1 Abstract

2 Hosts and viruses are constantly evolving in response to each other: as hosts attempt to suppress the virus, 3 the virus attempts to evade and suppress the host's immune system. This arms race results in the evolution 4 of novel pathways in both the host and virus to gain the upper hand. Here we describe the coevolution 5 between Drosophila species and a common and virulent DNA virus. We identify two distinct viral types 6 that differ 100-fold in viral titer in infected individuals, with similar effects across multiple species. Our 7 analysis suggests that one of the viral types appears to have recurrently evolved at least 4 times in the past 8 \sim 30,000 years, including in another geographically distinct species, due to the high effective mutation rate 9 which increases with titer. The higher titer viral type is associated with suppression of the host immune 10 system and an increased transmission rate compared to the low viral titer type. Both types are maintained 11 in all populations, likely due to an increased virulence in the high titer type creating a trade-off between 12 effective transmission and virulence and resulting in nearly equal reproduction rates (R_0) in both types. 13 Together these results suggest that the reciprocal selective pressures caused by the co-evolution between 14 host and virus has resulted in this recurrently evolving relationship.

15 Introduction

16 Antagonistic coevolution between hosts and their parasites is nearly ubiquitous across the tree of life. As a 17 result, genes involved in immune defense are among the fastest evolving genes in host genomes (NIELSEN 18 et al. 2005; SACKTON et al. 2007; ENARD et al. 2016; SHULTZ AND SACKTON 2019). Viruses are a particular 19 fitness burden on hosts; for viruses to persist within populations, they must successfully invade the host 20 organism, contend with the host immune system, replicate and then transmit the newly produced particles 21 to a new host (HOLMES 2007; GIFFORD 2012). Once successfully established in a population, natural 22 selection acts to modulate the rate the virus propagates relative to its virulence, optimizing the ratio of viral 23 virulence to transmission (WILLIAMS AND NESSE 1991; MAY AND NOWAK 1995; LIPSITCH et al. 1996). 24 Thanks to their elevated mutation rate and high population sizes, viruses can easily do all of this, and even 25 co-opt or manipulate host-pathways in the process (BURGYAN AND HAVELDA 2011; DAVEY et al. 2011; 26 PALMER et al. 2019). As a result, proteins that interact with viruses often show the fastest rates of evolution, 27 and the highest rates of adaptation compared to the rest of the genome, as the host attempts to suppress the 28 pathogen, or escape infection (OBBARD et al. 2006; OBBARD et al. 2009a; MUKHERJEE et al. 2013; ENARD 29 et al. 2016; PALMER et al. 2018a).

Hosts have evolved numerous immune pathways to reduce viral burden and enhance survival after infection (MERKLING AND VAN RIJ 2013; WEST AND SILVERMAN 2018). Interestingly, several of these pathways (IMD, Toll, JAK-STAT) are generally associated with other pathogens, yet also respond to infection by viruses, though the specific mechanisms are not yet known (HOFFMANN 2003; HULTMARK

34 2003; COCCIA et al. 2004; ZAMBON et al. 2005; COSTA et al. 2009; FERREIRA et al. 2014; WEST AND 35 SILVERMAN 2018). In Drosophila melanogaster, the RNA interference (RNAi) pathway is involved in 36 resisting viral infection by generating suppressive RNAs complementary to the viral sequence (HULTMARK 37 2003). As might be expected, this antiviral RNAi pathway is also rapidly evolving in many species 38 (OBBARD et al. 2006; WANG et al. 2006; OBBARD et al. 2009b; MERKLING AND VAN RIJ 2013). 39 Drosophila innubila Nudivirus (DiNV), which infects the host D. innubila, is the one of the few 40 DNA viruses to naturally infect Drosophila, and the only documented case of a DNA virus infection at high 41 frequency in natural Drosophila populations (UNCKLESS 2011; HILL et al. 2019). Drosophila innubila is a 42 mushroom feeding species of the Drosophila subgenus found inhabiting woodlands found on mountains 43 across Arizona & New Mexico, separated by large expanses of desert. D. innubila radiated north from 44 Mexico during the last glaciation period and came to inhabit these forests after the glacial retreat, creating

45 a subdivided population with high rates of gene flow between locations (DYER AND JAENIKE 2005; HILL
46 AND UNCKLESS 2020).

During this period *D. innubila* likely became infected with DiNV, suggesting a long-lasting hostpathogen relationship in multiple populations. This could lead to opportunities to study the coevolution of DiNV and *D. innubila* in replicate (HILL AND UNCKLESS 2020), which could potentially result in parallel or divergent evolution of the virus and interacting host pathways (ANDERSON AND MAY 1982; KALTZ AND SHYKOFF 1998).

A pair of previous studies examined the rates of evolution of DiNV and *D. innubila*, finding the envelope and replication machinery to be rapidly evolving in DiNV, suggesting its importance in viral propagation (HILL AND UNCKLESS 2018). In *D. innubila*, the antiviral RNAi machinery is not rapidly evolving, possibly as DNA viruses interact with different immune pathways to RNA viruses (the primary burden of *D. melanogaster*) (WEBSTER *et al.* 2015). Consistent with this, the Toll pathway is both rapidly evolving in *D. innubila* and suppressed by a related nudivirus upon infection in *D. melanogaster* (HILL *et al.* 2019; PALMER *et al.* 2019).

59 DNA viruses, and nudiviruses such as DiNV in particular, have much larger genomes (100kbp or 60 larger) than RNA viruses, with much more complicated replication cycles (ROHRMANN 2013). RNA viruses 61 also have much higher mutation rates than DNA viruses, yet much lower levels of diversity due to lower 62 recombination rates and efficient selection on variation in the genome (PENNINGS 2012; PENNINGS et al. 63 2014; WILSON et al. 2016; FEDER et al. 2019). As a result, we expect the evolutionary dynamics of DNA 64 viruses to differ dramatically from RNA viruses (ROHRMANN 2013; HILL AND UNCKLESS 2017). In fact, 65 because of their large genomes, high recombination rate and low mutation rate, we expect that DNA virus 66 coevolution with hosts will be qualitatively different than RNA viruses or bacteria. Together this paints a 67 picture suggesting that hosts can have different relationships with different pathogens (such as RNA viruses

68 or DNA viruses), and the pathogens themselves can behave differently within the host. Characterizing the 69 relationships between different species and their long-term pathogens, such as DiNV and *D. innubila*, will 70 help broaden and expand our understanding of how hosts and pathogens evolve in response to each other.

71 Here, we survey the genetic variation in DiNV to infer its co-evolutionary history with D. innubila 72 and two other associated hosts. We identify two viral multilocus genotypes (considered to be haplotypes) 73 that differ by 11 focal SNPs and show that these viral types are maintained within the same host population 74 and across multiple isolated host populations. Despite high rates of recombination, these SNPs are tightly 75 linked likely due to extremely strong selection and possibly incompatibilities between types. One viral type 76 is associated with 100-fold higher viral titer and increased virulence compared to the other. Further, we find 77 evidence that the high titer type evolved independently in at least four geographically-isolated host 78 populations. Together, these results suggest rapid evolutionary dynamics of host-virus interactions, due to 79 the multiple competing viral types that interact with different host pathways.

80 **Results**

81 DiNV segregates for linked variants strongly associated with viral titer

82 To characterize the evolutionary dynamics of wild Drosophila innubila Nudivirus (DiNV) in its host (D. 83 *innubila*), we sequenced wild-caught individuals from four populations with the expectation that some 84 (~40% in previous samples) individuals would be infected (HILL AND UNCKLESS 2020). We considered 85 strains to be infected with DiNV if they had at least 10x coverage for 95% of the genome. In total, we used 86 sequencing information for 57, 92, 92, and 92 individuals from the Huachucas (HU), Santa Ritas (SR), 87 Chiricahuas (CH), and Prescott (PR) populations with infection rates 26%, 44%, 63% and 79%, respectively 88 (Supplementary Table 1). We also used 35 individuals collected in the Chiricahuas in 2001 (52% infected 89 with DiNV) and 80 individuals collected in the Chiricahua's in 2018 (Supplementary Table 2, pre-selected 90 using PCR, 40 infected with DiNV and 40 uninfected).

We isolated and sequenced DNA from these samples and, after filtering and mapping to the genome
we called variation in the viral genomes to assess the extent of adaptation in each viral population.
Consistent with an arms race between host and virus, most envelope and novel virulence (GrBNV-like)
genes show strong signatures of adaptive evolution in each population compared to background viral genes
(using McDonald-Kreitman based statistic Direction of Selection (STOLETZKI AND EYRE-WALKER 2011)
and Selection Effect (EILERTSON *et al.* 2012), Supplementary Figure 1, DoS > 0, GLM *p*-value < 0.05).

97 Given these potential signatures of an arms race between *D. innubila* and DINV, we first attempted 98 to determine if any host or viral genetic variation is associated with within-host viral titer, which we use 99 here as a measure of virulence. For each virus-infected individual, we quantified viral titer (as viral genome 100 coverage normalized to host autosomal genome coverage) and identified both host and viral

polymorphisms. We then performed an association study across both host and virus variable sites to identify
 variants significantly associated with viral titer using PLINK (PURCELL *et al.* 2007).

