42 Abstract

43 Biogeochemical exports of C, N, S and H₂ from watersheds are modulated by the activity of 44 microorganisms that function over micron scales. This disparity of scales presents a substantial 45 challenge for development of predictive models describing watershed function. Here, we tested 46 the hypothesis that meander-bound regions exhibit patterns of microbial metabolic potential that 47 are broadly predictive of biogeochemical processes in floodplain soils along a river corridor. We 48 intensively sampled floodplain soils located in the upper, middle, and lower reaches of the East 49 River in Colorado and reconstructed 248 draft quality genomes representative at a sub-species 50 level. Approximately one third of the representative genomes were detected across all three 51 locations with similar levels of abundance, and despite the very high microbial diversity and 52 complexity of the soils, ~15% of species were detected in two consecutive years. A core floodplain 53 microbiome was enriched in bacterial capacities for aerobic respiration, aerobic CO oxidation, and 54 thiosulfate oxidation with the formation of elemental sulfur. We did not detect systematic patterns 55 of gene abundance based on sampling position relative to the river. However, at the watershed 56 scale meander-bound floodplains appear to serve as scaling motifs that predict aggregate capacities 57 for biogeochemical transformations in floodplain soils. Given this, we conducted a transcriptomic 58 analysis of the middle site. Overall, the most highly transcribed genes were *amoCAB* and *nxrAB* 59 (for nitrification) followed by genes involved in methanol and formate oxidation, and nitrogen and 60 CO₂ fixation. Low soil organic carbon correlated with high activity of genes involved in methanol, 61 formate, sulfide, hydrogen, and ammonia oxidation, nitrite oxidoreduction, and nitrate and nitrite 62 reduction. Thus, widely represented genetic capacities did not predict in situ activity at one time 63 point, but rather they define a reservoir of biogeochemical potential available as conditions change. 64

65

66 Introduction

67 Watersheds are geographic areas that capture precipitation that is ultimately discharged 68 into rivers and other larger water bodies. Of particular interest are watersheds in mountainous regions, as these are major sources of freshwater ^{1, 2}. Within mountainous watersheds, complex 69 70 interactions among vegetation, hydrology, geochemistry, and geology occur within and across 71 watershed compartments, including across bedrock-soil-vegetation compartments of terrestrial 72 hillslopes, across terrestrial-aquatic interfaces and within the fluvial system itself. Interactions 73 within a reactive watershed typically vary as a function of disturbance as well as landscape position 74 and topography. For example, interactions in an alpine region of a mountainous watershed are 75 likely to be quite different from a lower montane floodplain region ³. Floodplains, which extend 76 from the river banks to the base of hillslopes, comprise the riparian zone (a vegetated interface 77 between the river channel and the rest of the ecosystem), and are notable as they integrate inputs 78 from all watershed compartments. They also display depositional gradients and features associated 79 with past and current river channel positions. Unlike hillslopes, floodplains receive water and 80 constituents either by surface runoff or groundwater discharge. They are typically significantly

3

81 impacted by changes in river conditions and can be inundated when river flow and stage increases 82 following snowmelt. Consequently, floodplains are dynamic compartments in which 83 hydrobiogeochemical processes vary seasonally and potentially spatially. Overall, floodplains are 84 important watershed regions in which microbial activity can modulate the form and abundance of 85 nutrients and contaminants derived from hillslopes and river water prior to their export from the 86 watershed.

87 Here, we conducted a study of floodplain soils of the mountainous East River (CO) 88 watershed to investigate how patterns in the distribution of soil microorganisms and their 89 associated functions and activities can induce geochemical gradients that impact riverine nutrient and contaminant fluxes. We tested a 'system-of systems' approach ⁴ wherein meander-bound 90 91 regions were selected as scaling motifs (repeating patterns along the river that can be used for 92 ecosystem modeling at the watershed scale), in which microbially-mediated biogeochemical 93 processes that are shaped by reactions occurring at the micron-scale might be representative of 94 processes throughout the floodplain. Detailed analyses of meander-bound floodplain soils may 95 reveal patterns that approximate watershed processes at the tens of kilometers scale, and could 96 provide much needed input for watershed hydrobiogeochemical models. This study applied 97 genome-resolved metagenomic and metatranscriptomic bioinformatics methods to large nucleic 98 acid sequence datasets to investigate microbial community composition and distribution and to 99 infer capacities for microbially-mediated C, S, H and N cycling and *in situ* activity in floodplain 100 soil microbial communities.

101

102 **Results**

103

104 Metagenomes overview

105 Three meander-bound floodplains following the meandering pattern of the East River (Fig. 106 1a) were chosen for this study: one upstream (meander-bound floodplain G (Floodplain G); Fig. 107 1b), one midstream (meander-bound floodplain L (Floodplain L); Fig. 1c), and one downstream 108 (meander-bound floodplain Z (Floodplain Z); Fig. 1d). Sample number was prioritized over 109 sequencing depth to better resolve the types and distribution patterns of the most abundant 110 organisms across the meander-bound floodplains ('floodplains' subsequently). An average 6.4 111 giga base pairs (Gbp; 3.2 - 11.5 Gbp) of sequencing data was obtained from 90 DNA extractions 112 out of 94 floodplain soil samples collected in 2015. An average 12 Gbp (6.0 - 15.0 Gbp) of

4

113 sequencing data was obtained from the other four samples. In total, ~0.6 Tbp of DNA sequence 114 information was acquired from samples collected in 2015. Our strategy aimed to capture the most 115 abundant members of the microbial community (instead of the whole community), so it is not 116 surprising that an average 13% (3 - 30%) of reads mapped to their respective assemblies 117 (Supplementary Table 1). This result also reflects the large (but variable) tail on the abundance 118 distribution of microorganisms in soil ⁵; and the communities captured by the smaller assemblies 119 resulting from samples with lower sequencing depth.

We constructed 1,704 draft genomes from three floodplain datasets. About one third (622) of these genomes were classified as draft quality (237 from floodplain G, 150 from floodplain L, and 235 from floodplain Z). After dereplication at 99% average nucleotide identity (ANI) within each floodplain and correction of local assembly errors, we recovered 375 distinct genomes (173 from G, 94 from L and 108 from Z). Dereplication across floodplains at 98% ANI generated a final set of 248 representative genomes for further analyses, predominantly \geq 70% complete (Supplementary Table 2) and 46% of which were near-complete (\geq 90%).

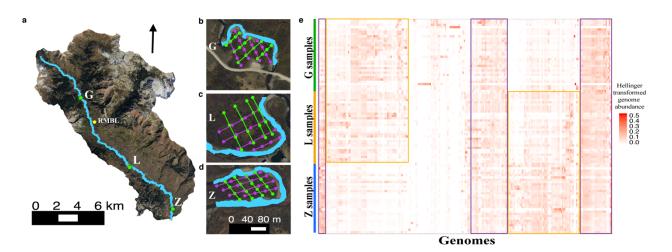

127 We assessed our genome recovery effectiveness by comparing the number of genomes 128 recovered to a secondary metric for quantifying unique species, the number of unique ribosomal 129 protein L6 (rpL6) marker sequences within unbinned assemblies (see Methods). The marker rpL6 130 has been shown to have high recoverability and species delineation accuracy ⁶, relative to methods 131 such as full genome ANI. From the 94 metagenomes, we detected 930 distinct organisms based 132 on rpL6 sequences clustered at 97.5% nucleotide identity. However, 571 of the distinct rpL6 133 sequences were on fragments with coverage that is too low for comprehensive genome sampling 134 (<7 X coverage given our sequencing depth). The disparity relative to 248 reconstructed 135 representative genomes relative to 359 rpL6 on contigs at >7 X coverage is attributed to significant 136 challenges associated with genome recovery from soil.

137 Candidate draft genomes were generated for almost all the organisms present at > 5-10 X 138 coverage in each sample. However, on average, only 5.5% of the total read dataset was stringently 139 mapped (2 mismatches per read of the pair) to the 248 genomes. This is not surprising, given that 140 most sequencing allocations per sample were sufficient to genomically sample only organisms at 141 > -0.25% relative abundance, and the most abundant organisms in each sample comprised only a 142 few percent of the community.

5

143 In 2016, we returned to one of the floodplain sites (floodplain L) to collect samples for 144 metatranscriptomics. We performed additional genomic sequencing from 19 of the original 32 145 sites (see Methods; Supplementary Table 1) to provide a reference database for transcript 146 mapping. These new DNA samples were sequenced at an average 3.7 Gbp per sample (2.7 - 4.7)Gbp), for a total ~ 0.2 Tbp of sequencing. The RNA samples were sequenced at an average 10.8 147 148 Gbp per sample (3.2 - 15.1 Gbp) for a total of ~ 0.15 Tbp of sequencing. A total of 299 draft genomes were recovered from these samples, 123 of which passed our quality thresholds after 149 150 curation. To examine stability across time we pooled the 2015 and 2016 genome sets and 151 dereplicated (at 95% ANI) the combined set of 371 genomes, generating 215 genomes 152 representative of distinct species. Notably, 32 species-level groups were detected in both years and 153 29 were only detected in 2016 (Supplementary Table 3).

Figure 1. (a) Overview of the East River, CO study site, highlighting the three sampled floodplains (green dots) and the Rocky Mountain Biological Laboratory (RMBL, yellow dot), (b) meander-bound floodplain G, (c) meander-bound floodplain L, (d) meander-bound floodplain Z. Sampling sites as green and purple dots along two sets of four transects. One set of transects in one direction (in green), and the second set of transects along another direction (in purple). (e) Hellinger transformed abundance of dereplicated genomes across samples based on cross-mapping. Genomes and samples clustered by average linkage and Euclidean distance respectively.

- 165
- 166

167 Distribution of organisms within and across meander-bound floodplains

168 To assess the presence of a representative genome in a sample we relied on the sensitivity 169 of read mapping to the dereplicated genome set. Based on our threshold for detection, about one-

6

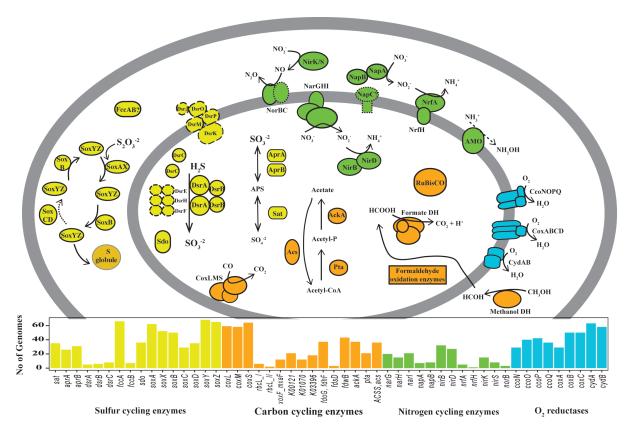

170 third of the genomes were from organisms that were consistently found across floodplains at 171 similar levels of abundance (Purple boxes in Fig. 1e). Regardless of their level of abundance, or 172 which floodplain a representative genome was reconstructed from, the genomes were present in a 173 median > 75% of the samples (78% of upstream floodplain G samples, 84% of mid-stream 174 floodplain L samples, and 87% of downstream floodplain Z samples; Supplementary Figure 1a). 175 Additionally, the 248 organisms were present in the majority (median 88-91%) of the other 176 samples from the same floodplain from which the genome was reconstructed from (Supplementary 177 Figure 1b).

