterations".

499 (c) Sensitivity to some input parameters

500 We tested the sensitivity of the EF image on variations in number of seeds (skip ratio), volume-
501 weighted averaging, number of sampling vectors and number of runs. This was done on three
502 test images, already used in the previous EF study [14]. The tests showed consistently that adding
503 more seeds was important to achieve a high filling percentage, and that an increased number of
504 runs (about 6) was necessary for good convergence (median change per run < 0.1). More seeds
505 and more runs come at the cost of a longer run-time, however. We therefore recommend setting a
506 low skip-ratio and averaging over 6 runs to users for EF experiments once they are satisfied with
507 the other settings.

508 (d) Some mathematical considerations on Ellipsoid Factor

509 (i) How is a difference of ratios of sorted random variable triplets distributed?

510 As seen in the main document text, EF is calculated as the difference of sorted axis ratios of the
511 fitted ellipsoids. The ellipsoid fitting is stochastic, which means that the ellipsoid axis lengths
512 will be randomly distributed, but their distribution is *a priori* unclear. It may therefore be useful
513 to know how the difference of ratios of sorted random triplets is distributed for some known
514 defined random distributions: the normal distribution (Figure S5) and the uniform distribution
515 (Figure S6).

516 These simple examples caution against the undiscerning interpretation of EF values. However,
517 it seems unlikely that a,b,c follow either of the distributions above. We can simulate this to an

518 extent with a gamma distribution (Figure S7). This also shows that EF values distribute in an
519 approximately triangular fashion.

520 Finally, we expect that a structure clearly divisible into rod and plate like parts would have the
521 properties displayed in Figure S8, i.e. the middle radius clustering into two clusters near where
522 the smallest radius and the largest radius are clustered.

523 This subsection shows that one difference of sorted ratio distribution does not imply a unique
524 underlying ellipsoid distribution: we have seen two ways of getting triangular distributions. It
525 also tells us that one way of getting a bimodal distribution is have bimodal axis ratios.

526 The R script used to perform these numerical experiments and plot their results can be found
527 at [27] under /R/null-case-EF.R.

528 (ii) Non-uniqueness of EF

529 Note that this locally maximal ellipsoid is not unique. For example, theoretically, one could have
530 two axis-aligned ellipsoids with (x,y,z)-axis lengths of (1,1,9) and (3,3,1) respectively. Both would
531 have volume 9, but very different EF. Assuming these ellipsoids are locally maximal, pixels within
532 the first ellipsoid would have $EF = 1 - \frac{1}{9} = \frac{8}{9}$ (i.e. rod-like) whereas pixels within the other would
533 have $EF = \frac{1}{3} - 1 = -2/3$ (i.e. rather plate-like (Figure S9)). The pixels in the intersection of the two
534 ellipsoid would have non-unique EF.

