Abstract:

T-box transcription factor 5 (*TBX5*) gene encodes the transcription factor TBX5, which plays a crucial role in developing the heart and upper limbs. Damaging single nucleotide variants in this gene alters the protein structure, disturbs the functions of TBX5, and ultimately causes Holt-Oram Syndrome (HOS). By analyzing available single nucleotide polymorphism information in the dbSNP database, this study was designed to identify the most deleterious *TBX5* SNPs through *silico* approaches and predict their structural and functional consequences.

Fifty-eight missense substitutions were found damaging by sequences homology-based tools like SIFT and PROVEAN and structure homology-based tools like PolyPhen-2. These SNPs were further scrutinized by various disease association meta-predictor tools. Additionally, the conservation profile of amino acid residues, their surface accessibility, stability, and structural integrity of the native protein upon mutations was assessed. From these analyses, finally 5 SNPs were detected as the most damaging ones [rs1565941579 (P85S), rs1269970792 (W121R), rs772248871 (V153D), rs769113870 (E208D), and rs1318021626 (I222N)]. Analyses of stop-loss, nonsense, UTR, and splice site SNPs were also conducted.

Through integrative bioinformatics analyses, this study has identified SNPs that are deleterious to the TBX5 protein structure and have the potential to cause HOS. Further wet-lab experiments can validate these findings.

Keywords: TBX5; SNP; Mutation; Holt-Oram Syndrome; Congenital Heart Disease

1. Introduction

The heart is the first organ to develop in the human body, and numerous genes and their products orchestrate this process. Among these genes, *TBX5* is an important one. It is a member of the T-box gene family, which encode transcription factors with a highly conserved DNA binding domain (T-box) of 180-200 amino acids [1]. Members of the T-box gene family have been found from metazoans to humankind, and in humans, more than 20 members of this gene family have been reported till now [2,3]. Moreover, several human diseases are associated with mutations in the T-box genes, namely, DiGeorge Syndrome (*TBX1*), Ulnar-Mammary Syndrome (*TBX3*), Small Patella Syndrome (*TBX4*), Holt-Oram Syndrome (*TBX5*), Spondylocostal Dysostosis (*TBX6*), Cousin Syndrome (*TBX15*), Isolated ACTH Deficiency (*TBX19*), Congenital Heart Defects (*TBX20*), X-Linked Cleft Palate with or without Ankyloglossia (*TBX22*) [4].

According to the recent information retrieved from NCBI and UniProt databases, the *TBX5* gene is located on the long arm of chromosome 12 at position 24.21 (12q24.21), contains ten exons, and has three known transcript variants (1, 3, and 4). Transcript variants 1 and 4 encode a polypeptide of 518 amino acid residues and transcript variant 3 encodes a 468 (51-518) amino acid polypeptide with a shortened N-terminus. In the TBX5 transcription factor, the T-box spans from amino acid position 58 to 238. The binding site of TBX5 has been identified to be present in the upstream regions of various cardiac-expressed genes, such as cardiac α actin, atrial natriuretic factor, cardiac myosin heavy chain α, cardiac myosin heavy chain β, myosin light chain 1A, myosin light chain 1V and *Nkx2-5*. The consensus binding site for TBX5 corresponds to the first eight bases from one-half of the Brachyury binding 22 palindromic consensus sequence [5]. It was shown *in vitro* that TBX5, when in total length, binds to the target site mainly as a dimer and, when truncated, tends to bind mainly as a monomer with reduced dimer formation [5]. It was further showed *in vitro* that they could form a heterodimer complex with Nkx2-5, another essential transcription factor for cardiac development in the course of DNA binding [6]. TBX5 acts mainly as a transcriptional activator of

genes responsible for cardiomyocyte maturation and cardiac septa formation during the early stages of heart development. It is necessary for the effective establishment of the cardiac conduction system [7]. TBX5 also plays a vital role in the very initiation of upper (fore) limbs [8], but the necessity of its presence during the limb outgrowth phase remains controversial [8,9].