Except for some genomes reconstructed from two floodplain G samples, the rest of the genomes were from organisms that shared more similar abundance levels if the floodplains were closer together within the river corridor (Yellow boxes in **Fig. 1e**). More specifically, floodplains G and L or floodplains L and Z shared more organisms than floodplains G and Z, which are located in the upper and lower reaches respectively. Additionally, floodplain G is narrow, and is at times completely flooded, floodplain L is wider and may only flood partially, whereas floodplain Z is the widest and least prone to flooding.

185 Finally, we examined the number of samples where members of a 98% ANI genome cluster 186 were reconstructed from. The 248 genome clusters contained genomes reconstructed from between 187 2 to 39 samples. The largest genome set was for a large group of Betaproteobacteria strains 188 generally related to strains detected in other environments such as soil, sediment and water 189 (Supplementary Figure 2; Supplementary Data 1). Genomes were reconstructed from two thirds of all samples from floodplain L. This result indicates that strains belonging to this 190 191 Betaproteobacterial clade may play important roles in floodplain biogeochemistry (Fig. 2), 192 especially in soils associated with floodplain L.

- 193
- 194

195 196

197 Figure 2. Diagram depicting Betaproteobacteria genomes and environmentally relevant capacities encoded 198 by representatives of 98% ANI clusters. Note that no single genome harbors all of these genes, but 199 combinations of them instead (Supplementary Table 4). Some genomes harbor methanol dehydrogenases 200 that are potentially able to turn methanol directly into formate (XoxF type). Enzymes delineated with solid 201 lines were predicted using KOFAM HMMs, and the number of genomes $(> 1^*)$ encoding those genes are 202 shown in the bars plot. Enzymes that were predicted using methods as part of ggKbase are shown with 203 dashed lines (long dashes) and enzymes or subunits that are presumably encoded are shown with dotted 204 lines. For more information about metabolic potential see Methods. *AMO was included in this diagram 205 even though it was detected in only 1 genome, to indicate aerobic ammonia oxidation is also possibly 206 carried out by members of this clade.

207

208 Taxonomic composition of the community

Based on the 248 representative genomes detected in each sample, the phylum- or classlevel community composition was broadly consistent both within and across floodplains (**Fig. 3a**). This is also reflected in measures of alpha diversity between sites, as there was no significant difference in Shannon's diversity indices or unique number of organisms (Supplementary Figure 3). Some exceptions to this were Candidate Phyla Radiation (CPR) bacteria that seemed to be detected mostly in floodplain Z, while Thaumarchaeota seemed least present in this floodplain. Additionally, the number of the 248 genomes detected in each sample varied from sample to

8

216 sample (min = 35 and max = 212). We detected particularly low numbers of genomes in five 217 samples (T157 and T800 from floodplain G and T133, T266 and T620 from floodplain Z), 218 although only samples T133 and T266 from floodplain Z may have been affected by lower 219 sequencing depths (Supplementary Table 1).

220 Betaproteobacteria was the group with the highest number of representative genomes (80) 221 in all three floodplains. Other abundant taxa across floodplains included Deltaproteobacteria (27 222 representatives), Acidobacteria (21 representatives), Nitrospirae and Planctomycetes (both with 223 13 representatives), Gemmatimonadetes, Gammaproteobacteria, Chloroflexi and Ignavibacteria 224 (12, 11, 11, and 10 respectively).

225

226

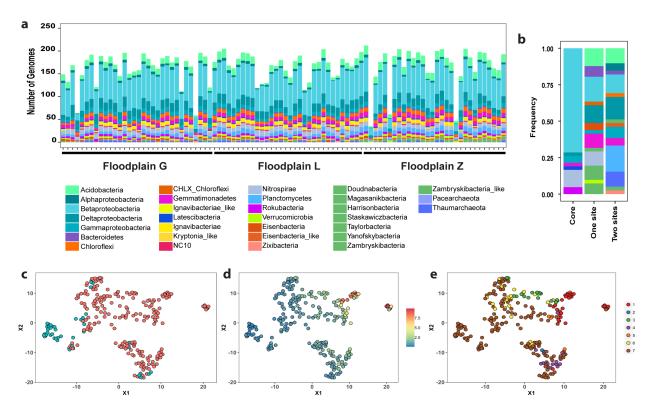

Uncovering a core floodplain microbiome

227 To define a set of organisms representing a core floodplain microbiome we identified organisms that were detected in most sampled sites (≥ 89 of the 94 samples; 90t^h percentile), and 228 229 whose abundance did not indicate a statistically significant enrichment in any specific floodplain 230 (by Indicator Species Analysis (ISA); see Methods and Supplementary Table 5). This operational 231 definition resulted in the identification of 42 high prevalence organisms with low variance 232 abundance profiles across all 3 meander-bound sites, which we refer to as the core floodplain 233 microbiome (Fig. 3c). In general, genomes with a low coefficient of variation of their abundance 234 (blue dots in Fig. 3d) overlapped with genomes that did not display a statistically significant 235 association with any given floodplain (group 7, brown dots in Fig. 3e), suggesting a wide 236 distribution of these organisms across floodplains at similar abundance levels. The core floodplain 237 microbiome was dominated by Betaproteobacteria, with lower abundances of Nitrospirae, 238 Rokubacteria, Gemmatimonadetes, Gammaproteobacteria, Deltaproteobacteria, and Candidatus 239 Letescibacteria (Fig. 3b).

240 Genomes from organisms not considered to be part of the core floodplain microbiome were 241 associated with one floodplain (G, L, or Z; n = 41) or two floodplains (n = 39; Fig. 3e). Other 242 genomes were not classified as part of the core microbiome because although they were not 243 statistically associated with one or two floodplains, they were not detected in ≥ 89 samples (n = 244 126). Genomes affiliated with Acidobacteria, Bacteroidetes, and Chloroflexi were not part of the 245 core floodplain microbiome and were associated with one or two floodplains. The ISA analysis 246 supports the association of some CPR with one floodplain (*i.e.*, between floodplain Z and

9

- 247 Yanofskybacteria, Taylorbacteria, Harrisonbacteria, Staskawiczbacteria, and Zambryskibacteria-
- 248 like bacteria). Similarly, bacteria in the Verrucomicrobia were associated with one floodplain (Z).
- 249 Alphaproteobacteria, Thaumarcheota, Planctomycetes, other CPR (e.g., Zambryskibacteria and
- 250 Doudnabacteria) and Eisenbacteria-like bacteria were associated with two floodplains.
- 251

252 253

254 Figure 3. (a) Taxa at the phylum or class level detected across samples and floodplains, samples are in 255 numerical order (Supplementary Table 1) from the upstream to the downstream floodplain. (b) Taxonomic 256 composition of genomes in the core floodplain microbiome (core), genomes associated with 1 floodplain 257 (one site), and genomes associated with two floodplains (two sites). UMAP showing clustering of Hellinger 258 transformed genome abundances of (c) genomes in the core floodplain microbiome (n = 42; in teal) and 259 genomes not in the core floodplain microbiome (n = 242; red), (d) and overlay of the coefficient of variation 260 (ratio of standard deviation to the mean) of genome abundances across samples, and (e) overlay of genomes 261 associated with individual, pairs, or all floodplains based on an Indicator Species Analysis (ISA). Genomes 262 that were present in 89 samples or more (teal) were not associated with any particular floodplain by ISA 263 (group 7 in brown) and their abundance displayed a low coefficient of variation across samples. ISA 264 genome associations: with floodplain G (1), with floodplain L (2), with floodplain Z (3), with both 265 floodplain G and floodplain L (4), with both floodplain G and floodplain Z (5), with both floodplain L and 266 floodplain Z (6), not associated with any particular floodplain (7).

267

268 Geochemical functions, including those enriched in the core floodplain microbiome

10

To determine what role floodplain soil Bacteria and Archaea may play in nutrient exports to the East River, we investigated a set of pathways involved in biogeochemical cycling and the microorganisms potentially responsible for them. The biogeochemical processes investigated include oxidation/reduction reactions associated with nitrogen, sulfur and hydrogen, C1 compound metabolism (*e.g.*, CO₂-fixation, CO oxidation, methanogenesis, methane oxidation, methanol oxidation, formate oxidation, methylamine oxidation, formaldehyde oxidation), H₂ consumption or production, and the ability to use O_2 as a terminal electron acceptor for aerobic respiration.

276 A set of HMMs was used to annotate genes encoding for individual protein subunits that 277 make up key enzymes and complete or partial metabolic pathways. For a given 'function' (defined 278 as the capacity to carry out a given biogeochemical transformation) to be encoded in a genome, 279 certain criteria for presence had to be met (see Methods; Supplementary Table 4). A total of 32 280 functions comprised the final set of biogeochemical transformations under investigation 281 (Supplementary Table 6). It is important to note that in some cases we also examined individual 282 steps that are involved in a function, recognizing that some functions could be absent in a single 283 genome because the pathway is carried out by multiple taxa (*i.e.*, steps are encoded in multiple 284 genomes). For example, denitrification occurs in separate steps involving different enzymes, and 285 these steps can be performed by multiple different organisms. Complete ammonia oxidation, 286 anaerobic ammonia oxidation, and methanogenesis (of any kind), were not detected in the 287 dereplicated genome set, although some intermediary steps may still be ecologically relevant. 288 Therefore, some steps involved in these pathways were included in downstream analyses.

289 To study the distribution of the functions of interest among genomes and across 290 floodplains, we determined whether a function was present or absent in each genome in addition 291 to where genomes were detected within and across floodplain samples. To describe the distribution 292 of functions, we calculated the proportion of genomes with a given function compared to the total 293 number of genomes detected in a sample. We found that the ability to use oxygen as an electron 294 acceptor (aerobic respiration) was the most prevalent function among genomes (a median of 70 -295 85% of genomes in each sample), followed by acetate metabolism (a median of 40 - 65% of 296 genomes in each sample), aerobic carbon monoxide (or other small molecule) oxidation, formate oxidation, and sulfide oxidation (a median of 30 - 50% of genomes in each sample; Fig. 4a). This 297 298 set of functions was consistently present across all three floodplains, whether encoded by the same 299 or different taxa.