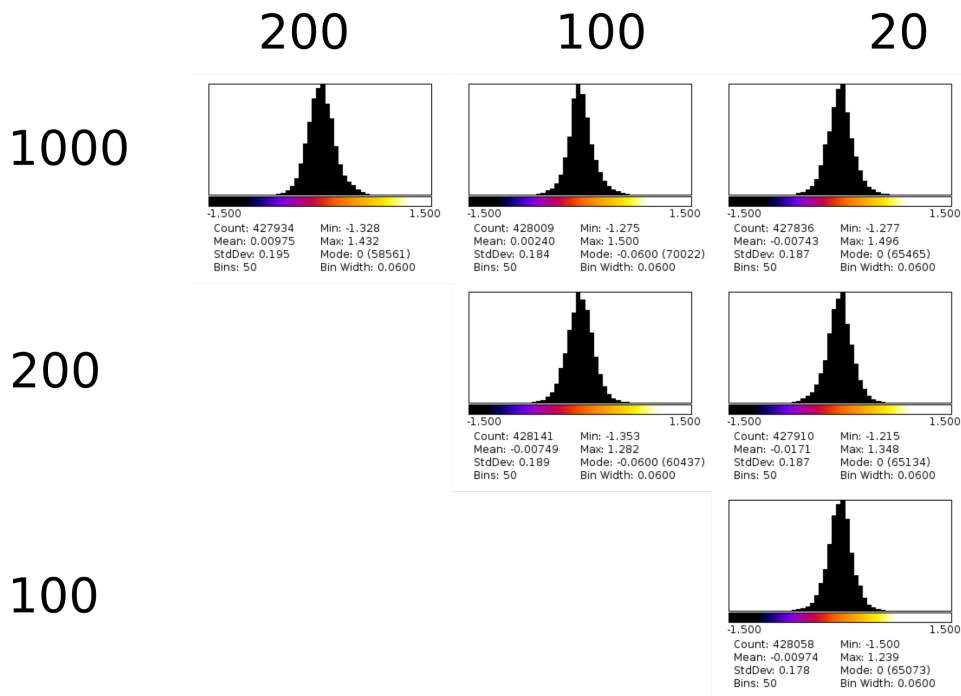

535 (iii) Sensitivity to some more input parameters

536 [ht] We used vertebral sample 57 to investigate how the sampling increment ("step"), the contact
537 sensitivity and a semi-axis length filter (see next paragraph) affected the EF distribution. The
538 results are for contact sensitivity values of 1 and 5 are shown in Figure S10 and S11, respectively.

539 Small ellipsoids may get caught within a thin feature when growing, especially when the
540 step-size is close to some stair-case-like feature and the contact-sensitivity is low (Supplementary
541 Material iii). For this reason, we built an option to remove ellipsoids whose longest semi-axis c is
542 smaller than a user-defined threshold (in pixel units, but does not have to be an integer number)
543 into our code. We refer to this as the minimum valid longest semi-axis length filter.

544 We observed that at contact sensitivity 5 S11, reducing the step size was enough to remove
545 spurious small ellipsoids, and using larger filters did not really affect the EF distribution. We
546 therefore removed the minimum valid longest semi-axis filter in the interest of reducing an
547 already high number of input parameters, and ran the vertebral measurements with contact
548 sensitivity 5 and the lowest step size.

Shrew difference histograms

Emu difference histograms

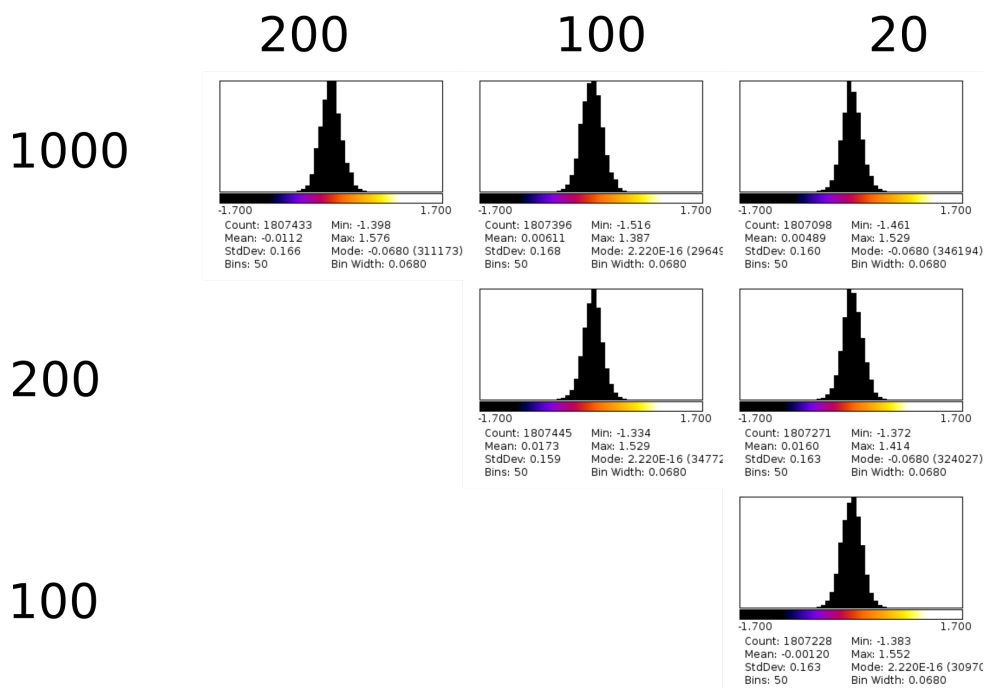

Figure S1. Histograms of the difference between EF outputs for the "max iteration" value on the x and on the y axis. A higher "max iteration value" did not alter the EF distribution much.