103 Of 5,283 viral SNPs in the 155kbp DiNV genome, 1,403 SNPs are segregating in at least 5 infected 104 host individuals. Of those 1,403 SNPs, 78 are significantly associated with viral titer after multiple testing 105 correction (FDR < 0.01, Figure 1A). Of these, 16 are within 2000bp of the start site of a gene, 18 are coding 106 nonsynonymous, 11 are coding synonymous and 33 are intergenic. The most significantly associated SNP 107 is a non-synonymous polymorphism in the active site of *Helicase-2* (Figure 1A, Supplementary Figure 2). 108 The *Helicase-2* polymorphism is the only significantly associated polymorphism found segregating at a 109 range of frequencies within individuals (Supplementary Figure 2). The frequency of this derived 110 polymorphism has a negative relationship between viral titer and the derived SNPs frequency (GLM t-value 111 = -20.516, p-value = 5.55e-62). However, when ranking samples by viral titer, the SNP frequency does not 112 fit this expectation and several samples fixed for the ancestral allele also have a lower viral titer 113 (Supplementary Figure 2).

114 We also identified a striking association between viral titer and eleven nearly perfectly linked 115 polymorphisms found across the DiNV genome (Figure 1A, highlighted SNPs, Table 1, Supplementary 116 Figures 2-4, Sig. SNPs). We refer to these two types as the 'High Type' and 'Low Type' (Figure 1B). 117 This multilocus genotype includes three non-synonymous SNPs and five SNPs in the UTRs of known 118 virulence factor genes and three intergenic SNPs. Viral titer is, on average, 100-fold higher in individuals 119 infected with High type virus compared to the ancestral Low type (Figure 1B). Though we found few 120 strains with an intermediate number of SNPs, viral titer increases as the number of High type SNPs 121 increases (Figure 1C, GLM t-value = 34.971, p-value = 5.912e-16), though the rate of increase slows as 122 the number of High type SNPs increases suggesting diminishing returns (Figure 1C). Some of these 123 polymorphisms are associated with known virulence factors, or are related to the formation of the viral 124 envelope co-opting the host vesicle trafficking system and are rapidly evolving in nudiviruses (e.g. VLF-125 1, ODV-E56, PIF-3) (ROHRMANN 2013; HILL AND UNCKLESS 2017; HILL AND UNCKLESS 2018). 126 Additionally, several are associated with orphan genes thought to be novel virulence factors, including a 127 gp83, a gene that downregulates Toll-induced antimicrobial peptides (AMPs) and upregulates those 128 induced by IMD (gp83) (PALMER et al. 2019). Both pathways may interact with DNA viruses (ZAMBON 129 et al. 2005; COSTA et al. 2009; MERKLING AND VAN RIJ 2013; FERREIRA et al. 2014; LAMIABLE et al. 130 2016; PALMER et al. 2019). 131 Among populations there is a positive correlation between the frequency of the High type and

Anong populations there is a positive correlation between the frequency of the right type and
 overall DiNV infection frequency (Figure 1D, GLM logistic regression z-value = 6.104, *p*-value =
 0.00883), suggesting that the High type may have a higher effective transmission rate, resulting in a
 higher number of new individuals infected, per DiNV infected individual. The transmission rate appears

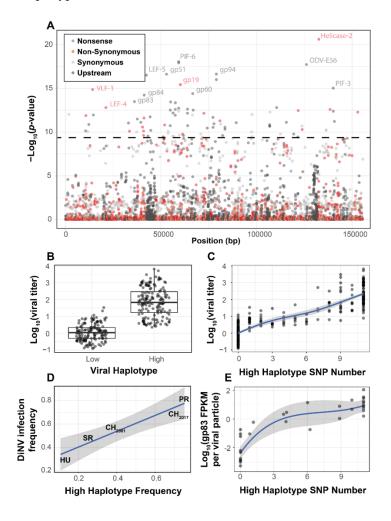

- to be higher for the High type, despite a possibly higher death rate than the Low type. We also find both
- 136 viral types in collections from 2001 and 2017, with the High type significantly more common in the 2017
- 137 collection (Fisher Exact Test *p*-value = 0.0167, Figure 1D).
- 138 **Table 1:** Candidate viral SNPs associated with viral titer, their loci, associated genes and the functional
- 139 category of that gene.

SNP loci	Nearest gene	SNP functional annotation	Nearest gene functional annotation
G14249T	VLF-1	Non-Synonymous	Required for late stage virus activity and particle assembly
C41210T	LEF-4	Non-Synonymous	RNA polymerase subunit for RNA modification
G42389T	gp83	Upstream	Suspected virulence factor which suppresses Toll activity
A59194G	gp51	Intergenic	Suspected virulence factor
C59275A	PIF-6	Upstream	Per OS Infectivity factor envelope
			protein, required for oral infection
T59276C	PIF-6	Upstream	Per OS Infectivity factor envelope
			protein, required for oral infection
G66615A	gp19	Non-Synonymous	Suspected virulence factor
C78978T	gp94	Intergenic	Suspected virulence factor
G78991A	gp94	Intergenic	Suspected virulence factor
C126118A	ODV-E56-2	Upstream	Occlusion-derived virus envelope
			protein required for particle formation
A132593C	Helicase-2	Non-Synonymous	Unwinds DNA and is critical for DNA
			replication
T140117C	PIF-3	Upstream	Per OS Infectivity factor envelope
			protein, required for oral infection

140

Further, the expression of the virally encoded suppressor of Toll signaling, *gp83*, per viral particle is greater in strains containing at least one derived SNP of the high type increase (Figure 1E, GLM t-value = 10.32, *p*-value = 7.34e-12), suggesting enhanced virulence in the high type. For these SNPs, few are found at intermediate frequencies within samples (Supplementary Figure 2), and no samples contain more than two SNPs at a similar frequency (Supplementary Figure 2). This suggests that hosts are either infected completely with Low type or High type virus particles and the two types may be partially

- 147 incompatible with each other. Together, these results suggest that the high viral type is more virulent
- 148 possibly because it is better able to suppress host Toll signaling.

- 157 titer of a sample. **D.** Across five populations, the frequency of the High DiNV haplotype is correlated with
- 158 the frequency of the virus infection. E. Expression (in FPKM per viral particle) of gp83 increases with the
- 159 number of High DiNV haplotype SNPs.

161 The High DiNV viral type suppresses the Drosophila immune system and has elevated virulence

162 Given the striking difference in viral titer and infection frequencies across populations between High and 163 Low type viruses, we sought to further characterize the differences in infection dynamics between the types. 164 We sequenced mRNA from 80 wild D. innubila males collected in 2018 (Supplementary Table 2, 40 165 infected with DiNV, 40 uninfected) and performed a differential expression analysis between infected and 166 uninfected individuals. Few genes were differentially expressed (DE) between infection states in D. 167 *innubila* (Supplementary Figure 5A, p-value < 0.01 after FDR multiple testing correction, above the dotted 168 line), but these DE genes were enriched for several interesting categories. Specifically, we found IMD-169 induced antimicrobial peptides (AMPs) were upregulated upon DiNV infection, while one Toll-induced 170 AMP, and several chorion genes and heat shock proteins were downregulated (Supplementary Figure 5A). 171 We also compared these results to a laboratory experiment in D. melanogaster of differential expression 172 after infection with a close relative of DiNV (PALMER et al. 2018b). These same genes are also differentially 173 expressed in D. melanogaster. Of the 12 genes which are differentially expressed in the same direction in 174 both species, five are AMPs and five are chorion genes (Supplementary Figure 5B).

175 We then compared gene expression between D. innubila infected with High or Low type. We find 176 17 DE host genes and 9 DE viral genes between types (after controlling for virus copy number as 177 FPKM/titer, Figure 2, FDR corrected p-value < 0.01, GLM t-value = -4.6239413, p-value = 9.876143e-05). 178 Specifically, four Toll-mediated immune peptides (Listericin, IM33, Bomanins BomBC2 and BomT2) have 179 reduced expression in High Type infected individuals compared to the Low Type (Figure 2, Supplementary 180 Figure 6). Finally, viral genes of interest (PIF-3, VLF-1, gp83) have higher expression per viral particle 181 (FPKM/titer) in the High type compared to the Low type, all also increase in expression per viral particle 182 (FPKM/titer) as the number of High type alleles increases (Figure 1E & 2, t-value = 13.732, p-value 3.36e-183 15). This pattern may be driven by the allele of the non-synonymous SNP in VLF-1 (GLM t-value = 2.13, 184 p-value = 0.04272) and the alleles of the SNPs upstream of gp83, PIF-3, gp51 and ODV-E56 (GLM t-value 185 = 3.518, p-value = 0.00162). Together these results suggest that the high viral type has increased expression 186 of key virulence factors, which in turn, manipulate the expression of host genes involved in immune defense 187 to result in the observed differences in viral titer. These results suggest that higher gp83 expression may 188 cause the lower Toll-mediated AMP expression, possibly due to lowering Myd88 expression, which in turn 189 prevents the host from enacting a proper immune response to DiNV infection (Figure 2, Supplementary 190 Figure 5).

191 Experimental infections recapitulate differences in viral type virulence

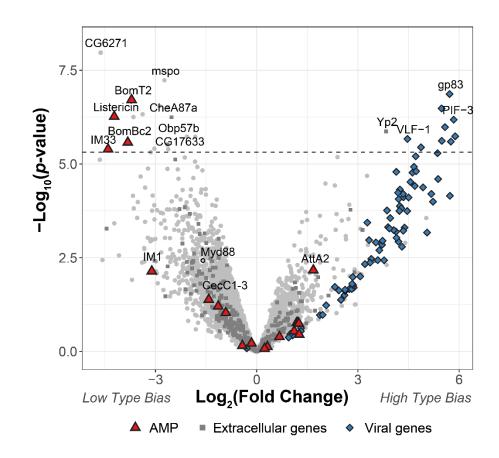

192 To assess if the virulence of the virus types differs in experimental infections, we performed experimental

193 infections of *D. innubila* males using viral filtrate of strains infected with one of the two types of DiNV.