Holt-Oram Syndrome (HOS) is an autosomal dominantly inherited disease due to mutation in the *TBX5* gene. It is considered 100% penetrant with varying expressivity in the heart and upper extremity [10]. However, incomplete penetrance [11], lack of penetrance [12], somatic mosaicism [12], and probable germinal mosaicism [13] have also been reported for this disease. The majority of the patients suffer from this syndrome due to *de novo* mutations [14]. Cardiac presentations include atrial septal defect, ventricular septal defect, atrioventricular septal defect, pulmonary atresia/ stenosis, double outlet right ventricle, aortic valve insufficiency/ stenosis, tricuspid valve atresia, mitral valve abnormality, patent ductus arteriosus, tetralogy of pentalogy of Fallot, common arterial truncus, dextrocardia, right aortic arch, and other non-specified congenital heart diseases [15]. Upper limb anomalies may include the hypoplastic or absent thumb, triphalangeal thumb, accessory/ bifid thumb, aplasia/ hypoplasia of hand and fingers, syndactyly, radial with or without ulnar aplasia or hypoplasia, radio-ulnar synostosis, hypoplasia of humerus, aplasia of humerus, and clavicle abnormalities [15].

Nonsense mutation [16], missense mutation [17], frameshift mutation [16,17], deletion [18], duplication [19] and splice site mutation [20,21,22] of *TBX5* gene have been reported to be responsible for HOS. It has been found that missense mutations tend to cause more serious cardiac anomalies than mutations that cause a truncated TBX5 protein (nonsense, frameshift, splice site point variants, intragenic deletions, or duplications) [12]. HOS is caused by heterozygous mutation. To the best of our knowledge, only one homozygous missense mutation in the *TBX5* gene has been reported until present but only with cardiac involvement (atrioventricular septal defect) and no skeletal involvement [23].

TBX5 missense mutations are also associated with familial [24] and sporadic dilated cardiomyopathy [25], atrial fibrillation, and lone atrial fibrillation [26]. *Furthermore, TBX5* non-synonymous (missense and nonsense) mutations have also been reported in association with tetralogy of Fallot without skeletal abnormality [27], and a *TBX5* 3′UTR variant makes its carriers more prone to congenital heart diseases [28]. Considering the above-stated findings, this study was conducted to find out the most deleterious *TBX5* SNPs and analyze their structural and functional outcomes *in silico*.

2. Materials and Methods

The overall methodology adopted in this study is graphically presented in Figure 1.

Fig. 1: An overview of the steps followed to identify deleterious *TBX5* SNPs and analyze their structural and functional consequences.

2.1 Retrieval of Sequence and Wild Structure: Amino acid sequence of the human *TBX5* protein was downloaded in FASTA format from the UniProt database (UniProt ID: Q99593) (https://www.uniprot.org/uniprot/Q99593). Experimental structures of TBX5 were collected from Research Collaboratory for Structural Bioinformatics Protein Data Bank (RCSB PDB) (https://www.rcsb.org/).

2.2 Retrieval of SNPs: SNP information of the human *TBX5* gene was collected using NCBI Variation Viewer (*https://www.ncbi.nlm.nih.gov/variation/view/*). Nonsense, stop lost, splice acceptor, splice donor, and UTR SNPs of *TBX5* gene along with their rs (reference SNP) IDs were retrieved from Variation Viewer applying the following filters: dbSNP under Source database menu, single nucleotide variant under 'Variant type' menu, and nonsense (stop gained)/ stop lost/ splice acceptor variant/ splice donor variant/ 5 prime UTR variant/ 3 prime UTR variant under 'Molecular consequence' menu. In addition, information about missense SNPs was downloaded directly from the NCBI dbSNP database (*https://www.ncbi.nlm.nih.gov/snp/*).

2.3 Identification and Analysis of Damaging Missense SNPs: A total of 355 missense SNPs were retrieved from dbSNP.

2.3.1 Prediction of Damaging Missense SNPs by Sequence-Homology Based Tools: The missense SNPs were first subjected to analysis by sequence-homology-based predictor PROVEAN [29]. PROVEAN predicts the effect of single or multiple amino acid substitutions or indel mutations on the functions of a protein. In PROVEAN, BLAST hits with more than 75% global sequence identity are clustered first. The top 30 clusters constitute the supporting sequence set, and a delta alignment score is computed for every supporting sequence. These scores are averaged within and across

clusters to obtain the final PROVEAN score. An amino acid substitution is predicted 'Deleterious' if the PROVEAN score is below or equal to a predefined threshold value of -2.5 and is considered 'Neutral' if the PROVEAN score is above this threshold value [29]. In this study, a list of *TBX5* gene SNPs defined by their chromosomal positions, reference alleles, and variant alleles was used as input to the PROVEAN server.