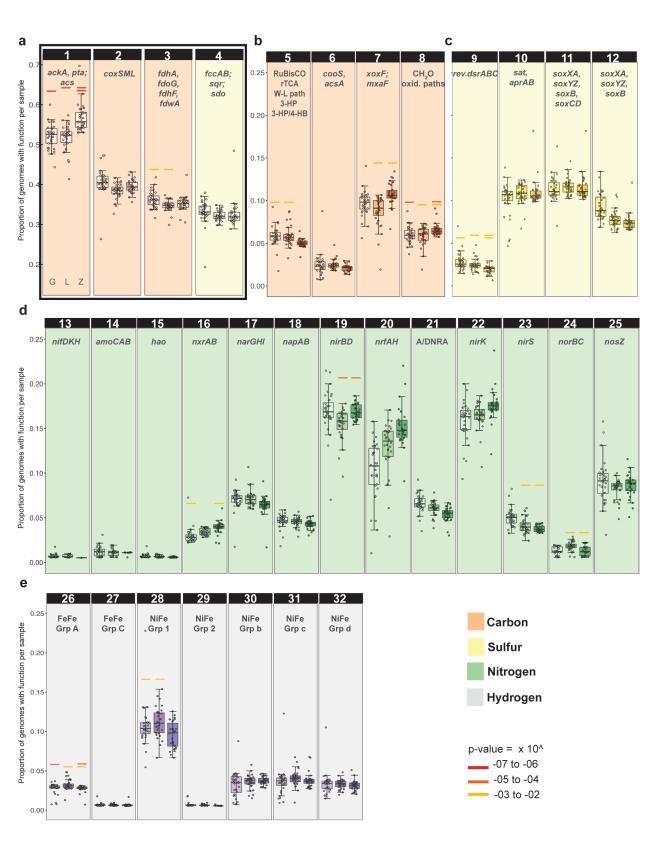

Figure 4. Proportion of representative genomes at the sub-species level with a function among genomes
 detected in each sample within each floodplain. In each panel the box plot on the left shows floodplain G,

12

304 the box plot in the middle shows floodplain L, and the boxplot on the right shows floodplain Z. (a) Most 305 abundant functions: 1. Acetate formation, 2. Oxidation of CO and other small molecules, 3. Formate 306 oxidation: CH_2O_2 to $CO_2 + H_2$, 4. Sulfide oxidation: H_2S to S^0 . (b) Geochemical transformations in the 307 Carbon cycle: 5. CO₂ fixation pathways, 6. Anaerobic CO oxidation, 7. Methanol oxidation, 8. Formaldehyde oxidation pathways (see Supplementary Table 4). (c) Geochemical transformations in the 308 309 sulfur cycle: 9. Sulfide oxidation (reverse dsr) from hydrogen sulfide: H₂S to SO₃²⁻, 10. Sulfite oxidation 310 to sulfate (or vice versa): $SO_3^{2^2}$ to $SO_4^{2^2}$, 11. Thiosulfate oxidation without sulfur deposition: $S_2O_3^{2^2}$ to $SO_4^{2^2}$, 311 12. Thiosulfate oxidation with sulfur deposition: $S_2O_3^{2-}$ to $SO_4^{2-} + S^0$. (d) The nitrogen cycle: 13. Nitrogen 312 fixation: N₂ to NH₃, 14. Ammonia oxidation: NH₃ to NH₂OH, 15. Hydroxylamine oxidation (requires 313 additional, undetermined enzyme): NH₂OH to NO₂⁻, 16. Nitrite oxidation: NO₂⁻ to NO₃⁻ (reversible), 17. 314 Nitrate reduction (cytoplasmic): NO_3^- to NO_2^- , 18. Nitrate reduction (periplasmic): NO_3^- to NO_2^- , 19. 315 Assimilatory nitrite reduction: NO_2^- to NH_4 , **20**. Dissimilatory nitrite reduction: NO_2^- to NH_4 , **21**. 316 Assimilatory or dissimilatory nitrate reduction (ANRA or DNRA): 17 or 18 + 19 or 20, 22 & 23. Nitrite 317 reduction (Denitrification): NO_2^- to NO, 24. Nitric oxide reduction: NO to N_2O , 25. Nitrous oxide reduction: 318 N₂O to N₂. (e) Hydrogen metabolism via hydrogenases: 26. FeFe hydrogenases group A (fermenting and 319 bifurcating), 27. FeFe hydrogenases group C (H₂ sensors), 28. NiFe hydrogenases group 1 (H₂ oxidation), 320 **29**. NiFe hydrogenases group 2 (H₂ oxidation), **30**. NiFe hydrogenases group 3b (bidirectional), **31**. NiFe 321 hydrogenases group 3c (bidirectional), 32. NiFe hydrogenases group 3d (bidirectional). Paired colored bars 322 above any two given boxplots with the same color and at the same level indicate statistically significant 323 differences between those two floodplains (two-way ANOVA).

324

We also considered the distribution of functions that were detected in < 25% of genomes (Fig. 4b-e). Of the remaining C1 transformations examined, methanol oxidation to formaldehyde was found in a median of ~10% of the genomes. Of the sulfur transformations, sulfite (SO₃⁻²) oxidation to sulfate (SO₄⁻²), and thiosulfate (S₂O₃⁻²) oxidation without sulfur (S⁰) deposition and thiosulfate oxidation with sulfur deposition were most prevalent. For reactions involving hydrogen consumption or formation, genes encoding group 1 NiFe hydrogenases (likely used for H₂ oxidation) were found in a higher proportion of genomes than any other types of hydrogenases.

332 Nitrogen transformations were studied individually and as part of the nitrogen cycle. We 333 found the capacity for nitrate (NO₃⁻) use as a terminal electron acceptor in dissimilatory NO₃⁻ 334 reduction in a substantially lower proportion of genomes (2 - 10%) than the capacity to use O₂ as 335 a terminal electron acceptor. Of the reactions involved in nitrification, namely ammonia oxidation, 336 hydroxylamine oxidation and nitrite (NO₂⁻) oxidation, genomes encoding the oxidation of nitrite via nitrite oxidoreductase (NXR) were more common than genomes encoding the first two steps. 337 338 The capacity for NO₃⁻ reduction as part of denitrification (NapAB or NarGHK) was encoded by far fewer genomes than NO₂⁻ reduction (which can be carried by via multiple enzymes, including 339 340 NirK, NirS, NrfAH for dissimilatory nitrite reduction or NirBD for assimilation). Fewer genomes

13

are predicted to encode the capacity to reduce nitric oxide (NO, the product of nitrite reduction) to nitrous oxide (via NorBC) than genomes with the capacity for nitrous oxide (N₂O) reduction to N₂. Overall, the most prevalent genomically encoded function was nitrite reduction, and capacities for consecutive nitrogen cycling steps were typically encoded in multiple different genomes. In other words, there is evidence to support the prevalence of metabolic handoffs ⁷ in the nitrogen cycle.

We identified functions that were significantly enriched (FDR ≤ 0.05 ; hypergeometric test) in the core floodplain microbiome (a subset of ISA group 7) and found that the capacities to use O₂ as a terminal electron acceptor, to perform aerobic CO or other small molecule oxidation, and thiosulfate oxidation (both with and without sulfur deposition) were enriched in these organisms.

351

352 Environmental factors as drivers of function distribution across and within floodplains

353 Environmental variables (Supplementary Figure 4) may explain in part the patterns of 354 enrichment of genomically encoded functions described above. We first looked into correlations 355 involving the following variables: total carbon (TC), total organic carbon (OC), total inorganic 356 carbon (IC), total nitrogen (TN), organic carbon to nitrogen ratio (OC:N), distance of a sample to 357 the river (Dist. to river), easting and northing (cartesian coordinates for position on the floodplain), 358 distance to the inner bank edge (from here on: toe distance) and distance to middle of the meander-359 bound floodplain as alternative measures of position on the floodplain (Supplementary Figure 5), 360 topographic position index (TPI; as a proxy for the likelihood a site would be flooded during 361 periods of high discharge or snowmelt), and elevation. Statistical analysis indicated that TC, OC, 362 TN, and OC:N were all highly correlated with each other across the same set of metagenomic 363 samples (Supplementary Figure 6) and their individual effects were not possible to disentangle. 364 Thus, we chose either TC or OC for downstream analyses. Given the Northwest to Southeast 365 orientation of the watershed, elevation, Easting, and Northing were all highly correlated with 366 floodplain (G vs L vs Z), so only floodplain was included as a categorical variable. In summary, 367 TC, floodplain, IC, TPI, distance to the river and toe distance were the variables evaluated with 368 the fourth corner method ⁸ to assess the response of each function at the gene level to the selected 369 environmental or soil chemistry and GIS variables (see Methods).

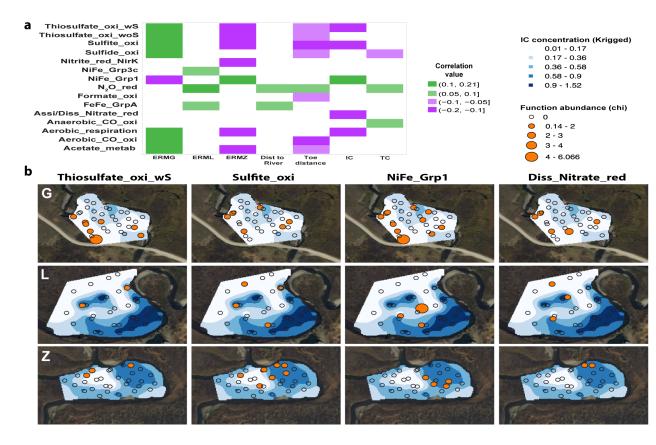

A group of biogeochemical transformations (gene level) displayed some correlation with environmental variables, particularly with individual floodplains (**Fig. 5a**). Genome abundances

14

372 were used as proxies for abundance of functions each genome encoded. The upstream floodplain 373 G was positively correlated with thiosulfate oxidation (with and without S deposition), sulfite 374 oxidation, sulfide oxidation, O₂ as a terminal electron acceptor, aerobic CO or other small molecule oxidation, and acetate metabolism. Only N₂O reduction was positively correlated with the middle 375 floodplain L. The downstream floodplain Z was positively correlated with H₂ oxidation via group 376 377 1 NiFe hydrogenases (a function that was negatively correlated with upstream floodplain G). Most 378 sulfur compound transformations, as well as nitrite reduction, aerobic respiration and acetate 379 metabolism were negatively correlated with floodplain Z (Fig. 5a).