194 As infectious viral titer is increased, survival decreases regardless of viral type (Supplementary Figure 7 & 195 8, ANOVA residual deviance = 3.536, p-value = 2.454e-07, Cox Hazard Ratio z-value > 2.227, p-value < 196 0.02592), with survival decreasing as titer increases (Supplementary Figure 7, Cox Hazard Ratio z-value > 197 5.428, p-value < 5.69e-08). In both cases viral titer also increases for the first 3 days of infection (GLM t-198 value = 9.817, *p*-value = 3.6e-14).

199

200 Figure 2: Differential expression of *D. innubila* and DiNV genes between *D. innubila* infected with either 201 the Low type or High type DiNV multilocus genotypes. For host genes, the log-fold change of mRNA 202 fragments per million fragments is compared, while for viral genes the log-fold change of viral mRNA 203 fragments per million fragments per viral particle is compared. Genes are colored/labelled by categories of 204 interest, specifically antimicrobial peptides (AMPs), proteins involved in the extracellular matrix and viral 205 proteins. Specific genes of interest, such as Myd88, are also named. The FDR-correct significance cut-off 206 of 0.01 (10,320 tests) is shown as a dashed line.

208 For a set of independent viral isolates, four High type- and four Low type-infected samples, we 209 diluted samples to roughly equal concentrations of viral particles (about 0.5 particles per host genome prior

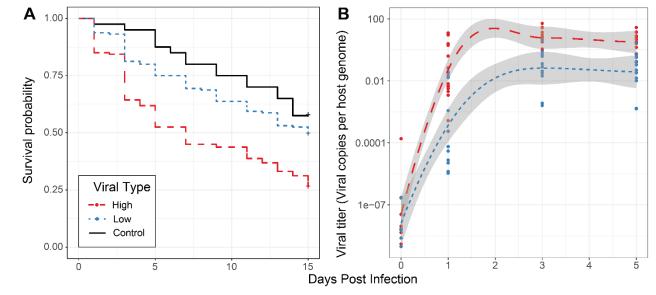

210 to filtration) and performed infections for replicates of 10 males with microneedles dipped in one of the 211 filtrate samples. Survival is significantly lower for flies infected with High type viruses when compared to 212 either flies pricked with sterile media (Figure 3A, Cox Hazard Ratio z-value = 3.671 p-value = 0.000242) 213 or those pricked with Low type virus (Figure 3A, Cox Hazard Ratio z-value = 4.611 p-value = 4e-06). Flies 214 pricked with Low type virus do not show a significant reduction in survival compared to control flies (Cox 215 Hazard Ratio z-value = 1.353, p-value = 0.176). We also measured viral titer over time using qPCR, and 216 find titer increases through time in flies infected with either type (Figure 3B, GLM Log_{10} (titer) ~ days + 217 type, days t-value = 9.912, p-value = 1.76e-14). Flies infected with High type virus have significantly higher 218 viral titer compared to flies infected with Low type virus (Figure 3B, GLM Log₁₀(titer) ~ days + type, type 219 t-value = 3.934, *p*-value = 0.000211). These results suggest that while the High type strain has higher viral 220 titer and potentially higher transmission rate in wild flies, it also has higher virulence, even after controlling 221 for initial infection titer.

Figure 3: Effect of viral type in experimental infections. A. Survival curves of *D. innubila* infected with

high and low viral types compared to control flies pricked with sterile media, for 15 days post infection.

224 Survival 5 days post-infection separated by strain is shown in Supplementary Figure 8. **B.** qPCR copy

number of viral *p47* relative to *tpi* in *D. innubila* infected with DiNV filtrate of high and low types.

226

227 DiNV types are under strong selection in the host

228 Recombination is required during nudivirus replication and recombination start sites can be at any point

in the single chromosome circular genome (KELLY 1982; ROHRMANN 2013). These factors likely cause

the incredibly high recombination rates observed in nudiviruses (BLISSARD AND ROHRMANN 1990;

231 WANG AND JEHLE 2009; ROHRMANN 2013). In DiNV, the eleven key SNPs that distinguish the High and

Low haplotypes are spread across the genome yet are nearly perfectly linked. In contrast, other SNPs in

the genome have relatively low linkage disequilibrium, suggesting that selection to maintain eachhaplotype is strong (Supplementary Figure 4 and 9).

235 Using McDonald-Kreitman based statistics for detecting selection (MCDONALD AND KREITMAN 236 1991; STOLETZKI AND EYRE-WALKER 2011; EILERTSON et al. 2012), we tested whether genes that are 237 associated with the High and Low haplotypes exhibited different signatures of natural selection compared 238 to other viral genes. Envelope and virulence proteins show significantly elevated signatures of adaptation 239 (Figure 4, envelope & virulence versus background paired T-test t-value = 2.1761, *p*-value = 0.03814). 240 Genes found in the initial GWAS for virulence, which defined the High and Low types (such as VLF-1, 241 PIF-3, LEF-4 and LEF-5) have significantly higher rate of substitutions being fixed due to selection than 242 background genes (Figure 4, type-associated genes versus all other, t-value = 2.718, p-value = 0.00068). 243 We also performed a GWAS using the host polymorphism and find few associated SNPs, after 244 controlling for the viral haplotype (Supplementary Figure 10). Consistent with the arms race model, host 245 genes we suspect are interacting with DiNV (such as the GWAS hits, AMPs, chorion genes, piRNA genes 246 and extracellular genes) show elevated levels of substitutions fixed by selection compared to background 247 genes in D. innubila (Figure 4 & Supplementary Figure 1). Finally, DE chorion genes, extracellular genes 248 and AMPs have significantly more adaptive substitutions than similar non-DE genes (Figure 4, blue dots, 249 differentially expressed versus all other T-test: D. innubila t-value = 4.755, p-value = 0.000671). Overall 250 these results suggest strong selection is acting on both the host to suppress viral activity and the virus to 251 escape this suppression.

252 The High viral type of DiNV evolved repeatedly in three D. innubila populations

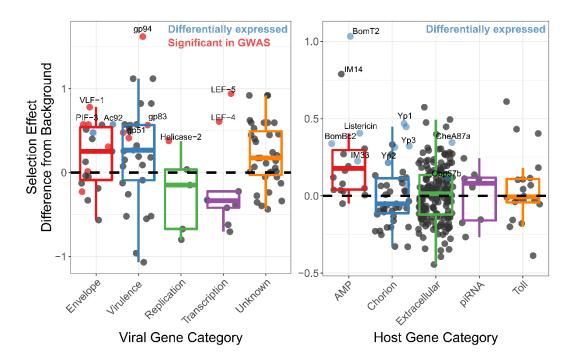

We next sought to understand the evolutionary origin of the two types. Given that both types are found in all populations surveyed (Figure 1D), we hypothesized that this could occur one of three ways: First, the derived haplotype was present ancestrally and has been maintained since before geographic isolation occurred. Second, the derived haplotype evolved following geographic isolation and has spread via migration between locations. Third, the derived haplotype has recurrently evolved in each location.

258 To distinguish between these possibilities and determine the timeframe of divergence, we used the 259 site frequency spectrum of silent DiNV polymorphism to estimate effective population size backwards in 260 time for all populations (LIU AND FU 2015). We find three populations (CH, HU and SR) expand from a 261 single viral particle (N_e = 1) to millions of particles during the last glacial maximum (30-100 thousand years 262 ago) when *D. innubila* settled its current range (Supplementary Figure 11). This supports a single invasion 263 event during a host-range change. PR appears to expand between 1 and 10 thousand years ago, suggesting 264 a much more recent bottleneck during the range expansion in PR (Supplementary Figure 11) (HILL AND 265 UNCKLESS 2020).

We aligned genomic regions containing SNPs to two related nudiviruses, Kallithea virus and Oryctes rhinoceros Nudivirus (OrNV) (WANG *et al.* 2008; HILL AND UNCKLESS 2018; PALMER *et al.* 2018b). The High haplotype alleles are not present in either Kallithea or OrNV, and are not found in short read information for wild *D. melanogaster* infected with Kallithea virus (WEBSTER *et al.* 2015), suggesting they are derived in DiNV.

271

Figure 4: Genes implicated in host/virus interaction are rapidly evolving by positive selection in the Chiricahua population. Difference in selection effect for viral and host gene categories of interest, and nearby background genes, as indicated by the proportion of substitutions fixed by adaptation, weighted by mutations in SnIPRE (EILERTSON *et al.* 2012). Genes that have associated SNPs from the GWAS are highlighted in red, while genes which are differentially expressed upon infection, or between viral types are labelled in blue. All GWAS hits are also differentially expressed and labelled in red. Genes of interest are named.

We generated consensus DiNV sequences for each infected *D. innubila* individual and created a whole genome phylogeny to infer geographic diffusion of samples using BEAST (BOUCKAERT *et al.* 2014). We then performed ancestral reconstruction of the presence of the High type across the phylogeny using APE (PARADIS *et al.* 2004). Our samples group as three populations (with HU and SR forming one population) and, consistent with our expectation, the Low type is the ancestral state (Figure 5A). Surprisingly, the High type appears to have evolved repeatedly and convergently within each population,

forming separate groups within each population (Figure 5A). The High type also clusters within each population in a principal component analysis of all viral SNPs (Supplementary Figure 9), and when repeating these analyses while excluding the eleven focal SNPs.