PROVEAN also provides scores from SIFT analysis, another prediction tool. SIFT (Sorting Intolerant From Tolerant) presumes that essential amino acids are well conserved in a protein family, and a replacement in a conserved zone is predicted as 'Damaging' [30]. SIFT scores lie between 0 and 1, and amino acid substitutions with a score of ≤0.05 are predicted to alter protein function, and hence, are considered 'Damaging' [31].

85 SNPs of the *TBX5* gene were predicted as 'Deleterious' by PROVEAN, and 236 SNPs were predicted as 'Damaging' by SIFT. 80 SNPs were predicted as harmful by both tools.

2.3.2 Prediction of Damaging Missense SNPs by Structure-Homology Based Tool PolyPhen-2:

PolyPhen-2 (Polymorphism Phenotyping version 2) prediction is made on eight sequence-based and three structure-based predictive features. Two pairs of datasets, viz. HumDiv and HumVar were recruited to train and test two PolyPhen-2 models. PolyPhen-2 computes the Naive Bayes posterior probability of a given mutation is being damaging and estimates the false-positive rate and the true-positive rate. It classifies SNPs as 'Probably Damaging,' 'Possibly Damaging,' or 'Benign' based on the false-positive rate (FPR) thresholds [32]. The 80 SNPs that were predicted harmful by both PROVEAN and SIFT were next analyzed by both PolyPhen-2 HumDiv and HumVar using the batch query option. A list of SNPs defined by chromosome number, chromosomal position, reference allele, and variant allele was used as input. 58 SNPs were predicted as 'Probably Damaging' by either HumDiv or HumVar, and these SNPs were considered high fidelity in disease association.

2.3.3 Prediction of Pathogenic Amino Acid Substitutions by MutPred2: MutPred2 integrates genetic and molecular information to predict pathogenicity caused by an amino acid substitution in the query protein [33]. The cutoff value for predicted pathogenicity is 0.5, and the higher the score, the greater the probability of that amino acid substitution's disease association. TBX5 protein sequence in FASTA format, and wild type and substituted amino acids of 58 high-confidence deleterious SNPs with their respective positions were submitted to the MutPred2 server using the default P-value threshold (0.05).

2.3.4 Scrutinization of Predicted Pathogenicity by Meta-predictors: Several meta-predictors have been developed for predicting disease-causing SNPs in recent years. Such meta-predictors employ various single pathogenicity prediction tools and provide a consensus score gained from different ensemble methods. It is well established that ensemble methods render improved predictive performance than any of its constituent algorithms alone. We decided to crosscheck the predicted 58 pathogenic SNPs against 5 such meta-predictors, namely, i) PredictSNP2, ii) PredictSNP1, iii) MetaLR, iv) MetaSVM and v) REVEL.

PredictSNP2 generates a consensus score from the prediction of five tools- CADD, DANN, FATHMM, FunSeq2, and GWAVA [34]. The input to PredictSNP2 was similar to that used for PolyPhen-2. After analysis by PredictSNP2, the SNPs were sent for analysis by PredicteSNP1. PredictSNP1 has incorporated six individual predictors- MAPP, PhD-SNP, PolyPhen-1, PolyPhen-2, SIFT, and SNAP [35]. MetaSVM and MetaLR are two meta-classifiers developed by the dbNSFP (database for non-synonymous SNPs' functional predictions) project. They calculate ensemble scores based on the prediction of deleteriousness by 10 component tools and the maximum frequency observed in the 1000 genomes project populations [36]. The difference between them lies in their adopted approaches- one uses the Support Vector Machine (MetaSVM) algorithm, and the other uses the Logistic Regression (MetaLR) algorithm. They were both accessed through Ensembl Variant Effect Predictor (VEP) (*http://www.ensembl.org/Tools/VEP*).