Overall, genomes with the capacity for aerobic respiration and sulfur compound oxidation are most prevalent towards the headwaters (floodplain G), and within this floodplain sulfur compound oxidation apparently is associated with low IC (**Fig. 5b**). Within the downstream meander where aerobic respiration is least prominent in the genomes, bacteria able to oxidize H_2 via Group 1 NiFe hydrogenases appear correlated with somewhat elevated concentrations of IC (**Fig. 5b**).

4 Potentially active genes encoding key biogeochemical transformations in the riparian zone

To determine whether key functions encoded in the genomes were transcriptionally active at the time of sampling (early September 2016; during base flow conditions like previous year), we re-sampled floodplain L for metatranscriptomics and metagenomics. This floodplain was chosen among the three because it shared the majority of organisms detected in 2015 with the other two floodplains.

400 Considering potential differences between the two years, metatranscriptomic reads were 401 mapped to a dereplicated genome set at the species level (95% ANI), which comprised 215 402 genomes reconstructed from samples collected in 2015 and 2016. We calculated transcript counts using read pairs mapped to predicted open reading frames (ORFs) with at least 95% nucleotide 403 404 identity (see Methods). The highest median transcript counts were observed for Nitrospirae and 405 Betaproteobacteria, followed by Candidatus Latescibacteria and Eisenbacteria-like bacteria, 406 Rokubacteria, and Deltaproteobacteria (Fig. 6a). We also evaluated the number of reads mapping 407 to genes encoding key functions and determined what percentile in the distribution of transcription 408 levels each gene fell in.

409 Key genes involved in potentially active biogeochemical transformations with a median 410 transcription $> 75^{\text{th}}$ percentile of all the genes transcribed in a given genome included *amoCAB*, 411 and nxrAB, involved in nitrification. The amoCAB genes for aerobic ammonia monooxygenase 412 were found in the 90th percentile of transcribed genes across genomes. However, these genes were 413 present in very few genomes (one Nitrospirae and two Thaumarcheota). Similarly present in few 414 genomes and also highly transcribed were genes involved in CO₂ fixation, specifically RuBisCO 415 forms I and II and enzymes in the reductive TCA cycle (OFOR and citrate lyase). Other highly 416 transcribed genes were for methanol oxidation to formaldehyde (xoxF, mxaF) and formate 417 oxidation (fdhAB, fdoG, fdhF, fdwA, fdsD, fdwB) as part of C1 metabolism.

Functions enriched in the core floodplain microbiome (aerobic CO or other small molecule oxidation, thiosulfate oxidation, and the ability to use O_2 as a terminal electron acceptor via *coxABCD*, *cydAB* or *ccoN*) and functions that displayed some degree of correlation with environmental variables in gene abundance (*e.g.*, sulfite oxidation via *sat* and *aprAB* or *dsrAB* and

16

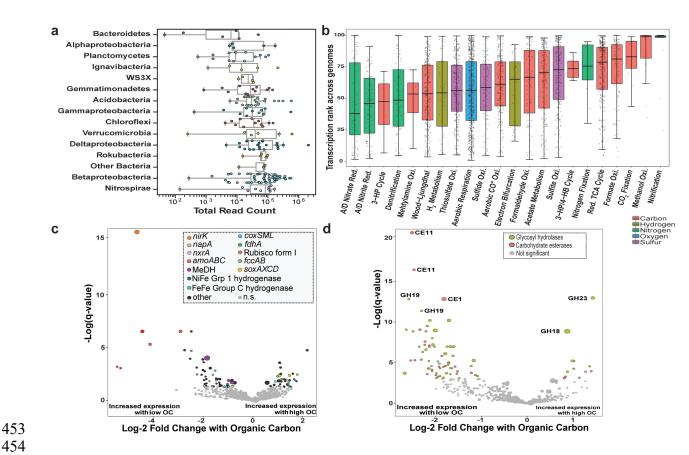

422 sulfide oxidation via *fccAB*) were most often between 50^{th} - 75^{th} percentile of transcribed genes per 423 genome. Surprisingly given their prominence in genomes, genes involved in nitrogen cycling such 424 as *narGHI or napA* and especially *nrfAH* responsible for dissimilatory nitrite reduction, *nirK* and 425 *nosZ* responsible for some denitrification steps, displayed transcription levels only between the 426 35^{th} - 50^{th} percentiles (**Fig. 6b**).

427 We tested for differential transcription levels in response to changes in environmental 428 variables (Supplementary Table 7) using DESeq2⁹. Of the four environmental variables that were highly correlated with each other (TC, OC, TN, OC:N; either positively or negatively 429 430 Supplementary Figure 7), we observed the strongest differential gene expression in response to 431 OC (Fig. 6c). In samples with higher concentrations of OC, genes involved in the Sox pathway for 432 thiosulfate oxidation (soxAX and soxCD) and those involved in aerobic CO or other small molecule 433 oxidation (coxLMS) were highly transcribed. More specifically, transcripts mapped to one coxL 434 form I gene (true carbon monoxide dehydrogenase, CODH) and the rest mapped to four other *coxL* 435 form II genes (carbon monoxide-like dehydrogenase). The form I transcripts were correlated with 436 high OC, and the form II transcripts with both low (1 hit) and high OC (3 hits).

In samples with low OC, highly transcribed genes included those involved in methanol oxidation (xoxF, mxaF), formate oxidation (fdhA), sulfide oxidation (fccAB), hydrogen metabolism (NiFe Grp1), ammonia oxidation (amoABC), nitrite oxidoreduction (nxrA), nitrate reduction (napA), and nitrite reduction (nirK). Samples with low OC also have low TN, which may in part be attributed to high activity of microbial nitrification followed by denitrification, with denitrification reliant on consumption of OC.

443 As might be expected, RuBisCO form I was highly transcribed under conditions of low 444 OC. Activity of the Calvin Benson Bassham (CBB) pathway for CO₂ fixation is linked to 445 Betaproteobacteria, Deltaproteobacteria, Gammaproteobacteria, and NC10, some of which have 446 metabolisms fueled by oxidation of intermediate sulfur compounds (e.g., sulfide or thiosulfate 447 oxidation). The observations reveal a potentially important source of organic carbon in some 448 floodplain soils. In terms of overall transcriptional activity, autotrophic pathways may not be 449 expressed but the organisms may otherwise be highly transcriptionally active. In fact, mostly 450 organisms from the phyla Thaumarchaeota, Rokubacteria, NC10 and Nitrospirae were active under 451 low OC conditions. Betaproteobacteria and Acidobacteria were transcriptionally active under 452 conditions of higher OC.

17

454

464

455 Figure 6. Analyses of transcription from samples collected in 2016 mapped to the species level 456 representative genome set. (a) Transcription activity of genomes grouped by phylum or class based on total 457 transcript read counts mapped to the representative genomes. Other Bacteria: Candidatus Latescibacteria 458 and Eisenbacteria-like bacteria. Phylogeny of the genomes at the species level was confirmed based on a 459 concatenated ribosomal proteins tree (Supplementary Data 2). (b) Average transcription percentile for all 460 genes encoding enzymes involved in a given biogeochemical transformation in each representative genome 461 across all 2016 metatranscriptomes. (c) Differentially transcribed genes in response to soil OC. Statistically 462 significant (DESeq2; q < 0.05) genes are colored by function and not significant (n.s.) genes are in grey. 463 (d) Differentially transcribed genes encoding CAZY in response to soil OC.

465 We also investigated the potential for organic matter degradation through transcription of 466 genes encoding carbohydrate-active (CAZY) enzymes (Supplementary Table 8)¹⁰. We narrowed 467 our search to CAZY enzyme types that were present in at least 60% of the genomes, as a proxy for 468 widespread distribution in the floodplain soil microbial community. The most abundantly 469 transcribed CAZY genes were in the glycosyl hydrolase (GH) and carbohydrate esterase (CE) 470 classes. In general, the highly transcribed enzymes in the CE class use hemicellulose and amino 471 sugars as substrates, resulting in acetate as a byproduct. Acetate could be utilized by many 472 floodplain organisms, considering the prevalence of genes involved in acetate metabolism among

18

473 the genomes. Enzymes in the GH class use cellulose, pectin, chitin and starch as substrates, 474 releasing a variety of sugars as byproducts, which can be utilized for central metabolism during 475 growth. We then tested for CAZY differential expression in response to changing concentrations 476 of organic carbon. 12 CAZYs (both GH and CEs) expressed by three strains of Betaproteobacteria 477 increased in expression in samples with high OC. Many of the same classes of GH and CE 478 displayed high levels of transcription correlated with both low and high OC levels (e.g., GH23, 479 GH28, CE4, and CE11 Fig. 6d), although gene expression by three strains of Betaproteobacteria 480 correlated with high levels of OC. Similar CAZY enzymes were expressed by NC10, Nitrospirae, 481 and Rokubacteria, the same organisms commonly associated with high levels of transcription 482 under low OC.

483

484 Discussion

485 Biogeochemical processes modulate C, S, and N exports from watersheds, including the 486 East River ¹¹. Important questions relate to the sources and sinks of these compounds and the 487 biological controls on them. Some data indicate that a subset of the organic carbon in sediments 488 from East River floodplains derives from the shale, although plants are the obvious central source for fixed carbon in areas of more developed soils ¹². CO₂ fixation genes were relatively rarely 489 490 detected in the bacterial genomes, which might be interpreted to support this deduction. However, 491 genes for CO₂ fixation in a few organisms were very highly transcribed, indicating at least periodic 492 inputs of microbially-produced organic carbon into riparian zone soils. Spatially, high activity of 493 genes involved in CO₂ fixation was correlated with low organic carbon concentrations in soil. 494 Many organisms predicted to rely on CO₂ fixation as their main carbon source are aerobic chemolithoautotrophs that oxidize inorganic compounds (e.g., NH₃⁺, NO₂⁻, S⁰, H₂S, H₂, CO, S₂O₃) 495 496 as a source of energy. Thus, we infer significant linkages amongst these key element nutrient 497 cycles.

Low concentration of organic carbon also correlated with high activity of genes involved in methanol oxidation. Methanol results from the breakdown of plant material, such as pectin and lignin, and the activity of methanol dehydrogenases may be indicative of decomposed organic matter. Similarly, low concentration of organic carbon correlated with high activity of genes involved in sulfide and H₂ oxidation, nitrification and interconversion of nitrite and nitric oxide. The organisms responsible for these reactions are primarily autotrophs.