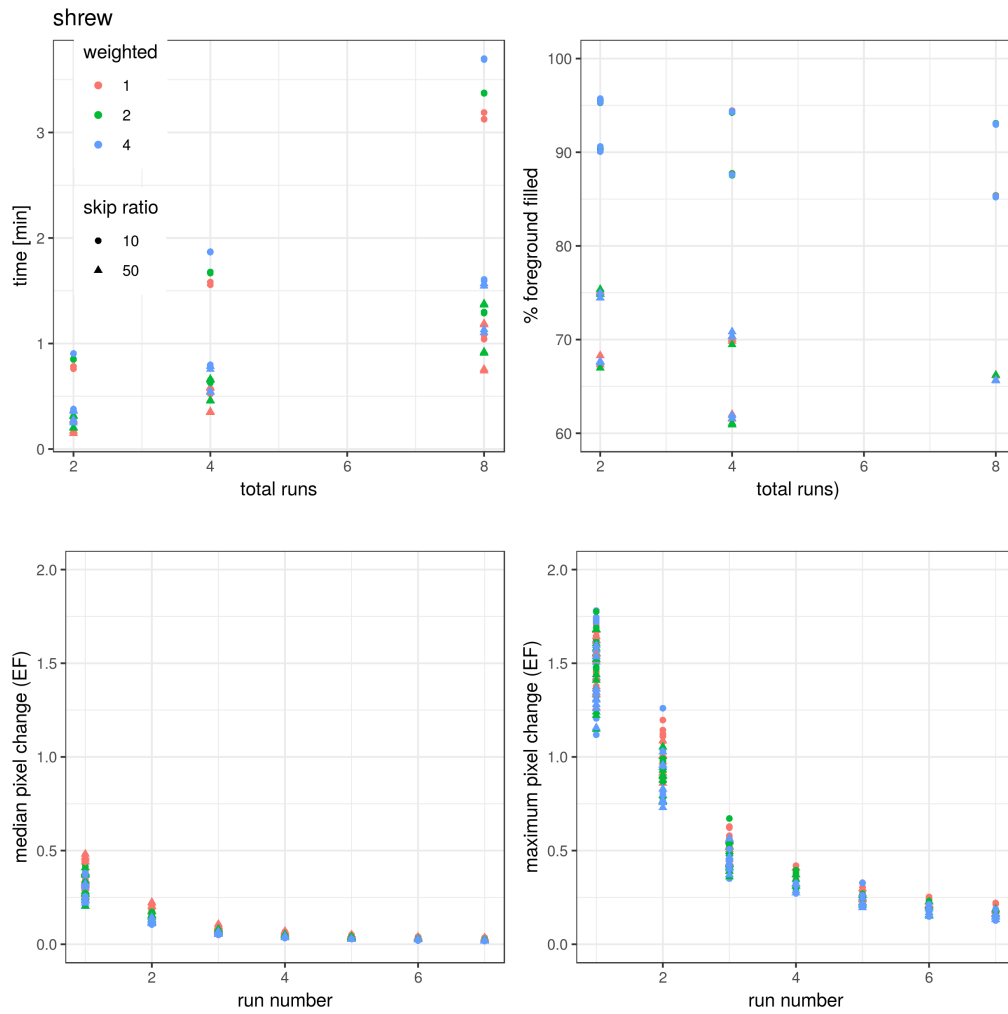

Figure S2. Convergence parameter sensitivity of the shrew test image to variation in skip ratio (shape of symbols), volume-weighted average over several local ellipsoids (colour), the number of vectors (10 and 100 were run, distinguishable only by location on plot) and the number of runs averaged over (x-axis). Within run volume-weighted averaging had little effect on any convergence parameter. Skipping over 5 times more seeds reduced the run-time of the algorithm by roughly a factor of 2, but reduced the filling percentage by 15-20%. Increasing the number of sampling vectors roughly doubles the run-time, and increases the filling percentage by about 5%. Median and maximum changes per additional run in EF value per pixel required 6 runs to be less than 0.1 and 0.4 respectively, which we defined as satisfactorily converged. These statements are also true for two other test images, emu (Figure S3) and rods_plates (Figure S4).