We next surveyed each background SNP (not associated with the High or Low type) to determine if the general background supports one of the three outlined ways in which the High type evolved and spread in each location. We grouped SNPs by their presence in just the High type or Low type (supporting a single origin and spread by migration) or if they were unique to a single population but shared between the High and Low types (supporting recurrent evolution with recombination).

In total, 391 SNPs (28% of SNPs surveyed) are unique to a single population yet are still shared between both High and Low types (Figure 5 and Supplementary Figure 9), compared to 23 SNPs shared between locations but exclusive to High type samples.

These unique SNPs (161 for CH, 127 for HU and SR, and 53 for PR), are present in all High type samples of a population but a variable proportion of Low types for that population (between 19% and 94%) and are unique to that population. This pattern fits with the High type recurrently evolving on a single background (a different background in each location), supporting recurrent evolution of the High type. The population-specific background SNPs are spread throughout the DiNV genome, with little evidence of recombination with the high type SNPs, making it unlikely that these SNPs recombined onto different backgrounds (Supplementary Figure 4).

Though there is strong linkage between the High type SNPs, they are not perfectly associated with each other (Supplementary Figure 4). Using this slight disassociation and APE (PARADIS *et al.* 2004), we performed ancestral reconstruction of SNP origins in each population (assuming recurrent evolution) and find that, excluding three variable SNPs, the evolution of these SNPs was the same order in each population (Figure 5B).

309 To determine if this recurrent evolution is plausible in our estimated timeframe (~10,000 years), 310 we simulated viral populations using a modified discrete SIR model using deSolve (SOETAERT et al. 2010) 311 with estimated baculovirus mutation rates, ranges of viral titer taken our samples and estimated population 312 sizes for each viral population (parameters described in the methods). In this model we used an effective 313 mutation rate scaled to viral titer, considering the mutation rate per particle, so total mutations per 314 generation increase with viral titer. The simulations suggest that waiting time for the first mutation that 315 increases titer is highly variable between replicates but usually occurs within 1000 generations (~200 years 316 assuming 5 generations per year, in >99.1% of replicates, Figure 5C). The average wait time for each 317 subsequent mutation decreases monotonically (GLM t-value = -2.389, p-value = 0.03686). In each case, 318 the next mutation appears in the background of the previous high titer mutation (Figure 5C) due to the 319 elevated effective mutation rate and increased basic reproduction number (R_0) . The accumulation of

mutations therefore occurs at a geometric (approximately exponential) rate. Additionally, the standard deviation of time wait times also decreases with each new mutation (GLM t-value = -2.441, *p*-value = 0.04241), increasing the certainty that the entire multilocus genotype will appear in a population rapidly once the initial mutations appear. This chain reaction of adaptation facilitates the repeated evolution of the virulent High type independently in three populations, with all eleven mutations fixing in a population within 6000 generations (~1200 years) in all replicates (3372 generations on average, ~675 years), a plausible amount of time given our estimated timeframe.

327 Both viral types are found in two other Drosophila species and have also evolved in a geographically 328 distinct population

329 Since we find two types of DiNV are maintained, and that other species are infected with DiNV, we 330 hypothesized that another species could be a reservoir for the less effective Low type. We chose to study 331 D. azteca from the Chiricahuas since it is frequently infected with DiNV (~33% infection), overlaps with 332 D. innubila, and is genetically divergent (40-60 million years) which could mean a very different genetic 333 interaction between host and virus (UNCKLESS 2011). We also examined DiNV-infected D. falleni 334 (collected in Georgia) as an outgroup. In all, we sequenced 36 D. azteca and 56 D. falleni. Both types are 335 present in all examined species, but the high type is rare in *D. azteca* (Figure 6B). The High type has a 336 significantly higher titer than the low type in all cases (Figure 6A). Viral titer is not significantly different 337 across species for either High or Low type (Figure 6A, GLM t-value = -1.351, p-value = 0.179). We also 338 find the D. azteca samples cluster with CH D. innubila samples and contain the CH background SNPs 339 (Supplementary Figure 9C), suggesting no differentiation in the virus infecting different species. 340 Interestingly, D. falleni DiNV clusters completely separately from the other samples, likely due to its 341 geographic separation, but still has a derived cluster of High type virus, suggesting a fourth separate 342 evolution of the High type in Georgia. Despite the lack of difference between species samples in Arizona, 343 a lower proportion of the *D. azteca* population is infected with DiNV, and the High Type is less common 344 than the Low type DiNV (Figure 6B). Thus perhaps, even though the relative differences in titer are 345 preserved between the two species, the Low Type is favored in D. azteca because this reduced virulence 346 leads to a greater R_0 in D. azteca. Thus, the two types of the virus may be maintained in both host species 347 because though they have become specialized to maximize fitness in one host, messy transmission between 348 host species could lead to their continued presence in both hosts.

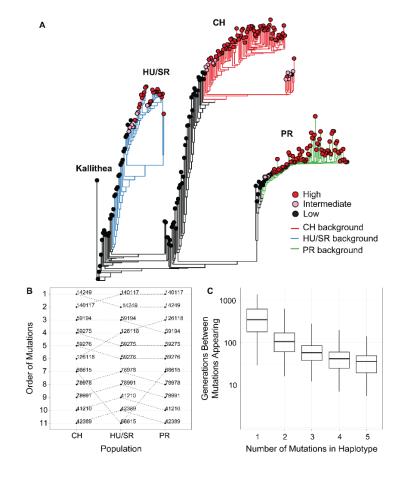

We also repeated the GWAS for viral titer in DiNV infecting *D. azteca* and *D. falleni*. In both cases we again found the 11 High type SNPs associated with viral titer (GLM t-value > 4.28, *p*-value > 0.0001 in both cases), but not the *Helicase-2* SNP (despite its presence in *D. falleni* DiNV samples). After controlling for the High type, we find no other significant DiNV SNPs in *D. azteca* associated with viral titer. For

353 DiNV infecting *D. falleni*, we find 478 significant SNPs (FDR corrected *p*-value < 0.01), though none of 354 them with as large an effect as the High type associated SNPs.

355

356 Figure 5: The evolution and maintenance of two viral types. A. Phylogeographic reconstruction of the 357 spread of DiNV through D. innubila, rooted on the Kallithea virus reference sequence, including a 358 reconstruction of the High type evolution (with strains containing all 11 High type variants shown in red, 359 strains with an intermediate number of high type variants are shown in pink, and strains with no high type 360 variants are shown in black). Branches are colored when the SNPs found in the background for each High 361 haplotype are present in the population, showing that the background differs per population. Black branches show states where branch tips do not contain all the shared High/Low population specific 362 363 background SNPs. **B.** Order of mutations in the viral haplotype appearing in each population. Apart from 364 three mutations the order is consistent between locations. C. The number of generations needed for 'High 365 titer' mutations to evolve in simulated populations, given that each mutation increases the mutation rate.

366 The number of generations between each mutation appearing decreases as titer increases.

Low

371 type DiNV.

373 Two DiNV types may be maintained due to a trade-off between transmission and virulence

374 Given the ease that the High type appears to evolve recurrently in populations (Figure 5C), its apparent 375 association with increased infection frequency, and its apparent inability to coinfect with the low type, it is 376 surprising that the High type has not outcompeted the Low type. There are several possible explanations 377 for the maintenance of the two types. First, a soft selective sweep may be occurring on the High type, where 378 recurrent mutation followed by a change in environment changes the fitness of the High type that will 379 eventually result in its fixation (HERMISSON AND PENNINGS 2005). Second, both types may be maintained 380 due to a trade-off (ALIZON AND VAN BAALEN 2008). Such a trade-off might even be associated with 381 frequency-dependent selection and cycling frequencies over time. This trade-off could involve different 382 transmission and virulence strategies or might be related to specific adaptation to different hosts.

High Low Uninfected

383 In a simple model of viral infection dynamics, the success of the virus is measured by its basic 384 reproduction number (R_0) which is the ratio of the instantaneous transmission rate (β) to the virulence of 385 the virus (γ). If there is a trade-off between transmission and virulence, we might expect that although the

386 High type has a higher instantaneous rate of transmission, it also has higher virulence, killing infected 387 individuals before they can infect other possible hosts. In contrast, those infected with the Low type persist 388 with the infection and can therefore transmit proportionally more virus due to more interactions with 389 susceptible individuals, despite a lower instantaneous transmission rate. To test this, we simulated 390 populations with two viral types using a modified SIR model in deSolve (SOETAERT et al. 2010). We varied 391 transmission and virulence rates and estimated sets of parameters in which types are maintained within 392 populations. We find that a stable infection frequency depends on both the magnitude of instantaneous 393 transmission rate, and the R_0 , with higher transmission rates increasing the infection frequency, to a 394 maximum of 1 - (γ / β) (Figure 7A). The total infected proportion effectively saturates due to the increased 395 death rate (virulence) of infected individuals, suggesting a trade-off between transmission and virulence as 396 titer increases (Figure 7A). This is consistent with our results in experimental infections in DiNV 397 (Supplementary Figures 7 & 8, Cox Hazard Ratio z-value \geq 2.227, *p*-value \leq 0.02592), and other theoretical 398 treatments (MAY AND NOWAK 1995; ALIZON AND VAN BAALEN 2008). Two types are only maintained 399 when the R₀ is equal for each type ($\gamma_1/\beta_1 = \gamma_2/\beta_2$). As the transmission rate of the High type increases, it 400 infects a larger proportion of the population and outcompetes the Low type (with High and Low types at 401 equal proportions when the transmission rates equal), the High type proportion saturates due to the equally 402 increasing virulence rate which keeps the R_0 equal to the Low type (Figure 7A). Given the requirement for 403 an equal R₀ for maintenance, the actual proportion of individuals infected with each type depends on the 404 starting infection frequencies of each type and the difference in absolute transmission rate (Figure 7B). 405 Based on the infection frequencies of our sampled populations, we suspect that the High type was able to 406 evolve earlier in the recently bottlenecked PR population (consistent with the High type background being 407 shared with 94% of PR Low types), or the absolute transmission rate (and virulence rate) may have 408 increased in PR population, which is likely what has occurred in CH over time (Figure 7B). Together this 409 suggests that differences in population infection frequencies may depend on a combination of demographic 410 factors, host genetic factors and the instantaneous transmission rate in each population (with lower 411 transmission rates in HU and SR compared to PR and CH). This also implies there is a limit to how virulent 412 a strain can become before it becomes detrimental, as even with higher transmission rates per individual, 413 DiNV may kill the host before it can transmit, reducing its basic reproduction number (R_0).