19

504 Interestingly, the capacities for thiosulfate oxidation/elemental sulfur formation, sulfite 505 oxidation and H₂ oxidation, as well as assimilatory or dissimilatory nitrate reduction to ammonia 506 (ANRA or DNRA) were patchily spatially distributed (Fig. 4b), possibly localized by lower 507 inorganic carbon concentrations. Further, genes for sulfur compound oxidation were more 508 prominent in genomes of organisms from the upstream floodplain, which is closer to the adjoining 509 hill, possibly reflecting higher inputs of intermediate sulfur compounds from rock weathering 510 reactions in the headwater compared to downstream regions. The sources of thiosulfate could be 511 weathering of detrital grains of shale-associated pyrite and/or reoxidation of microbially-produced 512 sulfide in anoxic OC-rich regions of the soil or underlying river sediment. Closer proximity to 513 igneous intrusives in the upstream part of the drainage (e.g., near Floodplain G) leads to greater 514 incidence of pyrite-bearing shales. It has been shown previously that hydrological connectivity can 515 shape microbial activity, with low connectivity linked to higher abundance of genes involved in 516 sulfur metabolism ¹³. In the East River, sulfur compounds may be redistributed from upstream to 517 downstream regions, but the degree of hydrologic connectivity within and across floodplains is uncertain and varies dramatically over the course of the year ¹⁴. Additionally, these shallow soils 518 519 may only be hydrologically connected to the river during high water flood events or through 520 vertical transport.

521 By contrast, high OC levels correlated with high activity of genes involved in oxidation of 522 CO (form I CODH), and other small carbon compounds (form II or other subtypes), which may 523 be substrates for carbon monoxide dehydrogenases ⁵. CO may be sourced from the atmosphere, by 524 thermochemical, photochemical, and chemical degradation of organic matter in soils and marine 525 sediments, and from biological production by microbes, leaves, roots and animals ¹⁵. East River 526 CO oxidizers are most likely carboxydovores that require organic carbon to grow, even though 527 they can oxidize CO at atmospheric levels (*i.e.*, they use a high affinity form I CODH)^{16, 17}. This 528 is in contrast to carboxydotrophs that grow with CO as the sole energy and carbon source and 529 require CO at greater than atmospheric concentrations (for a low affinity form I carbon monoxide 530 dehydrogenase (CODH); ¹⁵). Additionally, form II CO dehydrogenases seem to play a key role in 531 this ecosystem, although very little is known about their actual function. Detection of a high 532 prevalence of CODH and CODH-like enzymes echoes results from a grassland soil system 533 Diamond, et al.⁵, reinforcing the suggestion that small carbon compounds such as plant exudates, 534 may be an important carbon currency under some conditions.

20

535 High organic carbon levels also correlated with high activity of genes involved in 536 thiosulfate oxidation, and carbohydrate esterases and glycosyl hydrolases such as GH23 537 (lysozyme) and GH18 (chitinase). These GHs would be required for organic matter degradation at 538 locations of higher carbon availability, where presumably plants and fungi are more abundant. 539 Bacteria that degrade plant biomass are also known to employ catabolite repression of CAZy 540 enzymes ^{18 3517}, perhaps explaining the lower diversity of CAZys under these conditions. Different 541 variants of these carbohydrate-active genes were highly expressed in a variety of taxa including 542 Rokubacteria, Nitrospirae and NC10 in soil with low organic carbon, where diverse carbon sources 543 must be exploited for survival.

544 Many watershed ecosystems are limited by access to biologically available nitrogen, the important sources of which are likely to be shale bedrock weathering ¹⁹, atmospheric deposition 545 546 ²⁰, and nitrogen fixation. A complex interplay of biological processes impact nitrogen speciation 547 and bioavailability, including ammonia oxidation (nitrification), denitrification to N₂, and nitrite 548 assimilation via ANRA or DNRA. The nitrogen budget can be addressed by direct measurement 549 of inputs, plant-associated inventories, and the concentration of inorganic and organic nitrogen 550 compounds exported from the watershed via rivers ^{21, 22}. By comparing these numbers, it may be 551 possible to estimate the fraction of the bioavailable nitrogen that is lost from the system via loss 552 as N₂ and trace gases. What is missing from this analysis is an estimate of the degree to which 553 nitrogen compounds are recycled, the role of riparian zone soils in these processes, and the 554 potential for subsurface storage of nitrogen compounds in microbial biomass.

555 Using genome-resolved metagenomics we identified the capacity for nitrogen fixation and 556 ammonia oxidation to nitrite and nitrate in relatively few organisms, yet the metatranscriptomic 557 data show these to be highly active functions. Thus, we infer important microbial contributions to 558 reservoirs of oxidized nitrogen compounds in riparian zone soils, with the potential to substantially 559 augment inputs from atmospheric deposition and bedrock weathering. Genes involved in nitrite 560 reduction (dissimilatory nitrate reduction to ammonium or denitrification to N_2), while abundant 561 in comparison to other capacities for nitrogen transformation, displayed surprisingly low levels of 562 transcription at the time of sampling. Over the course of the year, the fluctuating water table and 563 periodic flooding should provide environmental niches for both obligately aerobic, and anaerobic 564 processes. Furthermore, the soil oxidation state and the carbon to nitrate ratio, particularly in 565 nitrogen-limited systems, may favor DNRA over denitrification ²³. The current study was

21

566 conducted during base flow conditions (both years), well after the snowmelt season, when high 567 river discharge induces flooding and therefore anoxic conditions. In the meander-bound 568 floodplains, snowmelt-derived flow in this ecosystem persists well into the year ¹², so shallow soils 569 may be flooded long after discharge levels drop. The results raise the possibility of coupling of 570 nitrification and dissimilatory nitrate pathways on a temporal basis, under baseflow conditions 571 (when nitrification is dominant), or under snowmelt conditions (when dissimilatory processes 572 occur). High net nitrification has been reported for riparian zones when the water table is below -30 cm²⁴, accordingly the water table in floodplain L was observed to be below this level in 573 574 September 2016. Overall, re-assimilation of nitrogen as ammonium may be important in this 575 ecosystem, particularly if nitrogen limited.

576 An important result from the current study was that there appears to be a core floodplain 577 microbiome composed of specific bacterial species from Betaproteobacteria, 578 Gammaproteobacteria, Deltaproteobacteria, Nitrospirae, Candidatus Latescibacteria, and 579 Rokubacteria; and all of these groups were transcriptionally active at the time of sampling. Many 580 of the clusters of related genomes are relatively distantly related to previously described bacterial 581 types. Thus, we conclude that many of the most abundant taxa in these riparian zone soils are 582 organisms that have, until now, remained essentially outside of the range of scientific 583 investigations. Importantly, capacities for aerobic respiration, aerobic oxidation of CO and other 584 small molecules, as well as thiosulfate oxidation with formation of elemental sulfur, were enriched 585 in the core floodplain microbiome. Notably, the most abundant functions of the core microbiome 586 were only moderately transcribed at the time of sampling.

587 In general, we found that gene and organism abundances do not predict transcription levels. 588 The *in situ* transcription data revealed the potentially very high importance of rare genes and 589 organisms. However, it is important to note that transcript datasets are a snapshot from a moment 590 in time, and that transcription patterns will vary across seasons and maybe even daily. Notably, 591 our analyses showed organismal and functional overlap in microbial communities found both 592 within and across the three floodplains over two consecutive years (~15% of species in common, 593 despite the very high diversity and complexity of the soils). Thus, in contrast to potentially 594 substantial transcriptome variability, gene inventories reflect metabolic potential that likely 595 remains fairly constant throughout the year. Thus, we conclude that, at the watershed scale, 596 meander-bound regions of floodplain soils are "functional zones" that likely predict

22

597 biogeochemical transformations along the riparian corridor, thereby providing broadly 598 generalizable inputs to ecosystem models.

602 Study site and samples collection

The East River (ER) watershed has been described elsewhere ³. In brief, the ER watershed is a 300 km² area largely underlain by marine shales of the Cretaceous Mancos formation located in the Elk Mountains in west-central Colorado. The ER is a headwaters catchment in the Upper Colorado River basin, with an average elevation of 3350 m. At about 62 km long, the ER traverses an elevational gradient that includes alpine, subalpine, and montane life zones as a function of stream reach. The average annual temperature is ~ 0 °C, with long cold winters and short cool summers, and the majority of precipitation is received in the form of snow ²⁵.

610 The sampling sites are located across an altitudinal gradient followed by the river (~2700 611 -2900 m). The floodplain at the highest elevation is located ca. 6 km from the headwaters, nearby Gothic, Colorado, site of the Rocky Mountain Biological Laboratory (RMBL, Fig. 1). Therefore, 612 613 samples collected from this site were named East River Meander-bound floodplain G (ERMG). 614 The second site was located ca. 8 km downstream of Gothic, among a series of floodplains, one of 615 which is situated adjacent to an intensive research site of the Watershed Function SFA³. This 616 floodplain stands out because of its larger size, and samples were named ERML (L for large). The 617 third site was located ca. 18 km downstream of Gothic and just upstream of the confluence with 618 Brush Creek. Samples from this site were named ERMZ, with the stream reach between ERML 619 and ERMZ being characterized by a relatively low gradient with high sinuosity.

620 In September 2015, during base flow conditions, two series of perpendicular transects were 621 laid out at each site. Each set of transects comprised four transects that were parallel between them 622 (Fig. 1). One set of transects were approximately North to South (T1-T4) and the other set of 623 transects were East to West (T5-T8). The starting point of each transect was designated "0 m" and 624 the location of the other sites along the transect was relative to the point of origin. A Trimble Geo 625 7X GPS was used to determine the exact location of each site along the transects with an accuracy 626 of 0.5 m. The distance (in meters) of each sample to the point of origin was included in the sample 627 name, which comprised the initials of the study area (ER), the initials for each meander-bound

23

floodplain (*i.e.*, MG, ML or MZ), the transect number (*i.e.*, T1-T8), and the distance in meters from the first sample collected at the start point (*e.g.*, 19 m). We sampled an area ~ 4,600 m² in floodplain G, ~ 8,000 m² in floodplain L, and ~ 5,400 m² in floodplain Z.