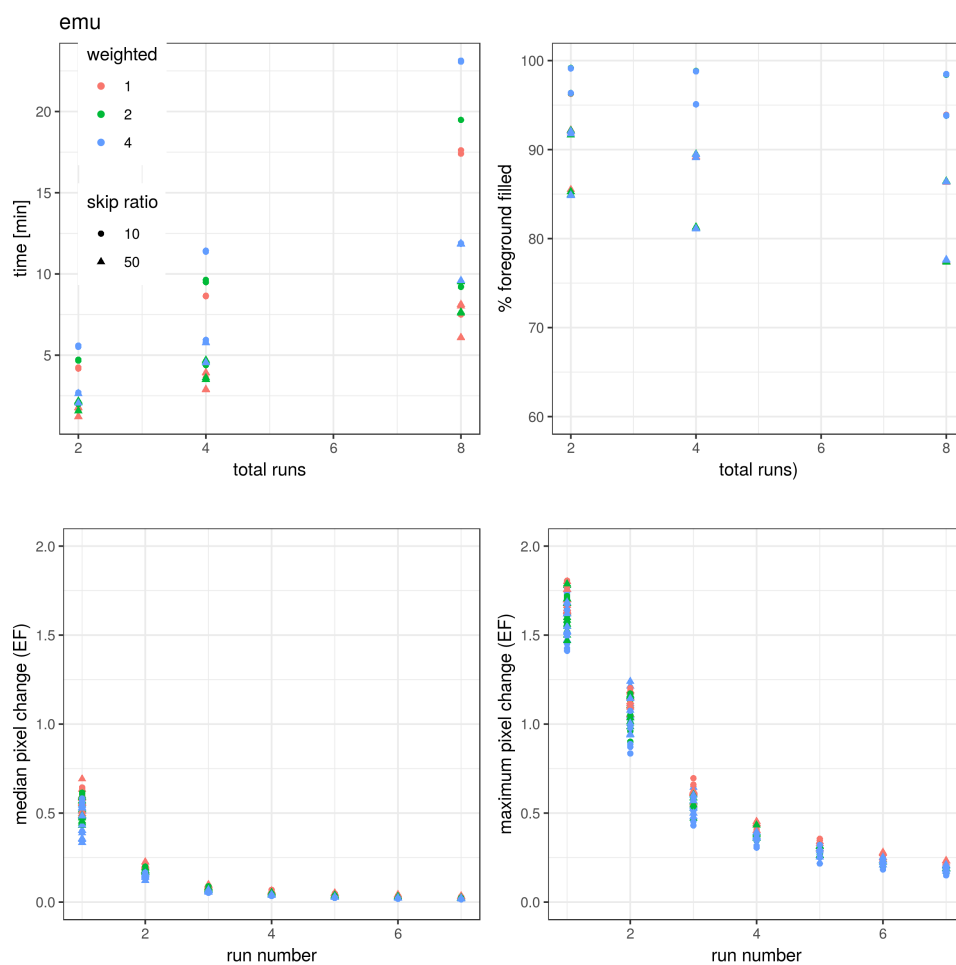

Figure S3. Please refer to the caption of Figure S2.

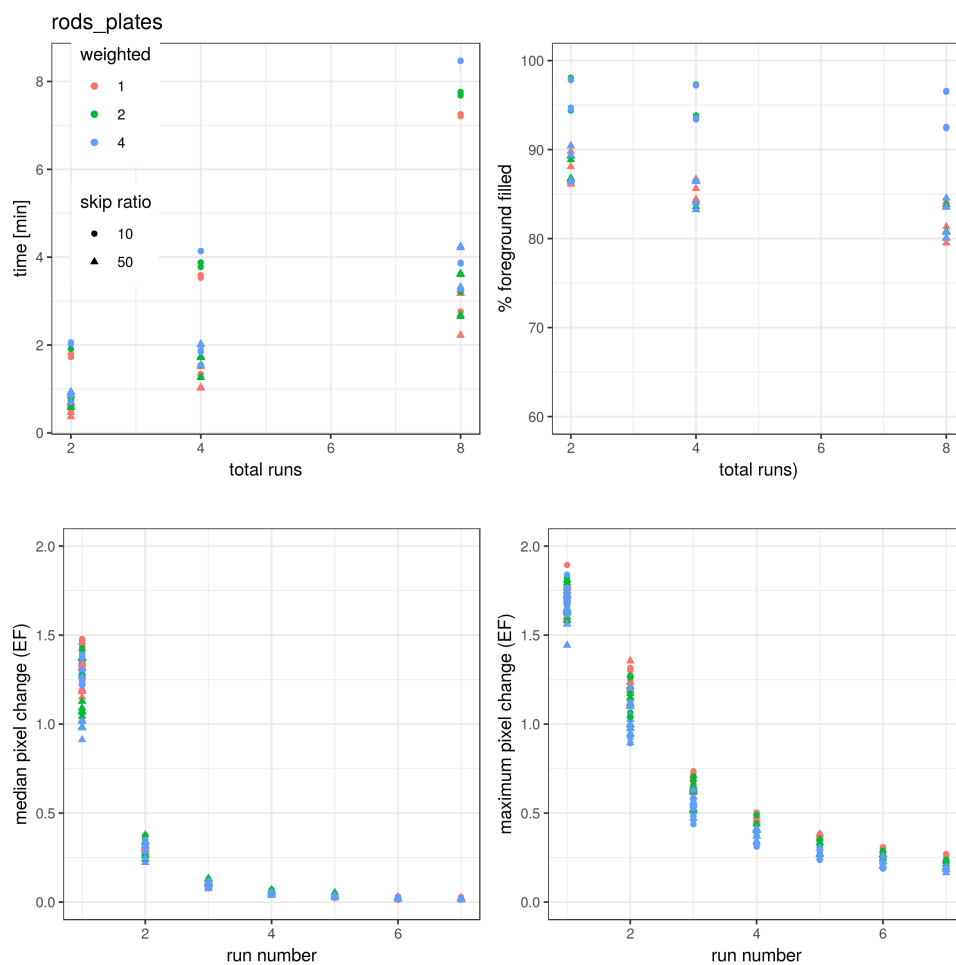

Figure S4. Please refer to the caption of Figure S2.