414 Discussion

415 Viruses are constantly evolving not just to better infect their host, but also to optimize their infection, to

416 infect as many individuals as possible without preventing the transmission to new hosts (MAY AND NOWAK

417 1995; LIPSITCH et al. 1996; ALIZON AND VAN BAALEN 2008). Since the host is also evolving in response

418 to the virus, an evolutionary arms-race often ensues (DAWKINS AND KREBS 1979; KALTZ AND SHYKOFF

419 1998; DAUGHERTY AND MALIK 2012). Here, to work towards expanding our understanding of the co-420 evolution of viruses and their hosts, we examine the population dynamics of Drosophila innubila Nudivirus 421 (DiNV), a DNA virus infecting *D. innubila* (UNCKLESS 2011). DNA viruses have large genomes and often 422 recombination, placing them as a somewhat transitionary pathogen between RNA viruses, bacteria and 423 eukaryotic pathogens and parasites. Within our set of viral samples, we find two DiNV haplotypes which 424 differ by 11 SNPs (Figure 1, named High and Low types). One haplotype (the High type) is associated with 425 higher viral titer, likely due to an increased manipulation of the host immune system and increased 426 expression of viral factors. This derived (High type) has likely recurrently evolved in each population since 427 the last glacial maximum (~10,000 years ago). The two types appear to be incompatible to some degree, as 428 we find little evidence of co-infections, and mutations appear in a similar order as if navigating an epistatic 429 fitness landscape (DOBZHANSKY 1937; KONDRASHOV et al. 2002; GAVRILETS 2004). Finally, despite the 430 higher titer and transmission rate of the High type, we find that the two types are maintained in all 431 populations sampled, possibly because the increased viral titer also increases the virulence, leading to 432 similar basic reproduction numbers in the High and Low type (ALIZON AND VAN BAALEN 2008).

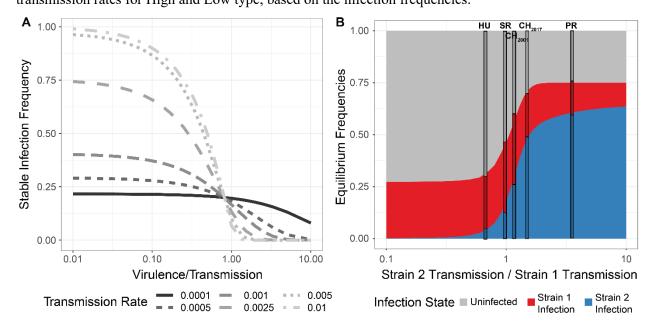

433 If the reproduction rate, R_0 , was equal between the two viral types we would expect the infection 434 frequencies to be equal in our sampled populations, which is not the case. This could be caused by the 435 starting frequencies of each type not being equal (with the Low type starting at a higher frequency, Figure 436 7). There could also be time or host dependent variation, so over time (and between locations), changes in 437 the environment could alter transmission rates of each type, also altering the ratio of High type to Low type. 438 We also do not consider frequency dependent selection in our model, where the transmission rate depends 439 on an interaction between the infection frequencies of the two types.

440 The R_0 could be similar between types, but not identical, resulting in slow changes in the ratio of 441 types over time (as seen between 2001 and 2017, Figures 1D & 7). As we only have two time points, we 442 could be witnessing a selective sweep of the High type spreading to fixation (NIELSEN 2005), with 443 recombination causing the observed differences in the background. As we find the High type appears to 444 have evolved recurrently, it would be unlikely that we have caught these sweeps partway through in all four 445 populations sampled (Figure 1D). Using the frequency of the High type between 2001 and 2017 CH 446 samples, we can calculate the selection coefficient for the High type if increasing at an exponential rate 447 (which is likely given the intermediate frequency at both time points, Figure 7B). If we assume 5 448 generations per year and an increase among infected individuals from 39% on 2001 to 71% in 2017, the 449 selection coefficient = 0.007, which suggests the High type would take \sim 275 years to fix in a population 450 once it has arisen. Given the coalescence time of the two types is close to the expansion time of the two 451 viruses (2-30 thousand years), this does not fit with our results, suggesting the two types are being

452 maintained and not sweeping. Further, if the High type was sweeping, it would be remarkable for us to 453 catch these sweeps occurring in all four populations sampled, given our estimated time to fixation.

454

455 Figure 7: Simulated infected populations to determine parameters of stable infection frequencies of two 456 viral types. A. The frequency of stable infection, given the ratio of virulence to transmission, for different 457 magnitudes of transmission but the same starting frequency (0.001%). **B.** Stable infection frequencies given 458 the difference in transmission rates (β) between two viral strains, as strain 2 transmission rate (starting 459 frequency 0.001%) increases relative to strain 1 transmission rate (starting frequency 25%). The difference 460 in infection frequencies of each strain given differing transmission rates of both strains. Stacked bars show 461 the observed frequencies of High type infection (Strain 2, Blue), Low type infection (Strain 1, Red) and 462 Uninfected (Grey) for four sampled populations, positioned on the X-axis to show the estimated ratio of 463 transmission rates for High and Low type, based on the infection frequencies.

464 465

Previous surveys of nudivirus evolution found that a few replication-related genes (including *VLF*-467 *I* and *ODV-E56*), likely key targets for host suppression, are under recurrent positive selection (HILL AND 468 UNCKLESS 2017; HILL AND UNCKLESS 2018). Given that these repeatedly rapidly evolving genes are also 469 associated with the High and Low types and show the highest levels of adaptation (Figure 1, Figure 4), it is 470 entirely possible that these genes are key factors for infection in nudiviruses. They may also be associated 471 with virulence in other nudiviruses or baculoviruses. It is interesting that we find the same SNPs recurrently 472 evolving in each population, opposed to different SNPs affecting the same genes in each population.

473 One important factor for DNA virus replication is the *Helicase* gene (BLISSARD AND ROHRMANN 474 1990; ROHRMANN 2013), and we find variation in *Helicase-2* is associated with viral titer in our survey 475 (Figure 3A & C). As in other nudiviruses, there is extensive adaptive evolution in the *Helicase* gene (Figure 476 4A) (HILL AND UNCKLESS 2017; HILL AND UNCKLESS 2018) which has previously been posited to be 477 associated with change in host range (MAEDA et al. 1993; CROIZIER et al. 1994; ARGAUD et al. 1998; 478 AFONSO et al. 2001). It is possible the Helicase-2 variants allow for optimized infection of different species 479 (CROIZIER et al. 1994). In fact, DiNV infects several Drosophila species in the New World at varying 480 frequencies (including high prevalence in *D. munda*) (UNCKLESS 2011), and so could have an alternate 481 variant reservoir in any species, with some migration into D. innubila (but not D. azteca or D. falleni), 482 resulting in the appearance of two competing strains. However, this hypothesis ignores the existence of the 483 high and low types which appear to explain the difference in viral titer across multiple species much more 484 convincingly than the *Helicase-2* polymorphism (Supplementary Figure 2).

Nudiviruses have extremely high rates of recombination, as they require at least one crossover during their replication (ROHRMANN 2013). Given this high rate of recombination, it is interesting we don't find more intermediate strains with a mix of High and Low SNPs, supporting the idea of an incompatibility or negative epistatic interactions between SNPs of the two types, similar to a Dobzhansky-Muller incompatibility (GAVRILETS 2003).

490 Some models suggest that viruses are under constant selection to maintain an optimum ratio of 491 virulence to transmission (MAY AND NOWAK 1995; LIPSITCH et al. 1996; ALIZON AND VAN BAALEN 2008). 492 This delicate balance of transmission to virulence could be disrupted with the evolution of a second, high-493 titer, viral type. In the case of DiNV, the High type has radically higher virulence and appears to compete 494 with the first type impacting the persistence of the virus in a host population. Additionally, the High type 495 appears to recurrently evolve, frequently affecting the persistence of the virus (Figure 5 & 6, Supplementary 496 Figure 9). This posits a situation where the optimum strategy for the ancestral viral type is a reduced 497 transmission rate and the fixation of mutations that are incompatible with High type mutations. Further, this 498 fits with the observed consistent order of fixation for mutations that form the High type (Figure 5B), similar 499 to navigating the neutral adaptive landscape between two incompatible forms in a Bateson-Dobzhansky-500 Muller incompatibilities (DOBZHANSKY 1937; ORR 1995; ORR AND TURELLI 2001; GAVRILETS 2003; ORR 501 2004). This type of viral type interaction is rarely considered in models used for studying infection and 502 could lead to a better understanding of viral dynamics and host-virus co-evolution (JACKSON et al. 2005; 503 JACKSON 2009).