rsID (Reference SNP ID number)s of the SNPs were used as inputs and the reference genome chosen was GRCh37. REVEL (Rare Exome Variant Ensemble Learner) is a meta-predictor that integrates 13 tools to predict the probability of disease causation of a missense SNP. It is particularly efficient in differentiating pathogenic from rare neutral variants with allele frequencies <0.5% [37]. REVEL scores range between 0 and 1, and the threshold score for pathogenic variants is 0.5. REVEL scores in this study were obtained alongside MetaSVM and MetaLR scores using the Ensembl VEP.

2.3.5 Prediction of Conserved Amino Acid Residues by ConSurf: structural and functional importance of an amino acid residue in a protein is often strongly related to its level of conservation. Consurf ranks evolutionary conservation status of amino acid or nucleic acid positions in a protein or DNA/ RNA molecule, respectively [38]. The continuous conservation scores of residues are split into an integer scale of 1 to 9 to depict a color scheme. The most variable positions (grade 1) are colored turquoise, intermediate conserved positions (grade 5) are colored white, and the most conserved positions (grade 9) are colored maroon. TBX5 protein sequence in FASTA format served as the input.

2.3.6 Solvent Accessible Surface Area (SASA) Prediction by NetSurfP-2.0: Knowing the solvent accessibility of amino acid residues is essential to identify the interaction interfaces or active sites in a fully folded protein. Amino acid substitutions in such sites may bring change in binding affinity [39] or disturb catalytic activity if the protein is an enzyme [40]. NetSurfP-2.0 predicted surface accessibility of TBX5 residues. It accepts a protein sequence in FASTA format as input and recruits deep neural networks that have been trained on crystal protein structures [41].

2.3.7 Prediction of Change in Stability of the Mutated Protein by Consensus Prediction: Amino acid substitutions caused by missense SNPs can significantly alter the folding free energy. Missense SNPs decreasing the stability of the native protein can affect the functions of the protein and ultimately result in diseases [42]. Missense SNPs causing destabilizing proteins are associated with

myopathy, von Willebrand disease, retinitis pigmentosa, hemophagocytic lymphohistiocytosis, and prion diseases. However, stabilizing missense SNPs can also cause disease [42]. In our study, changes in TBX5 protein stability due to missense SNPs were predicted by iStable 2.0 [43]. iStable 2.0 results are derived from 11 protein stability prediction tools [43]. For amino acid substitutions up to F232V in TBX5, chain A of the TBX5 dimer crystal structure containing 1-239 residues (PDB ID: 5BQD) was used as the native structure. Due to unavailability of an experimental structure of the rest of the substitutions, they were analyzed using the protein's FASTA sequence.

2.3.8 Prediction of the Effects of Amino Acid Substitutions on the Structural Integrity of TBX5 Protein by Missense3D and Normal Mode Analysis: To analyze the impacts of amino acid substitutions on TBX5 three-dimensional structure, the Missense3D server was utilized. Missense3D considers 16 structural features to differentiate disease-associated SNPs from the neutral ones [45]. For substitutions up to F232V, the 'Position on Protein Sequence' input option was chosen, and the UniProt ID (Q99593) and PDB code & chain ID (5BQD; A) along with the substitutions were used as input. For the rest of the substitutions, the energy minimized model generated by Robetta was used [see 2.8]. The mutated protein structures due to SNPs were later subjected to normal mode analysis by DynaMut [44]. DynaMut calculates probable consequences of an amino acid replacement on the stability of a submitted protein from vibrational entropy changes. Normal mode analysis is a widely applied tool for protein structure study [44]. Input was similar to Missense3D.

2.3.9 Molecular Dynamics Simulation: Molecular dynamics (MD) simulations of five mutant structures distilled from the consensus of Missense3D, DynaMut and iStable 2.0 [see 3.2.7], and native protein structure (PDB ID:5BQD, chain A) were conducted by SimpleRun module of PlayMolecule suite [46]. The proteins were initially prepared for MD by the ProteinPrepare module (https://www.playmolecule.org/proteinPrepare/). System for MD simulations were set by the SystemBuilder module (https://www.playmolecule.org/SystemBuilder/). To mimic physiological

environment, a solvation box (90×90×90 Å) with pH 7.4 and 0.9% (0.154 M) NaCl concentration was chosen. Selected solvation model was TIP3P. MD simulation was continued for 25 ns for each protein structure by applying AMBER (Assisted Model Building with Energy Refinement) force field. The trajectories were saved at 100 pico second intervals to calculate RMSD and RMSF.