631 Four soil samples from the 10-25 cm (± 1-2 cm) soil depth interval were collected in the 632 span of 10 days along each one of the eight transects, for a total of 32 samples per floodplain. Each 633 site was cleared of grasses and other vegetation with clippers, and the first ~ 10 cm of soil was 634 removed with a sterile shovel. Soil samples were collected using sterile tools, including a soil core 635 sampler and 7.6 x 15.2 cm plastic corer liners (AMS, inc), stainless-steel spatulas, and Whirl-pak 636 bags. Samples were immediately stored in coolers for transportation to RMBL, where samples 637 were prepared for archival and transportation to the University of California, Berkeley. Soil cores 638 were broken apart and manually homogenized inside the Whirl-pak bags. Subsamples for chemical 639 analyses, DNA extractions, and long-term archival were obtained inside a biosafety cabinet, kept at – 80 °C, transported in dry ice, and stored at – 80 °C at the University of California, Berkeley. 640

641 In September 2016, another round of samples collection was conducted at floodplain L for 642 metagenomics, metatranscriptomics, and chemical analyses. A subset of 19 out of the 32 sampling 643 sites from the previous year was targeted, and a subset (15) of those was also selected for 644 metatranscriptomics (Supplementary Table 1). Given that floodplain L was the site with the lowest 645 total number of draft genomes recovered in 2015, we added new sites closer to the original sites 646 with the intent of increasing this number by leveraging differential coverage across samples ²⁶. 647 Four new sites located in between the original transects (denominated ERMLIBT) and two sites 648 adjacent to ERMLT660 (ERMLT660 1 and ERMLT660 2) were sampled. Additionally, samples 649 were collected from above the water table (approximately below 40-50 cm from the surface) at a 650 depth of 32-47 cm (± 4-6 cm) from three sites (ERMLT200, ERML231 and ERML293) along T2. 651 Samples from the 11-25 cm (\pm 1-1 cm) soil layer were obtained following the same protocol as 652 the previous year, with the exception that subsamples for RNA sequencing were preserved *in situ*. 653 Once the soil cores were transferred to a Whirl-pak bag, they were manually homogenized inside 654 the bags. Eight grams (8 g) of soil were collected using sterile stainless-steel spatulas directly into 655 50 mL sterile falcon tubes containing 20 mL of LifeGuard Soil Preservation Solution (formerly 656 MoBio) for RNA preservation. The samples were mixed by hand to saturation with the LifeGuard 657 solution, stored in a chilled cooler for transportation to RMBL and later stored at -80 °C.

24

659 Soil chemistry

660 Total carbon (TC) and total inorganic carbon (TIC) were analyzed using a Shimadzu TOC-661 VCPH analyzer equipped with a solid sample module SSM-5000A (Shimadzu Corporation, 662 Japan). Total organic carbon (TOC) was obtained from the difference between TC and TIC. For 663 TC quantification, a subsample of the dried solids was weighed into a ceramic boat and combusted 664 in a TC furnace at 900 °C with a stream of oxygen. To ensure complete conversion to CO₂, the generated gases are passed over a mixed catalyst (cobalt/platinum) for catalytic post-combustion. 665 666 The CO₂ produced is subsequently transferred to the NDIR detector in the main instrument unit 667 (TOC-VCSH). Quantification of the inorganic carbon was carried out in a separate IC furnace of 668 the module. Phosphoric acid is added to the sample and the resulting CO₂ is purged at 200 °C and 669 measured.

Total nitrogen (TDN) was analyzed using a Shimadzu Total Nitrogen Module (TNM-1) coupled to the solid sample module (SSM-5000A) and TOC-VCSH analyzer (Shimadzu Corporation, Japan). TNM-1 is a non-specific measurement of TN. All nitrogen species in samples were combusted at 900 °C, converted to nitrogen monoxide and nitrogen dioxide, then reacted with ozone to form an excited state of nitrogen dioxide. Upon returning to the ground state, light energy is emitted. Then, TN is measured using a chemiluminescence detector.

676

677 DNA extraction and sequencing

678 Genomic DNA was extracted from ~10 g of thawed soil using Powermax Soil DNA 679 extraction kit (Qiagen) with some minor modifications as follows. Initial cell lysis by vortexing 680 vigorously was substituted by placing the tubes in a water bath at 65 °C for 30 minutes and mixing 681 by inversion every 10 minutes to decrease shearing of the genomic DNA. After adding the high 682 concentration salt solution that allows binding of DNA to the silica membrane column used for 683 removal of chemical contaminants, vacuum was used instead of multiple centrifugation steps. 684 Finally, DNA was eluted from the membrane using 10 mL of the elution buffer (10 mM Tris 685 buffer) instead of 5 mL to ensure full release of the DNA. DNA was precipitated out of solution 686 using 10 mL of a 3 M sodium acetate (pH 5.2) and glycogen (20 mg/mL) solution and 20 mL 687 100% sterile-filtered ethanol. The mix was incubated overnight at 4 °C, centrifuged at 15,000 x g 688 for 30 minutes at room temperature, and the resulting pellet was washed with chilled 10 mL sterile-689 filtered 70% ethanol, centrifuged at 15,000 x g for 30 min, allowed to air dry in a biosafety cabinet

25

690 for 15-20 minutes, and resuspended in 100 µL of the original elution buffer. Genomic DNA yields 691 were between $0.1 - 1.0 \ \mu g/\mu L$ except for two samples with 0.06 $\mu g/\mu L$. Power Clean Pro DNA 692 clean up kit (Qiagen) was used to purify 10 µg of DNA following manufacturer's instructions 693 except for any vortexing was substituted by flickering of the tubes to preserve the integrity of the 694 high molecular weight DNA. DNA was resuspended in the elution buffer (10 mM Tris buffer, pH 695 8) at a final concentration of 10 ng/ μ L and a total of 0.5 μ g of genomic DNA. DNA was quantified 696 using a Qubit double-stranded broad range DNA Assay or the high-sensitivity assay 697 (ThermoFisher Scientific) if necessary. Additionally, the integrity of the genomic DNA was 698 confirmed on agarose gels and the cleanness of the extracts tested by absence of inhibition during 699 PCR. For samples collected the following year, DNA was co-extracted with RNA (see next 700 section), in addition to extracting subsamples (10 g of soil) from the same core following the 701 extraction protocol described above (Supplementary Table 1).

702 Clean DNA extracts and co-extracts were submitted for sequencing at the Joint Genome 703 Institute (Walnut Creek, CA), where samples were subjected to a quality control check. Two of 704 the 96 samples from 2015 failed QC and thus were not sequenced (ERMZT233 and ERMZT446), 705 and four samples were sequenced ahead of the others (ERMLT700, ERMLT890, ERMZT100, and 706 ERMZT299). Ten out of 15 of the DNA co-extracts from 2016 failed QC due to low DNA yields 707 and were not sequenced either. Sequencing libraries for the first four samples were prepared in 708 microcentrifuge tubes. 100 ng of Genomic DNA was sheared to 600 bp pieces using the Covaris 709 LE220 and size selected with SPRI using AMPureXP beads (Beckman Coulter). The fragments 710 were treated with end-repair, A-tailing, and ligation of Illumina compatible adapters (IDT, Inc) 711 using the KAPA Illumina Library prep kit (KAPA biosystems). Libraries for the rest of the samples 712 were prepared in 96-well plates. Plate-based DNA library preparation for Illumina sequencing was 713 performed on the PerkinElmer Sciclone NGS robotic liquid handling system using Kapa 714 Biosystems library preparation kit. 200 ng of sample DNA was sheared to 600 bp using a Covaris 715 LE220 focused-ultrasonicator. The sheared DNA fragments were size selected by double-SPRI 716 and then the selected fragments were end-repaired, A-tailed, and ligated with Illumina compatible 717 sequencing adaptors from IDT containing a unique molecular index barcode for each sample 718 library.

All the libraries were quantified using KAPA Biosystem's next-generation sequencing library qPCR kit and a Roche LightCycler 480 real-time PCR instrument. The quantified libraries

26

were then multiplexed with other libraries, and the pool of libraries was prepared for sequencing on Illumina HiSeq sequencing platform utilizing a TruSeq paired-end cluster kit, v4, and Illumina's cBot instrument to generate a clustered flow cell for sequencing. Sequencing of the flow cell was performed on the Illumina HiSeq 2500 sequencer using HiSeq TruSeq SBS sequencing kits, v4, following a 2x150 indexed run recipe.

726

727 RNA-DNA co-extraction and sequencing

728 Total RNA was extracted from a subset of 15 samples using the RNA PowerSoil Total 729 RNA isolation kit (Qiagen). Soil samples (8 g) preserved in LifeGuard solution (Qiagen) were 730 thawed on ice and centrifuged at 2,500 x g for 5 minutes to collect the soil at the bottom of the 731 tubes. As a supernatant, the LifeGuard solution was extracted from the tubes and aliquoted into 732 three 15 mL conical tubes that were used to transfer three separate 2 g subsamples for later use. 733 The remaining 2 g were split in half into two of the kit's bead tubes with pre-aliquoted bead 734 solution (to disperse the cells and soil particles). The lysis solution (SR1) and the non-DNA organic 735 and inorganic precipitation solution (SR2) were not added to the bead tube until all the subsamples 736 to be processed in a given day had been aliquoted. Subsamples were kept at - 20 °C before 737 transferring them to a - 80 °C freezer for permanent storage. The remainder of the extraction was 738 carried out following the manufacturer's instructions. An RNA PowerSoil DNA elution accessory 739 kit was used to co-extract DNA from the RNA capture columns, which was quantified as 740 previously described. A DNase treatment was performed in all the RNA extracts with a TURBO 741 DNA-free kit (Ambion) using 4 U of TURBO DNase at 37 °C for 30 minutes. The absence of 742 DNA was tested by PCR with universal primers to the SSU rRNA gene, and the integrity of the 743 RNA was checked using a Bioanlayzer RNA 6000 Nano kit following the manufacturer's 744 instructions. Total RNA was quantified before and after DNase treatments using a Qubit high-745 sensitivity RNA assay (ThermoFisher Scientific). One of the RNA extracts (ERMLT590) did not 746 yield enough RNA for sequencing.

Total RNA and DNA co-extracts were submitted for sequencing at the Joint Genome
Institute in Walnut Creek, CA, where samples were subjected to a quality control check. rRNA
was removed from 1 µg of total RNA using Ribo-Zero(TM) rRNA Removal Kit (Illumina).
Stranded cDNA libraries were generated using the Illumina Truseq Stranded mRNA Library Prep
kit. The rRNA depleted RNA was fragmented and reversed transcribed using random hexamers

27

752 and SSII (Invitrogen) followed by second strand synthesis. The fragmented cDNA was treated 753 with end-pair, A-tailing, adapter ligation, and 8 cycles of PCR. For low input extracts, rRNA was 754 removed from 100 ng of total RNA using Ribo-Zero(TM) rRNA Removal Kit (Illumina). Stranded 755 cDNA libraries were generated using the Illumina Truseq Stranded mRNA Library Prep kit. The 756 rRNA depleted RNA was fragmented and reversed transcribed using random hexamers and SSII 757 (Invitrogen) followed by second strand synthesis. The fragmented cDNA was treated with end-758 pair, A-tailing, adapter ligation, and 10 cycles of PCR. The prepared libraries were quantified using 759 KAPA Biosystem's next-generation sequencing library qPCR kit and run on a Roche LightCycler 760 480 real-time PCR instrument. The quantified libraries were then multiplexed with other libraries, 761 and the pool of libraries was prepared for sequencing on the Illumina HiSeq sequencing platform 762 utilizing a TruSeq paired-end cluster kit, v4, and Illumina's cBot instrument to generate a clustered 763 flow cell for sequencing. Sequencing of the flow cell was performed on the Illumina HiSeq 2500 764 sequencer using HiSeq TruSeq SBS sequencing kits, v4, following a 2 x 150 indexed run recipe.