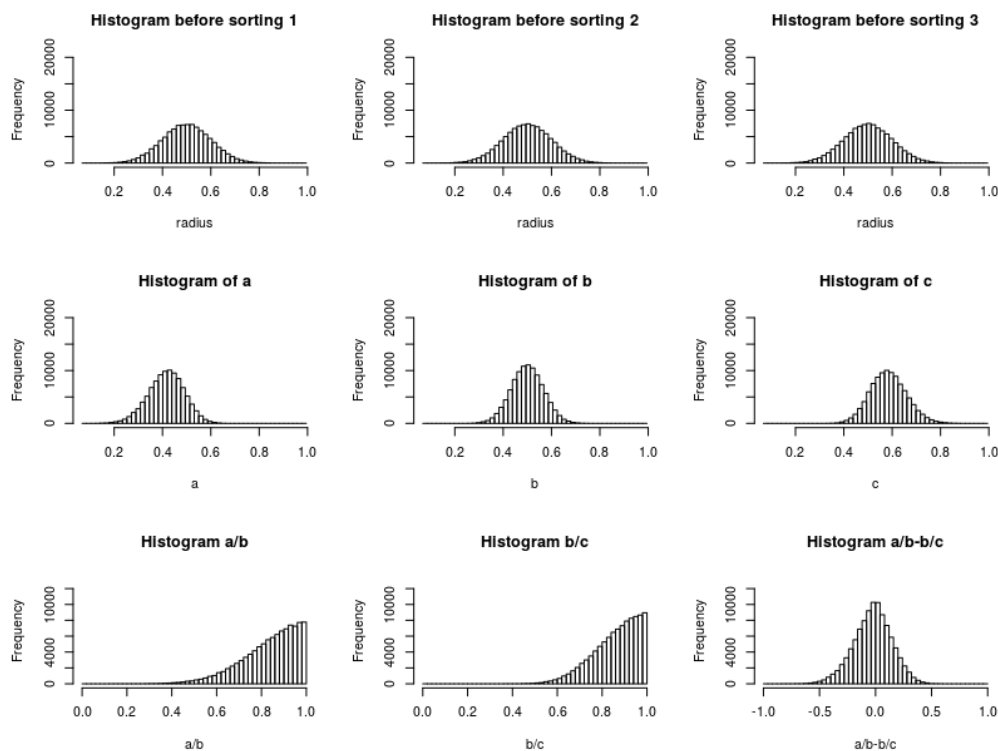

Figure S5. Numerical experiment with normally distributed radii (mean=0.5, standard deviation=0.1) (first row). Sorting causes a to have a lower mean, and c to have a higher mean (second row). The ratio of sorted, normally distributed triplets is heavily skewed to the left. The difference of sorted ratios appears triangular (third row).