504 DNA viruses such as DiNV have complicated replication cycles and large genomes. This makes 505 them a sort of evolutionary intermediate between RNA-viruses (small genomes, high mutation rates) and 506 eukaryotes (large genomes, low mutation rates) and tangential to bacteria and archaea (intermediate

507 genomes, low recombination rates). However, adaptation appears to occur through changes in a few key

- 508 proteins. Here we find the evolution of two competing viral types that differ in these few key genes. These
- 509 viral types are maintained in populations likely due to a trade-off between transmission and virulence.
- 510 Overall our results suggest that the high mutation rates and extremely high levels of selection can result in
- 511 the repeated and convergent evolution of novel host-virus interactions. Additionally, we find that these
- 512 host-virus interactions for large DNA viruses can be much more complicated than previous models suggest
- 513 (DOLAN *et al.* 2018; FEDER *et al.* 2019).

514 Materials and Methods

515 Fly collection, DNA isolation and sequencing

516 In this study we used previously collected and sequenced D. innubila (HILL AND UNCKLESS 2020). Briefly 517 we collected these flies across the four mountainous locations in Arizona between the 22nd of August and 518 the 11th of September 2017. Specifically, we collected at the Southwest research station in the Chiricahua 519 mountains (~5,400 feet elevation, 31.871 latitude -109.237 longitude), Prescott National Forest (~7,900 520 feet elevation, 34.540 latitude -112.469 longitude), Madera Canyon in the Santa Rita mountains (~4,900 521 feet elevation, 31.729 latitude -110.881 longitude) and Miller Peak in the Huachuca mountains (~5,900 feet 522 elevation, 31.632 latitude -110.340 longitude). Baits consisted of store-bought white button mushrooms 523 (Agaricus bisporus) placed in large piles about 30cm in diameter, at least 5 baits per location. A sweep net 524 was used to collected flies over the baits in either the early morning or late afternoon between one and three 525 days after the bait was set. Flies were sorted by sex and species at the University of Arizona and were flash 526 frozen at -80°C before being shipped on dry ice to the University of Kansas in Lawrence, KS. During these 527 collections we also obtained D. azteca during collections which we also sorted by species and sex and flash 528 froze. D. falleni were collected using a similar method in the Smoky Mountains (~6,600 feet elevation) in 529 Georgia in 2017 by Kelly Dyer, these flies were then sorted at the University of Georgia in Athens GA and 530 shipped on dry ice to the University of Kansas in Lawrence, KS.

531 For collected *D. falleni* and *D. azteca*, we attempted to assess the frequency of DiNV infection 532 using PCR, looking for amplification of the viral gene *p47*. Using primers from (UNCKLESS 2011), P47F: 533 5'-TGAAACCAGAATGACATATATAACGC and P47R: 5'-TCGGTTTCTCAATTAACTTGATAGC. 534 We used the following conditions: 95°C 30 seconds, 55°C 30 seconds, 72°C 60 seconds per cycle for 35 535 cycles.

We sorted 343 *D. innubila* flies, 60 DiNV positive *D. falleni* and 40 DiNV positive *D. azteca* which we then homogenized and used to extract DNA using the Qiagen Gentra Puregene Tissue kit (USA Qiagen Inc., Germantown, MD, USA). We prepared a genomic DNA library of these 343 DNA samples using a modified version of the Nextera DNA library prep kit (~ 350bp insert size, Illumina Inc., San Diego, CA,

540 USA) meant to conserve reagents. We sequenced the *D. innubila* libraries on two lanes of an Illumina
541 HiSeq 4000 run (150bp paired-end) (Data to be deposited in the SRA). We sequenced the *D. falleni* and *D. azteca* libraries on a separate run of a lane of an Illumina HiSeq 4000 (150bp paired-end).

543 For 80 male *Drosophila innubila* collected in 2018 (indicated in Supplementary Table 2), we split 544 the sample homogenate in half, isolated DNA from half as described above and isolating RNA using the 545 Direct-zol RNA Microprep protocol (R2061, ZymoResearch, Irvine, CA, USA). We then prepared a cDNA 546 library for each of these 80 RNA samples using a modified version of the Nextera TruSeq library prep kit 547 meant to conserve reagents and sequenced these samples on a NovaSeq NS6K SP 100SE (100bp single 548 end). We also sequenced DNA for these samples, with DNA isolated and prepared as above, also sequenced 549 on a NovaSeq NS6K SP 100SE (100bp single end) (Data to be deposited in the SRA).

550 Sample filtering, mapping and alignment

551 Following sequencing, we removed primer and adapter sequences using cutadapt (MARTIN 2011) and

552 Scythe (BUFFALO 2018) and trimmed all data using Sickle (-t sanger -q 20 -1 50) (JOSHI AND FASS 2011).

553 We masked the *D. innubila* reference genome (HILL *et al.* 2019), using *D. innubila* TE sequences and

554 RepeatMasker (SMIT AND HUBLEY 2008; SMIT AND HUBLEY 2013-2015). We then mapped short reads to

the masked genome and the Drosophila innubila Nudivirus genome (DiNV) (HILL AND UNCKLESS 2018)

using BWA MEM (LI AND DURBIN 2009) and sorted using SAMtools (LI et al. 2009). Following this we

added read groups, marked and removed sequencing and optical duplicates, and realigned around indels

558 in each mapped BAM file using GATK and Picard (HTTP://BROADINSTITUTE.GITHUB.IO/PICARD ;

559 MCKENNA et al. 2010; DEPRISTO et al. 2011). We considered lines to be infected with DiNV if at least

560 95% of the viral genome is covered to at least 10-fold coverage. We then filtered for low coverage and

561 mis-identified species by removing individuals with low coverage of the *D. innubila* genome (less than 5-

562 fold coverage for 80% of the non-repetitive genome), and individuals we suspected of being misidentified

as *D. innubila* following collection. This left us with 318 *D. innubila* wild flies with at least 5-fold

564 coverage across at least 80% of the euchromatic genome, of which 254 are infected with DiNV

565 (Supplementary Table 1). We also checked for read pairs which were split mapped between the DiNV

566 genome and the *D. innubila* genome using SAMtools.

For *D. falleni* we used a previously generated *D. innubila* genome with *D. falleni* variants
inserted (HILL *et al.* 2019). We masked the genome with Repeatmasker (SMIT AND HUBLEY 2013-2015)

and mapped short reads to the masked genome, the repeat sequences and the DiNV genome using BWA

570 MEM and SAMtools (LI AND DURBIN 2009; LI et al. 2009). Then, as with D. innubila we filtered for low

571 coverage and mis-identified species by removing individuals with low coverage (less than 5-fold

572 coverage for 80% of the non-repetitive genome) leaving us with 56 *D. falleni* samples infected with

573 DiNV.

574 For *D. azteca*, we downloaded the genome from NCBI (Accession: GCA_005876895.1) which

575 we then called repeats from with RepeatModeler (SMIT AND HUBLEY 2008). We masked the genome with

576 Repeatmasker (SMIT AND HUBLEY 2013-2015) and mapped short reads to the masked genome, the repeat

577 sequences and the DiNV genome using BWA MEM and SAMtools (LI AND DURBIN 2009; LI et al.

578 2009). As with *D. innubila* we then filtered for low coverage and mis-identified species by removing

579 individuals with low coverage of the D. azteca genome (less than 5-fold coverage for 80% of the non-

580 repetitive genome), which left us with 37 D. azteca samples infected with DiNV. We then called DiNV

581 variation using LoFreq (WILM *et al.* 2012).

582 Calling nucleotide polymorphisms across the population samples

583 For the 318 sequenced samples with reasonable coverage, for host polymorphism, we used the previously 584 generated multiple strain VCF file, generated using a standard GATK HaplotypeCaller/BCFTools pipeline. 585 We used LoFreq (WILM et al. 2012) to call polymorphic viral SNPs within each of the 254 DiNV infected 586 samples, following filtering using BCFtools to remove sites below a quality of 950 and a frequency less 587 than 5%. We then merged each VCF to create a multiple strain VCF file, containing 5,283 SNPs in the 588 DiNV genome. The LoFreq VCF (WILM et al. 2012) output contains estimates of the frequency of each 589 SNP in DiNV in each sample, to confirm these frequencies, in SAMtools (LI et al. 2009) we generated 590 mPileups for each sample and for SNPs of interest (related to viral titer), we counted the number of each 591 nucleotide to confirm the estimated frequencies of these nucleotides at each position in each sample. To 592 confirm that there are no coinfections of types, we also subsampled samples and randomly merged low and 593 high type samples and again generated mPileup files, for SNPs of interest we again counted the number of 594 each nucleotide at each position and confirmed these matched our expected counts in the merged files. We 595 then compared these artificial coinfections to actual samples to confirm the presence or absence of 596 coinfections, finding no samples consistent with coinfections. We then used SNPeff to identify the 597 annotation of each SNP and label synonymous and non-synonymous (CINGOLANI et al. 2012). We extracted 598 the synonymous site frequency spectrum to estimate the effective population size backwards in time using 599 StairwayPlot (LIU AND FU 2015).