765

766 Metagenomes assembly and annotation and ribosomal protein L6 analysis

Methods used for 2015 and 2016 metagenomes assembly and annotation are described 767 768 elsewhere ²⁷. In brief, after quality filtering, reads from individual samples were assembled 769 separately using IDBA-UD v1.1.1 with a minimum k-mer size of 40, a maximum k-mer size of 770 140 and step size of 20. Only contigs > 1Kb were kept for further analyses. Gene prediction was 771 done with Prodigal v2.6.3 in meta mode, annotations obtained using USEARCH against Uniprot, 772 Uniref90 and KEGG, and 16S rRNA and tRNAs predicted as described in Diamond et al.⁵. Reads were mapped to the assemblies using Bowtie2²⁸ and default settings to estimate coverage. To 773 774 estimate the number of genomes potentially present across all 94 metagenomes, we used the 775 ribosomal protein L6 marker RPxSuite and as gene 776 (https://github.com/alexcritschristoph/RPxSuite) as described in Olm et al. ⁶.

777

778 Genome binning, curation, and dereplication

Annotated metagenomes from both years were uploaded onto ggKbase (https://ggkbase.berkeley.edu), where binning tools based on GC content, coverage and winning taxonomy ²⁹ were used for genome binning. These bins and additional bins that were obtained with the automated binners ABAWACA1 (https://github.com/CK7/abawaca), ABAWACA2,

28

MetaBAT ³⁰, Maxbin2 ³¹ and Concoct ³² were pooled, and DAStool was used for selection of the
best set of bins from each sample as described by Diamond et al. ⁵. Notably, no bins were recovered
from sample ERMZT266 by any method.

- 786 Genomic bins were filtered based on completeness \geq 70% of a set of 51 bacterial single 787 copy genes (BSCG) if affiliated with Bacteria and a set of 38 archaeal single copy genes (ASCG); 788 and a level of contamination $\leq 10\%$ based on the corresponding list of single copy genes ³³. 789 Additionally, bins that were 59-68% complete with a highest taxonomic level defined as Bacteria 790 in ggKbase, or potential members of the candidate phyla radiation (CPR) were kept for further 791 scrutiny. To obtain a set of genomes for visual curation in ggKbase, genomes were dereplicated at 792 99% ANI across samples located within a given floodplain using dRep with the --793 ignoreGenomeQuality flag.³⁴. Any assembly error in the dereplicated set was addressed using 794 ra2.py ³⁵, and contigs that fell below the 1 Kb length minimum after this step were removed from 795 the bins. At this point, the level of completeness of CPR genomes was confirmed based on a list 796 of 43 BSCG ⁷. Genomes that did not meet the completeness thresholds post-assembly error 797 correction and that were not affiliated with CPR or novel bacteria were removed from the analysis. 798 Considering that bins changed as a result of this process, genes were re-predicted using Prodigal 799 in single mode, reads were mapped to the bins using Bowtie2, and bins were re-imported onto 800 ggKbase. Visual inspection of taxonomic profile, GC content and to a minor extent coverage, 801 allowed us to further reduce contamination. The final set of 248 curated bins from 2015 was 802 dereplicated at 98% ANI this time across floodplains including the --genomeInfo flag to take into 803 account completeness and contamination in the process of representative bin selection. Within this 804 set, genomes $\geq 90\%$ complete were deemed near-complete (Supplementary Table 2). Eight 805 relatively low coverage genomes fell just below the completeness requirement due to 806 fragmentation after curation to remove possible local assembly errors; these were retained as they 807 represent important taxonomic diversity.
- Similarly, genomes reconstructed from floodplain L samples collected in 2016 that passed the completeness (\geq 70%) and contamination thresholds (\leq 10%) were visually inspected and improved in ggKbase. Assembly errors were corrected with ra2.py ³⁵, and contigs that fell below the 1Kb length were removed, as well as genomes that did not pass the thresholds for completeness after assembly error correction. Genes were re-predicted using Prodigal in single mode and the final set of curated genomes were imported onto ggKbase.

29

To determine whether the same species were present in two different years, we pooled the genome set from 2015 and the curated 2016 set and dereplicated using dRep at 95% ANI including the --genomeInfo flag to take into account completeness and contamination in the process of representative bin selection ³⁴. In this set of genomes, 13 were reconstructed from a deeper depth (Supplementary Table 3). However, only 3 genomes were unique and the other 10 clustered with genomes reconstructed from the ~10-25 cm depth, indicating overlap between the species found at the two depths. Therefore, we kept these genomes for further analyses.

821

822 *Genome metabolic annotation*

823 We carefully chose a set of ecologically relevant proteins that catalyze geochemical 824 transformations related to aerobic respiration, metabolism of C1 compounds, hydrogen 825 metabolism, nitrogen cycling, and sulfur cycling (Supplementary Table 4). Hidden Markov 826 Models (HMMs) for the majority of these proteins were obtained from KOfam, the customized HMM database of KEGG Orthologs (KOs) ³⁶. Custom-made HMMs targeting nitrite 827 828 oxidoreductase subunits A and B (NxrA and NxrB), periplasmic cytochrome c nitrite reductase 829 (NirS, cd1-NIR heme-containing), cytochrome *c*-dependent nitric oxide reductase (NorC; cNOR), 830 hydrazine dehydrogenase (HzoA), hydrazine synthase (HzsA), dissimilatory sulfite reductase D 831 (DsrD), sulfide:quinone reductase (Sqr), sulfur dioxygenase (Sdo), ribulose-bisphosphate 832 carboxylase (RuBisCO) form I and form II, and alcohol dehydrogenases (Pqq-XoxF-MxaF) were 833 obtained from Anantharaman et al.⁷. NiFe and FeFe hydrogenases were predicted using HMMs from Méheust et al. ³⁷ and assigned to functional groups following Matheus Carnevali et al. ²⁹ (see 834 835 Phylogenetic Analyses below for tree construction methods; Supplementary Data 3 and 4 and 836 Supplementary Tables 9 and 10). No real group 4 membrane bound NiFe hydrogenases were 837 identified among the East River representative genomes (data not shown). HMMER3 ³⁸ was used to annotate the dereplicated sets of genomes following predefined score cutoffs ³⁶. A subset (10%) 838 839 of the hits to all of these HMMs were visually checked to determine whether the cutoffs were appropriate for this dataset as described in Lavy et al. ³⁹ and Jaffe et al. ⁴⁰. Only in the case of 840 841 formate dehydrogenase (FdhA (K05299 and K22516), FdoG/FdhF/FdwA (K00123)) the cutoff 842 was lowered to include additional hits.

For a protein to be considered potentially encoded in the genome, the catalytic subunit and the majority of the accessory subunits had to be detected by the corresponding HMMs at the

30

845 established cutoffs. The implication for these function definitions is that in some cases even if 846 some subunits that make up an enzyme were detected, the enzyme could have been deemed absent 847 because a key part was missing (Supplementary Table 4). Similarly, pathways that require the 848 activity of multiple enzymes were only detectable if all of the enzymes were present. Only in cases 849 like the Wood-Jungdahl pathway we required the majority of the genes to be present, taking into 850 consideration genome completeness. Furthermore, if multiple enzymes could catalyze a given 851 reaction (e.g., use O_2 as a terminal electron acceptor) the presence of genes encoding one such 852 enzyme in a genome would be indicative that this capacity was present in the genome. 853 Additionally, if different pathways lead to the same biogeochemical transformation (e.g., CO_2 -854 fixation), the presence of genes encoding one of those pathways (or key enzymes) was considered 855 as sufficient to indicate its presence (Supplementary Table 4). In a limited number of cases a given 856 pathway may also involve enzymes that are part of central metabolism or that are part of multiple 857 pathways, and in these cases we chose to define presence based on the key catalyst instead of the 858 whole pathway (e.g., RuBisCO in the Calvin Benson pathway). 859 Carbohydrate active enzymes were predicted using the Carbohydrate-Active enZYmes Database (CAZY; http://www.cazy.org/)¹⁰ (version 1.0) (e- value cut-off 1e-20). 860 861 862 Genome coverage and detection Reads were mapped to the dereplicated set of bins using Bowtie2²⁸ and a mismatch 863 864 threshold of 2% dissimilarity. Calculate coverage.py 865 (https://github.com/christophertbrown/bioscripts/tree/master/ctbBio) was used to estimate the 866 average number of reads mapping to each genome and the proportion of the genome that was 867 covered by reads (breadth). Genomes with a coverage of at least 0.01 X were considered to be 868 detected in a given sample. The Hellinger transformation was used to account for differences in 869 sequencing depth among samples and determine final genome abundance. To illustrate genome 870 detection across samples we used the ggplot2 package ⁴¹. Genomes were clustered by average 871 linkage using the Hellinger transformed abundance across samples (from read mapping), and the 872 samples were clustered by Euclidean distance in R⁴².