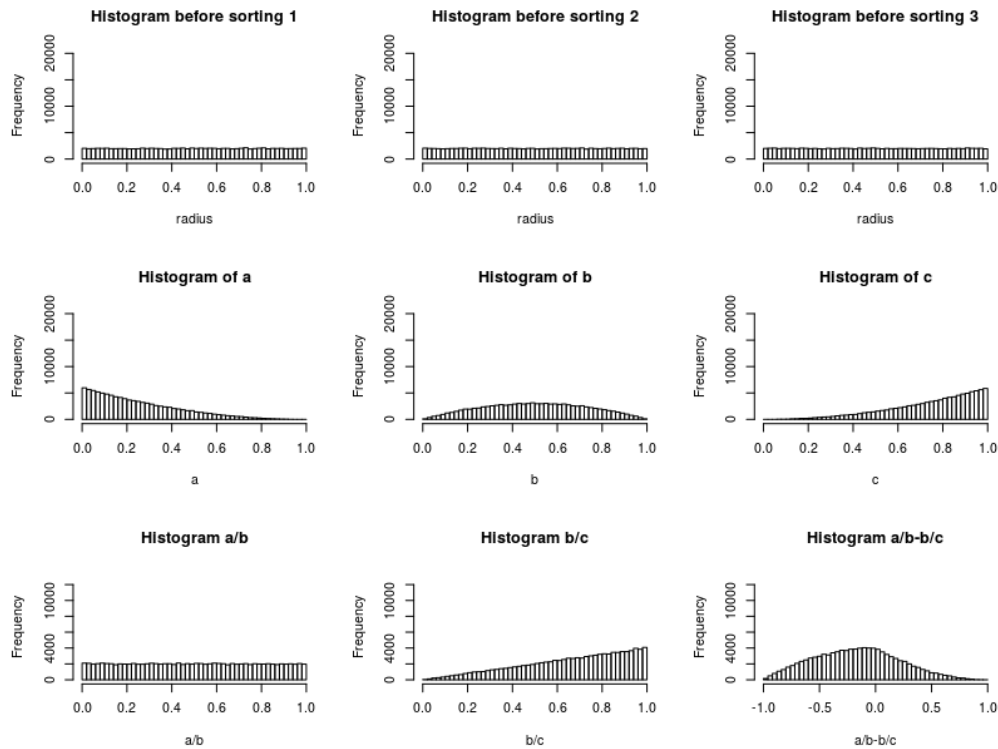

Figure S6. Numerical experiment with uniformly distributed radii on $[0, 1]$ (first row). Sorting causes a to be heavily skewed to the right, b to be distributed according to what resembles a parabola and c to be heavily skewed to the left (second row). The ratio of sorted, uniformly distributed triplets is either uniformly distributed (a/b) or heavily skewed to the left (b/c) depending on whether the larger radius is in the numerator or the denominator. The difference of sorted ratios resembles a shark fin, and is skewed to the right.

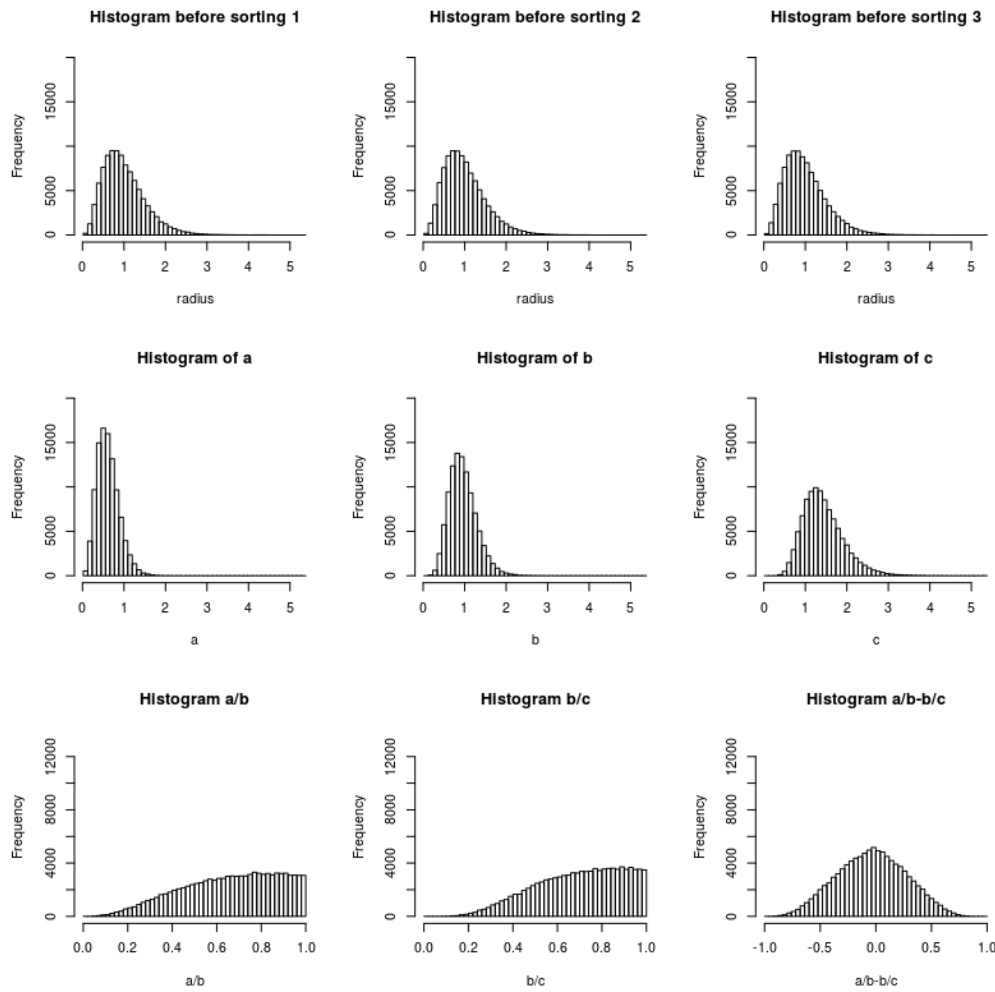

Figure S7. Numerical experiment with radii according to $\text{Gamma}(k=4, \theta=1)/4$ (first row). Sorting causes the median of a to decrease, and the median of c to increase, but the distribution shape stays the same (second row). The ratio of sorted, gamma-distributed triplets is heavily skewed to the left and their difference appears triangular.