600 Identifying differentially expressed genes between DiNV infected and uninfected Drosophila innubila

601 For 100 male *Drosophila innubila* collected in 2018 (indicated in Supplementary Table 2), we

602 homogenized each fly separately in 100µL of PBS. We then split the sample homogenate in half, isolated

603 DNA from half as described above and isolating RNA using the Direct-zol RNA Microprep protocol

604 (R2061). Using the isolated DNA, we tested each sample for DiNV using PCR for P47 as described

605 previously, using 40 DiNV infected samples and 40 uninfected samples. We then prepared a cDNA 606 library for each of these 80 RNA samples using a modified version of the Nextera TruSeq library prep kit 607 meant to conserve reagents and sequenced these samples on a NovaSeq NS6K SP 100SE (100bp single 608 end). We also sequenced DNA for these samples, with DNA isolated and prepared as above, also 609 sequenced on a NovaSeq NS6K SP 100SE (100bp single end). The DNA sequenced here was mapped as 610 described above, with variation called as described above for other DNA samples. 611 Following trimming and filtering the data as described in the methods, we mapped all mRNA 612 sequencing data to a database of rRNA (QUAST et al. 2013) to remove rRNA contaminants. Then we 613 mapped the short read data to the masked D. innubila genome and DiNV genome using GSNAP (-N 1 -o 614 sam) (WU AND NACU 2010). We estimated counts of reads uniquely mapped to D. innubila or DiNV 615 genes using HTSEQ (ANDERS et al. 2015) for each sample. Using EdgeR (ROBINSON et al. 2009) we 616 calculated the counts per million (CPM) of each gene in each sample and counted the number of samples 617 with CPM > 1 for each gene. We find that over 70.3% of genes have a CPM > 1 in at least 70 samples. 618 For the remaining genes, we find these genes are expressed in all samples of a subset of the strains (e.g. 619 DiNV uninfected, DiNV infected, DiNV high infected, DiNV low infected). This supports the validity of 620 the annotation of *D. innubila*, given most genes are expressed in some manner, and suggests our RNA 621 sequencing samples show expression results consistent with the original annotation of the D. innubila 622 genome.

623 We attempted to improve the annotation of the *D. innubila* genome to find genes expressed only 624 under infection. We extracted reads that mapped to unannotated portions of the genome and combined these 625 for uninfected samples, samples infected with high type DiNV and samples infected with low type DiNV 626 as three separate samples. We then generated a *de novo* assembly for each of these three groups using 627 Trinity and Velvet (SCHULZ et al. 2012; HAAS et al. 2013). We then remapped these assemblies to the 628 genome to identify other transcripts and found the consensus of these two for each sample. Using the 629 Cufflinks pipeline (GHOSH AND CHAN 2016), we mapped reads to the *D. innubila* genome and counted the 630 number of reads mapping to each of these putative novel transcript regions, identifying 15,676 regions of 631 at least 100bp, with at least 1 read mapping in at least 1 sample. Of these, 717 putative genic regions have 632 at least 1 CPM in all 80 samples, or in all samples of one group (DiNV uninfected, DiNV infected, DiNV-633 low infected, DiNV-high infected). We next attempted to identify if any of these genes are differentially 634 expressed between types, specifically between uninfected strains and DiNV infected strains, and between 635 low-type infected and high-type infected strains. Using a matrix of CPM for each putative transcript region 636 in each sample, we calculated the extent of differential expression between each type using EdgeR 637 (ROBINSON et al. 2009), after removing regions that are under expressed, normalizing data and estimating 638 the dispersion of expression. We find that 26 putative genes are differentially expressed between infected

- and uninfected types, and 69 putative genes are differentially expressed between high and low types. We
- took these regions and identified any homology to *D. virilis* transcripts using blastn (ALTSCHUL *et al.* 1990).
- 641 We find annotations for 37 putative genes are either expressed in all samples, or differentially expressed
- between samples. Of the 14 putative genes expressed in all samples, nine have the closest blast hit to an
- 643 rRNA gene, and five have hits to unknown genes. For 23 differentially expressed putative genes with blast
- hits, 3 genes are like antimicrobial peptides (IM1, IM14, IM3), these genes are significantly downregulated
- 645 upon infection, like other Toll regulated AMPs, and have significantly lower expression in strains infected
- 646 with high type DiNV compared to low types. The remaining 20 genes all have similarity to genes associated
- 647 with cell cycle regulation, actin regulation and tumor suppression genes.
- 648 Identifying genes associated with viral titer in Drosophila innubila
- 649 As the logarithm of viral titer was normally distributed (Shapiro-Wilk test W = 0.05413, *p*-value = 0.342),
- 650 we used PLINK (PURCELL et al. 2007) to associate nucleotide polymorphism to logarithm of viral titer in
- 651 infected samples. We fit a linear model in PLINK including population, sex, *Wolbachia* presence, the date
- of collection and the relationship matrix for relationship of each sample (inferred using PLINK).
- We first fit this model for all 5,283 viral polymorphisms, before performing the association study, we also pruned viral SNPs for both the total population and each subpopulation leaving 1,403 SNPs. For the total sample we identified associations between the logarithm of viral titer and the frequency of the viral polymorphism in each individual sample, resulting in the following model:
- $657 \qquad Log_{10}(viral titre) \sim SNP + hs + w + p + dc + (SNP * hs) + (SNP * p) + (SNP * w)$
- 658

+ relationship[strain]

- 659 Where hs = host sex, p = location of collection, w = *Wolbachia* presence, dc = date collected
- 660 Following model fitting, we found factors which seemed to show little or no effect on viral titre (p-value >
- 661 0.1) using an ANOVA in R (TEAM 2013), and removed these, refitting the model. This was done step-wise,
- 662 leaving the following model by the end:

$$Log_{10}(viral \ titre) \sim SNP + hs + p + (SNP \ * hs) + \ relationship[strain]$$

Following this we also performed a GWAS using PLINK (PURCELL *et al.* 2007) in the host, using
 previously called host variation, and considering viral haplotype as an additional covariate.

- $Log_{10}(viral titre) \sim SNP + hs + p + (SNP * hs) + vh + relationship[strain]$
- 667 Where hs = host sex, p = location of collection, w = Wolbachia presence, dc = date collected, vh = viral668 haplotype. We found no convincing significant associations (Supplementary Figure 11).
- 669 We repeated this analysis for DiNV variants in *D. azteca* and *D. falleni* separately. We performed 670 the GWAS twice, first using the original model, then including viral haplotype as an additional covariate.

671 Estimating viral titre using qPCR

Following the identification of the viral haplotype associated with viral titre we sought to determine the
effect of viral haplotypes in actual infections. For 20 samples with fly homogenate, we determine the viral
titer and haplotype following filtration with a 0.22µM filter.

We performed qPCR for the viral gene p47 (Forward 5-TCGTGCCGCTAAGCATATAG-3, Reverse 5-AAAGCTACATCTGTGCGAGG-3) on 1 µL of fly filtrate per sample and compared the estimated Cq values across 3 replicates to estimated viral copy number to confirm viral concentration (protocol: 2 minutes at 95°C, 40 cycles of 95°C for 30 seconds and 59°C for 20 seconds, followed by 2 minutes at 72°C). Following this we diluted samples to similar Cq values, relative to the sample with the highest Cq value. We confirmed this by repeating qPCR with p47 primers of 1 µL of each sample.

For each filtrate sample we performed infections on 30 *D. innubila* males 4-5 days following emergence using pricks with sterile needles dipped in viral filtrate. We recorded survival of each fly each day and removed dead flies. Finally, we took samples 1, 3 and 5-days post infection and measured viral copies of p47 relative to *tpi* at each time point.

685 *Phylogeography of DiNV infection and the evolution of the different viral haplotypes*

686 For each DiNV infected *D. innubila* sample, we reconstructed the consensus DiNV genome infecting them 687 using GATK AlternateReferenceMaker and the VCF generated for each strain (MCKENNA et al. 2010; 688 DEPRISTO et al. 2011). We then converted these genomes into Phylip format and used BEAST2 to build 689 the phylogeny of DiNV genomes using 100 million iterations with a burn in of 5 million (BOUCKAERT et 690 al. 2014). We considered phylogeography by providing the longitude and latitude of each samples 691 collection. We then generated a final consensus phylogeny using Tracer with at least 90% majority 692 consensus and removed trees that had not converged to the same joint density (BOUCKAERT et al. 2014). 693 To reconstruct the evolution of the high type viral type we used APE (PARADIS et al. 2004) to infer the 694 appearance order of the six perfectly linked SNPs on the phylogeny using the all different rates (ARD) 695 discrete model (PARADIS et al. 2004). We also confirmed these recurrent mutations across the phylogeny 696 using TreeTime to identify recurrently evolving SNPs (SAGULENKO et al. 2018). Finally, we also created 697 a matrix of SNPs present in at least 2 viral samples and used this matrix in a principle component analysis 698 in R (TEAM 2013), labelling each sample by their viral type in the PCA.