873

874 *Phylogenetic analyses*

31

875 Two phylogenetic trees were constructed with a set of 14 ribosomal proteins (L2, L3, L4, 876 L5, L6, L14, L15, L18, L22, L24, S3, S8, S17, and S19). One tree included Betaproteobacteria 877 genomes from this study at the subspecies level (98% ANI) and \sim 1540 reference Betaproteobacteria genomes from the NCBI (Supplementary Figure 2 and Supplementary Data 1). 878 879 The other tree included the set of 215 genomes dereplicated at 95% ANI and \sim 2,228 reference 880 genomes from the NCBI genome database (Supplementary Data 2). For each genome, the 881 ribosomal proteins were collected along the scaffold with the highest number of ribosomal 882 proteins. A maximum-likelihood tree was calculated based on the concatenation of the ribosomal 883 proteins as follows: Homologous protein sequences were aligned using MAFFT (version 7.390) (--auto option)⁴³, and alignments refined to remove gapped regions using Trimal (version 1.4.22) (-884 885 -gappyout option) ⁴⁴. Tree reconstruction was performed using IQ-TREE (version 1.6.12) (as implemented on the CIPRES web server ⁴⁵, using ModelFinder ⁴⁶ to select the best model of 886 evolution (LG+I+G4), and with 1000 ultrafast bootstrap ⁴⁷. Taxonomic affiliations were 887 888 determined based on the closest reference sequences relative to the query sequences on the tree 889 and extended to other members of the ANI cluster. In many cases, the phylogeny was not clear 890 upon first inspection of the tree and additional reference genomes were added if publicly available. 891

892 Phylogenetic trees for proteins of interest were reconstructed using the same methods 893 described above, except with different sets of reference sequences. East River homologs in the 894 dimethyl sulfoxide reductase (DMSOR) superfamily such as the catalytic subunit of formate 895 dehydrogenase (FdhA), nitrite oxidoreductase (NxrA), membrane-bound nitrate reductase (NarG; 896 H⁺-translocating), and periplasmic nitrate reductase subunit A (NapA) were confirmed by 897 phylogeny on a tree with reference sequences from Méheust et al. ³⁷ (Supplementary Table 11 and 898 Supplementary Data 5). To distinguish form I and form II CODHs and other other subtypes among 899 homologs to K03520 we used Diamond's et al. ⁵ dataset, which comprises reference sequences 900 from Quiza et al. ¹⁶ (Supplementary Table 12 and Supplementary Data 6). Similarly, homologs 901 identified using the Pqq-XoxF-MxaF HMM for alcohol dehydrogenases were placed on a 902 phylogenetic tree with reference sequences from Diamond's et al. ⁵ dataset, comprising references from Keltjens et al. ⁴⁸ and Taubert et al. ⁴⁹. In this tree, all East River homologs were clustered 903 904 with methanol dehydrogenases (Supplementary Table 13 and Supplementary Data 7) instead of 905 other types of alcohol dehydrogenases. To distinguish between dissimilatory (bi)sulfite reductase

32

906 oxidative or reductive bacterial types, DsrA and DsrB homologs from individual genomes were 907 concatenated to each other, aligned, and added to a phylogenetic tree with reference sequences 908 from Muller et al. ⁵⁰ (Supplementary Table 14 and Supplementary Data 8).

909

910 Community diversity and composition

911 Diversity indices for each sample were calculated from the Hellinger transformed 912 abundance table for the genome set at subspecies level (98% ANI) using the vegan package in R 913 ⁵¹. Species numbers and Shannon diversity per sample were quantified using the specnumber and 914 vegdist functions of vegan respectively (Supplementary Figure 3). An analysis of variance, 915 implemented in the aov function in R, was used to test for significant differences in mean species 916 number and Shannon diversity in relationship to the floodplain samples originated from. No 917 significant differences in group means were detected considering a p-value < 0.05 as significant.

918 To investigate community composition at the phylum/class level as determined by 919 phylogenetic analysis, the Hellinger-transformed abundance table for the genome set at the 920 subspecies level (98% ANI) was converted to a presence/absence table. The number of samples 921 where each genome was detected was counted and the number of genomes affiliated to a given taxon was summed by sample and plotted in R with ggplot2⁴¹. 922

923

924 *Identification of a core floodplain microbiome*

925 To identify organisms that were a "core" or "shared" set across all sampled sites, we 926 operationally defined a core set as: (1) organisms that were not statistically associated with any 927 specific floodplain using indicator species analysis, and (2) who were detected (displayed ≥ 0.01 X 928 coverage) in at least 89 of the 94 total samples (the 90th percentile for this level of presence across 929 all 248 genomes). Indicator species analysis was performed on the log transformed coverage 930 values that were filtered to include only coverage values ≥ 0.01 X using the indicspecies package 931 ⁵² in R version 3.5.2 (R core team 2018) ⁴² with 9999 permutations. All p-values for associations 932 of an organism genome with a floodplain or group of floodplains were then subsequently corrected 933 using False Discovery Rate with FDR ≤ 0.05 being considered a significant association. This 934 resulted in 42 genomes that were not statistically associated with any floodplain by ISA and were 935 also detected in \geq 89 samples (Supplementary Table 5). For visualization of organism abundance 936 profiles in relationship to their membership in the core floodplain microbiome, ISA clusters, and

33

relative to the coefficient of variation of their coverage, Hellinger normalized coverage data was projected onto a two dimensional space using Uniform Manifold Approximation and Projection (UMAP) implemented in the uwot package in R ⁵³ using the following parameters: umap(data = coverage_data, n_neighbors = 15, nn_method = "fnn", spread = 5, min_dist = 0.01, n_components = 2, metric = "euclidian", n_epochs = 1000).

942

943 Identification of enriched metabolic functions in core floodplain microbiome

944 Overrepresentation of metabolic functions within the set of genomes comprising the core 945 floodplain microbiome (n = 42) was assessed using hypergeometric testing. The probability of 946 observing the number of genomes in the core floodplain microbiome carrying each of 33 functions, 947 given the total number of genomes with that function across our full genomic dataset (n = 248), 948 was calculated using the phyper function in R. Probabilities calculated across all metabolic 949 functions were corrected for multiple testing using false discovery rate with the p.adjust function 950 in R and with FDR ≤ 0.05 being considered a significant enrichment of a function in the core 951 microbiome.

952

953 Analysis of correlations among environmental variables

Correlations between numeric soil biogeochemical variables across samples were calculated using spearman rank correlation implemented in the rcorr function of the Hmisc package in R (<u>https://github.com/harrelfe/Hmisc</u>). Correlations between variables were then plotted as a correlogram and ordered using hierarchical clustering with Ward's method using the corrplot package in R ⁵⁴.

959

960 Fourth corner analysis

A rlq-fourth corner analysis was performed on genome abundances, environmental data, and genome metabolic annotations using the R package *ade4* ⁵⁵. Specifically, the pre-Hellinger transformed genome abundance table was used for a correspondence analysis, the selected environmental variables (see *Soil Chemistry* and *GIS*) were used for a Hill-Smith analysis, and the genome metabolic annotations were used for PCA. A randomization test (as described by ter Braak et al. ⁵⁶ and Dray et al. ⁵⁷ was used to test the global significance of the trait-environment relationships. The fourth-corner statistic was then calculated on the same inputs as the rlq analysis

34

with 50,000 permutations and p-value adjustments using the FDR global methods. The results of
 the rlq-fourth corner analysis were plotted using the ggplot2 package ⁴¹.

970

971 *Metatranscriptomic analyses*

972 To determine differentially transcribed genes, potential levels of activity by phylum or 973 class, most transcribed CAZY, and most transcribed genes among key geochemical 974 transformations, metatranscriptomic reads were mapped using Bowtie2²⁸ to a set of high-quality 975 draft genomes dereplicated at 95% (see above). Read pairs were then filtered by a minimum 976 identity of 95% to the reference with MAPO>=2 and total number of mapped read pairs was counted for each gene. Counts for metabolic genes were analyzed with DESeq2 ⁹ to determine 977 978 differential expression in response to soil organic carbon and p-values were adjusted to correct for 979 multiple hypothesis testing (FDR<0.05).

980

981 GIS

982 All GIS operations and cartographic visualizations were performed in QGIS v2.12.1 except 983 where otherwise stated. The base remote sensed imagery used was obtained from USDA NAIP 984 (USDA-FSA Aerial Photography Field Office publication date 20171220; 1m ground pixel 985 resolution). Digital terrain model (DTM) at a ground resolution of 0.5 m/pixel was derived by 986 airborne LiDAR data acquired by Quantum Spatial in collaboration with Eagle Mapping Ltd ⁵⁸ 987 (doi:10.21952/WTR/1412542) in 2015. All maps were projected using EPSG:26913 NAD83/ 988 UTM zone 13N. Meander and adjacent river polygons were manually delineated in QGIS. The 989 distance from a sample point to the manually delineated river polygons was calculated using the 990 NNJoin tool. To calculate the sample distances to meander toe, lines were manually drawn 991 between all samples and the meander toe perpendicular to river flow and distances calculated using 992 NNJoin (Supplementary Figure 5). Similarly, to calculate sample distances to the middle of the 993 meander, a line perpendicular to the meander toe line was drawn across the middle of the meander 994 (Supplementary Figure 5). Sample distances to this line were also calculated using NNJoin and 995 samples on the downstream side of the line were converted to negative values to indicate upstream 996 and downstream sides of the meander. TPI is computed from the DTM as the difference between 997 the elevation of a center point and the average elevation measured in the neighboring area (3 by 3 998 m) ⁵⁹. To display genome abundances as used in the rlq-fourth corner analysis, filtered abundance

35

999 values were chi-square transformed in R using the *decostand* in the vegan package and exported 1000 to display in QGIS. Spatial kriging of inorganic carbon was performed in R. The manually 1001 delineated meander polygons were converted to SpatialPixelsDataFrame using the sp package. A 1002 simple variogram model was fit to the natural log transformed inorganic carbon values with a 1003 spatial cutoff of 60 m. Kriging was then performed using the sample points, the meander 1004 SpatialPixelsDataFrame, and the fitted variogram model. The natural log transformed inorganic 1005 carbon values were then back transformed and the kriged map exported for visualization in QGIS.

1006

1007 Data Availability

1008 Representative genomes in the subspecies level set (98% ANI) can be accessed at 1009 https://ggkbase.berkeley.edu/ER15 ALL curated dRep98/organisms and representative 1010 the genomes in species level set (95%) ANI) can be accessed at 1011 https://ggkbase.berkeley.edu/ER15ALL ERML16 dRep95/organisms. Please note ggKbase is a 1012 'live' site, genomes may be updated after this publication. Raw sequence reads for all metagenomes 1013 and metatranscriptomes included in this study can be accessed in the NCBI Bioproject Database 1014 using the umbrella accession number (PRJNA630765). Supplementary Table 1 includes NCBI 1015 Bioproject accession numbers for individual metagenomes metatranscriptomes.

1016

1017 Acknowledgements

1018 We are grateful to Chad Hobson, David McGrath, and Rosemary Carrol for support in the 1019 field during samples collection; and to Joel Rowland (Los Alamos National Lab) and Helen 1020 Malenda (USGS) for useful insights. We thank the Rocky Mountain Biological Laboratory for lab 1021 space at the field site. This work was supported as part of the Watershed Function Scientific Focus 1022 Area funded by the U.S. Department of Energy, Office of Science, Office of Biological and 1023 Environmental Research under Award Number DE-AC02-05CH11231. Sequencing was conducted at the Joint Genome Institute (a DOE Office of Science User Facility) under a CSP 1024 1025 award.