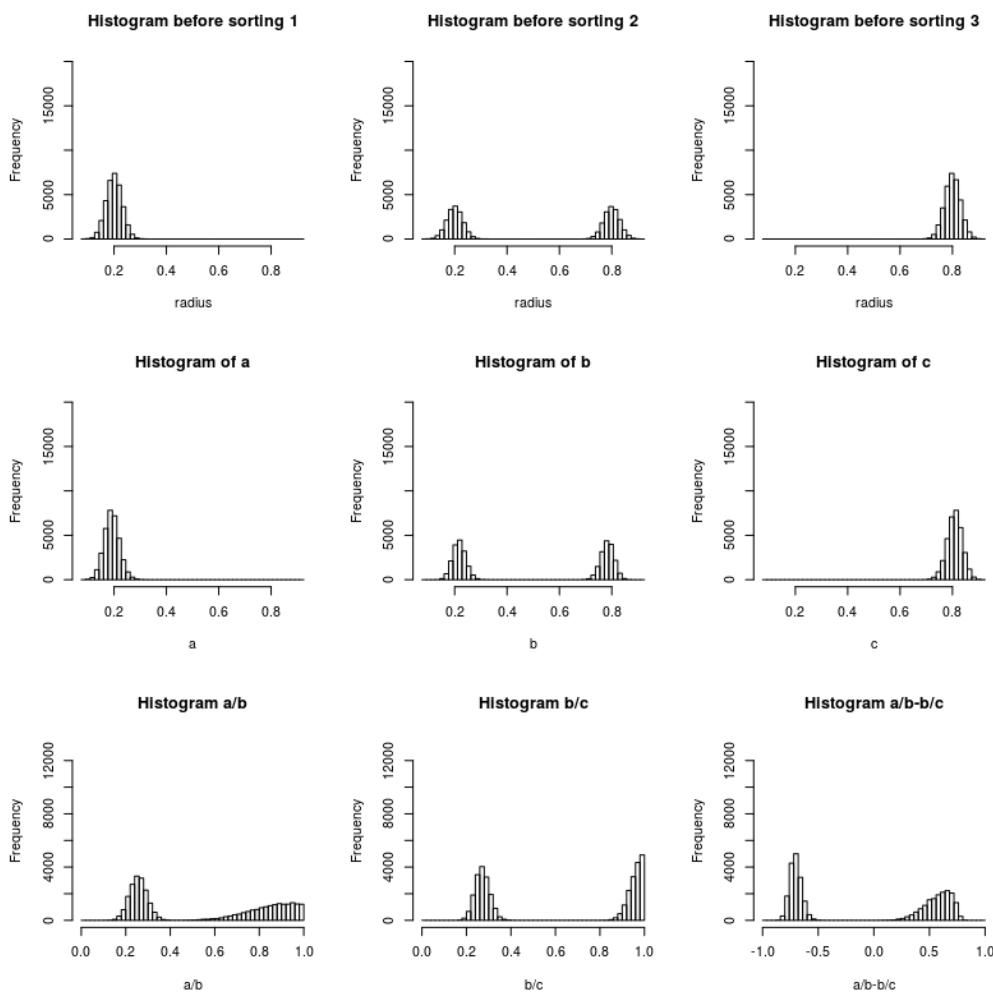

Figure S8. Numerical experiment with bimodal b radius.