699 *Simulating the evolution of the high and low viral haplotypes.*

700 We sought to simulate the infection of DiNV in *D. innubila* when considering the evolution of a high titer

viral haplotype, specifically if two viral types can be maintained against each other at stable frequencies,

and if the high viral haplotype with 5 shared mutations could evolve recurrently in the given time period

703 given realistic parameters. We used the R package DeSolve (SOETAERT et al. 2010) to simulate infection

dynamics in a modified SIR model. Specifically, we removed a resistant class, under the assumption that flies won't live long enough to shed the infection. Therefore, the proportion of population infected per generation is as follows:

707

$$p_{Infected} = (Susceptible * Infected * \beta) - (Infected * \gamma)$$

708 Where β represents an infection parameter and γ represents a virulence parameter (e.g. the increased 709 likelihood an infected individual has of dying before it can spread its infection). This equation can be 710 rearranged to show the stabilized maximum frequency of infection:

711
$$p_{Infected} = 1 - \frac{\gamma}{\beta}$$

712 Which is maintained while γ is greater than 0.01. The average frequency decreases as absolute transmission

rate decreases past this point. We then extended this to include two competing infection types, to represent

the two viral types, with the total proportion of population infected per generation as follows:

715
$$p_{Susceptible} = 1 - (Susceptible * Infected_1 * \beta_1) - (Infected_1 * \gamma_1)$$

716 + (Susceptible * Infected₂ * β_2) - (Infected₂ * γ_2)

717 This equation can be rearranged as before to show the stabilized frequency of infection for two viral types:

718
$$p_{Infected} = 1 - \frac{\gamma_1 + \gamma_2}{\beta_1 + \beta_2}$$

In this case, the two viral haplotypes can both be maintained within a population when the ratio of infectionto virulence are the same:

721 $\frac{\gamma_1}{\beta_1} = \frac{\gamma_2}{\beta_2}$

We assessed how starting frequency and difference in γ and β affects the evolution of each type and their stable frequencies but repeating these simulations for 10,000 generations for each set of parameters. We repeated simulations with transmission rates varying between 0.00001 and 1, and virulence rates set as the transmission rate, divided by a scaling factor between 0.01 and 10 (to vary virulence at multiple rates higher and lower than transmission rate), with all pairwise combinations across all parameters.

727 Next, we attempted to assess if the 'high titer' viral haplotype could possibly evolve recurrently in 728 each population in the time scale seen in our findings. We again used the modified SIR model, this time 729 discrete with population sizes set to 1 million individuals, based on *StairwayPlot* estimates (LIU AND FU 730 2015). For each infected individual in the population, we tracked the viral titer and also recorded the 731 presence of absence of five mutations, with each mutation increasing the titer of infection, but each further mutation having successively smaller increases in viral titer (*titer* $\sqrt{no.muts}$), representing the epistatic 732 733 interaction of high titer associated mutations seen in the viral haplotype. We multiplied the infection 734 parameter, mutation parameter and virulence parameter by viral titer, under the assumption that viral titer 735 increases both infection and death rate, and the mutation rate is per viral particle. We considered a per site

mutation rate of 10⁻⁶, based on estimated baculovirus mutation rate (ROHRMANN 2013; CHATEIGNER *et al.* 2015), with a specific mutation rate for the five haplotype mutations of 6.4e-12 (1e-6/155kbp) * viral titer. We then simulated populations in replicate 1000 times for 100,000 generations with a starting infection frequency of 10% for the 'low titer' haplotype, recording the frequency of the virus in a population, the frequency of the haplotype and the time that each 'high titer' mutation reaches high enough frequency to escape stochastic behavior and behave deterministically under selection (GILLESPIE 2004).

To estimate the possible selection coefficient for DiNV in the CH population, we assumed an exponential distribution and 5 viral generations per year (80 generations between 2001 and 2017). We then solved the following equation:

745
$$P_{2017} = P_{2001} * (1+s)^t$$

Where P_{2017} = the frequency of the High type among viral samples in 2017 (71%), P_{2001} = the frequency of the High type among viral samples in 2001 (39%), s = the selection coefficient and t = the number of generations (80). We then used this estimated selection coefficient in the same equation to find the number of generations (t) to go from 1/2N_es (0.0000714, assuming an N_e of 1000000) to fixation (0.99):

750

$$0.99 = 0.0000714 * (1 + 0.007)^{t}$$

751 Experimental infections of Drosophila innubila with DiNV

752 We chose D. innubila samples infected with DiNV and with sequenced genomes, 4 infected with the high 753 type DiNV and 4 infected with the low type. For these samples we estimated their viral copy number per 754 host genome as described previously. We used qPCR on p47 and tpi to find the differences in Cq values to 755 calculate the concentration of each sample relative to the lowest concentration sample and diluted 50µL of 756 filtrate for each sample to match the concentration of each sample to the samples with the lowest titer 757 (IPR07). For a separate 50 μ L of the IPR01 sample, we performed 1 in 10 serial dilutions to give 45 μ L of 758 filtrate at full concentration, 1 in 10 concentration, 1 in 100 concentration and 1 in 1000 concentration. 759 Using these sets of samples (matched titer and serial dilutions) we next performed experimental infections. 760 We transferred 50 D. innubila (of roughly equal sex ratio) to new food and let them lay eggs for 1

761 week, following this we collected male offspring aged 2-5 days for experimental infections.

Across 4 separate days in the mornings (between 9am and 11am), we infected the collected male flies with each sample. For flies in batches of 10, we performed pricks with microneedles dipped in the prepared viral filtrate. For each day we also had 2 control replicates of 10 flies pricked with microneedles dipped in sterile media. Following infections, we checked on each vial of 10 flies one-hour post infection and removed dead flies (likely killed by the needle instead of the virus). We also checked each vial each morning for 15 days, removing dead flies (freezing to determine the viral titer), and flipping flies to new

food every 3-4 days. Checking at 10am each day, we recorded the day that each fly died, what filtrate they
had been infected with, and what replicate/infection day set they belonged to. We next looked for
differences in survival over time compared to sterile wound controls using a Fit proportional hazards
regression model in R (TEAM 2013; KASSAMBARA *et al.* 2017), considering titer, infection sample and
replicate as co-variates (day of death ~ [titer or strain] + infection date).

For a second set of experimental infections (performed as described above, stabbed with diluted filtrate from different strains), we also removed 3 living flies 1 hour, 1 day and 5 days post infection. Using

qPCR, we found the difference in *p47* log-Cq and *tpi* log-Cq to estimate the viral copy number for each

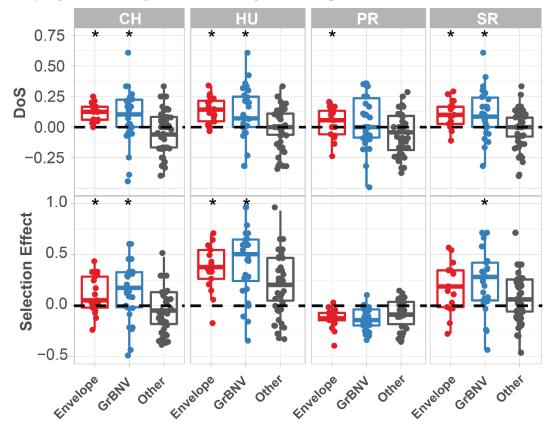

576 sample over time.

777 Acknowledgements

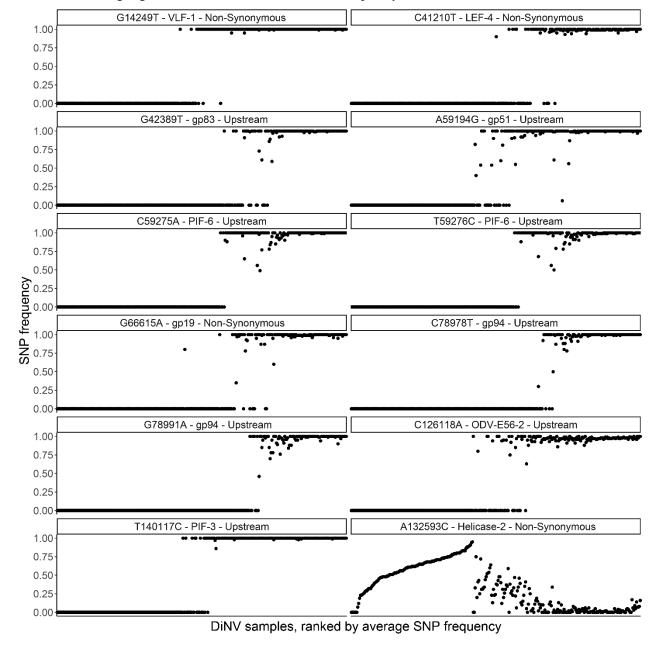

778 This work was completed with helpful discussion from Justin Blumenstiel, Joanne Chapman, John Kelly, 779 Stuart MacDonald, Andrew Mongue and Carolyn Wessinger. We would especially like to thank Maria 780 Orive, Kelly Dyer and Paul Ginsberg for helpful feedback in the writing of the manuscript and framing of 781 the discussion. Collections were completed with assistance from Todd Schlenke, Paul Ginsberg, Kelly Dyer, 782 Brandon Cooper, John Jaenike and the Southwest Research Station. We thank Brittny Smith and Jenny 783 Hackett at the KU CMADP Genome Sequencing Core (NIH Grant P20 GM103638) and K-INBRE 784 Bioinformatics Core for assistance in genome isolation, library preparation, sequencing and computational 785 resources. This work was supported by a K-INBRE postdoctoral grant to TH (NIH Grant P20 GM103418). 786 This work was also funded by NIH Grants R00 GM114714 and R01 AI139154 to RLU. D. falleni collection 787 was funded by NSF grant DEB-1737824.