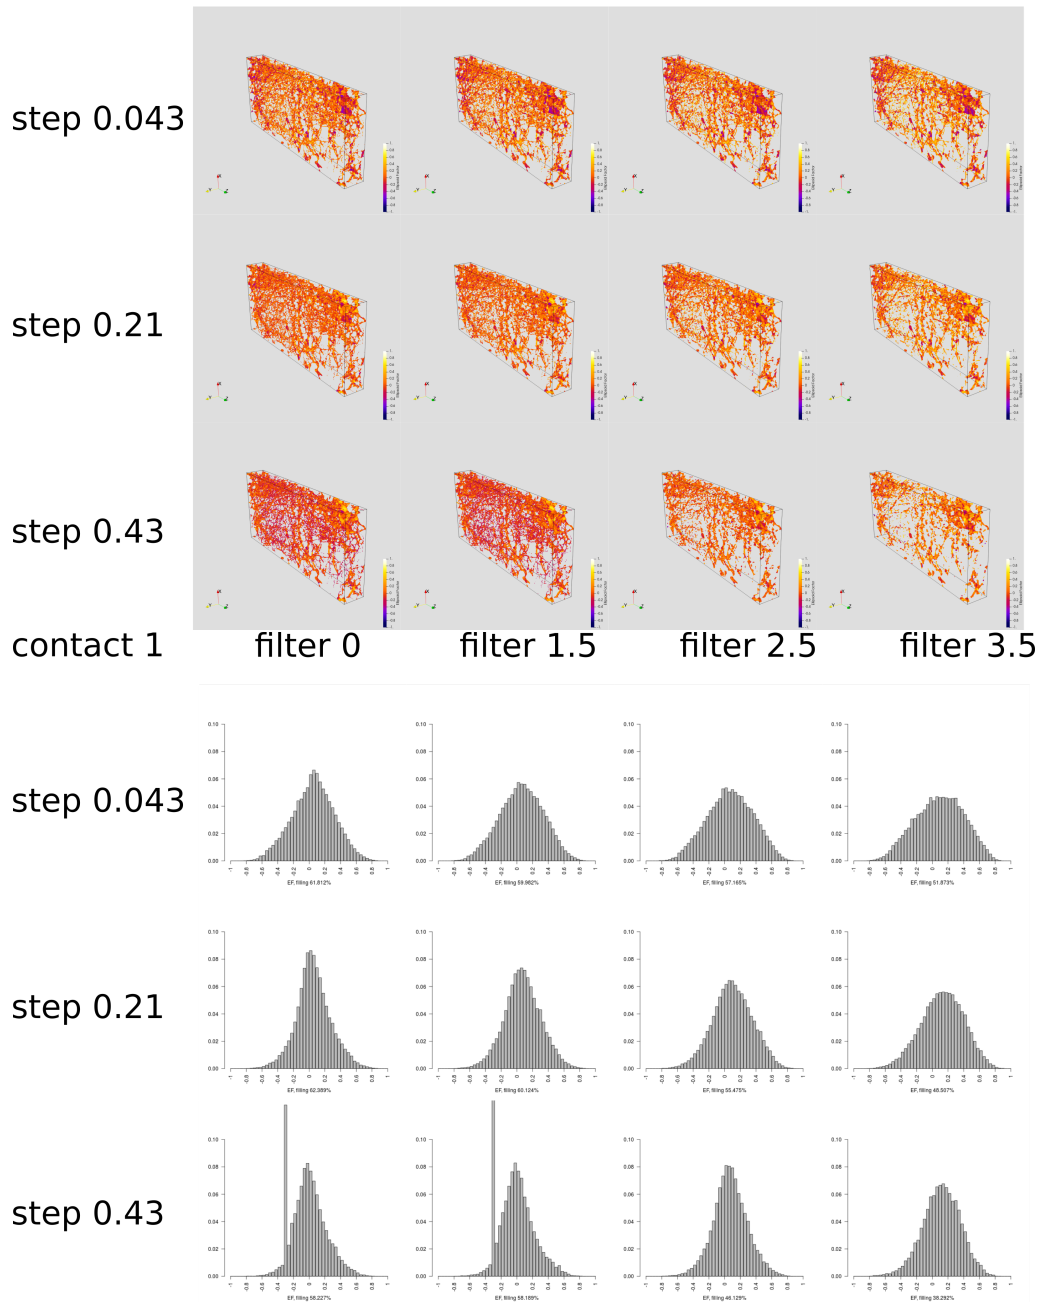

Figure S9. Two ellipsoids of same volume, but different axes as an example to show that EF can be non-unique. The yellow ellipsoid has (x,y,z) axis lengths of $(1,1,9)$, while the blue ellipsoid has (x,y,z) axis lengths of $(3,3,1)$. In this case, the pixels in the intersection of the two ellipsoids will have non-unique EF (assuming the two ellipsoids are locally maximal).

Figure S10. Renders and histograms of the EF image of vertebral sample 57 with a contact sensitivity of 1 and various step sizes and semi-axis filters. A large step size causes comparatively small features to fill up with ellipsoids that have taken only a few steps in every direction (e.g. 3,3 and 2). These ellipsoid cause the spurious mode in the corresponding histogram. This effect is reduced by using a smaller step size or a larger filter. The larger filter changes the distribution, however.