2.3.10 Prediction of Post-translational Modification Site Missense SNPs by AWESOME: Protein post-translational modification (PTM)s occur at the time of or after protein synthesis, and such modifications of protein structures are mediated by different enzymes or covalent bonds with other structures. SNPs in the PTM sites can result in diseases [47]. SNPs in the putative PTM sites of the TBX5 protein were detected by AWESOME [47]. AWESOME predicts the PTM site SNPs based on the evaluation of 20 PTM site predictors. Gene's name was used as input to AWESOME.

2.4 Analysis of Nonsense and Stop Lost SNPs by PredictSNP2: 31 nonsense (stop gained) and one-stop lost SNPs were retrieved from NCBI Variation Viewer. Among the 31 nonsense SNPs, 29 are already annotated as 'Pathogenic' in the ClinVar database (https://www.ncbi.nlm.nih.gov/clinvar/). Rest 2 nonsense SNPs, rs1393693495 (W514Ter) and rs1555226308 (Q156Ter), and 1 stop lost SNP, rs1394777873 (Ter519Q) were analyzed by PredictSNP2 [35].

2.5 Prediction of the Effects of UTR SNPs by UTRdb & MirSNP: Untranslated region (UTR)s play a pivotal role in the regulation of gene expression post-transcriptionally. They ascertain nucleo-cytoplasmic transport of mRNA, maintain translational efficiency, subcellular localization, and RNA stability [48]. The essential regulators in the 5′-UTR are Kozak consensus sequence (ACCAUGG) [Shine-Dalgarno consensus sequence (AGGAGG) in prokaryotes], CpG (5'—C—phosphate—G—3') sites, uORFs (upstream open reading frames), IRESs (Internal Ribosome Entry Sites), and RBP (Ribosome-binding protein) binding sites. 3′-UTR length, RBP binding sites, and miRNA binding sites are the critical players in the 3′-UTR [49]. Single nucleotide variants in these regions have been found to be associated with many diseases like thalassemia intermedia, atrial

septal defect [50], campomelic dysplasia [51], hereditary chronic pancreatitis [52], Marie Unna hereditary hypotrichosis [53], Charcot-Marie-Tooth disease [54], cerebral amyloid angiopathy [55], to name a few. So, it is essential to identify potentially harmful SNPs in the 3′ & 5′-UTR. UTR SNPs that were predicted to affect transcriptional motifs have been retrieved from the UTRsite database [56]. 'UTRef' (NCBI RefSeq transcripts) as the searching database and 'Gene Name' as the accession type were chosen during retrieval.

MicroRNA (miRNA)s also have critical roles in post-transcriptional regulation of gene expression through mRNA cleavage or post-translational repression [57]. miRNAs are small non-coding RNAs having about 22 nucleotides. miRNA seed region (positions 2-8 on miRNA) is the most crucial sequence in finding the complementary sequence on mRNA and subsequently binding with it. SNPs in the miRNA target sites in the 3′ UTR may create or delete a miRNA target or change the binding efficiency between miRNA and mRNA. The creation or deletion of a miRNA target site may also affect binding in its neighboring miRNA target sequences. Such SNPs have been reported in several diseases, including cancers, psychiatric illnesses, cardiomyopathy, asthma, and Parkinson's disease [58,59]. In our study, SNPs in the predicted miRNA target sites were identified using the MirSNP server [59]. Gene name was used as input to MirSNP.

2.6 Prediction of the Effects of Splice Site SNPs by HSF (Human Splicing Finder): RNA splicing is necessary for converting precursor mRNA to a mature mRNA ready for translation. Various *cis*-regulatory elements and *trans*-acting elements maintain this splicing process. *Cis*-regulatory elements include 5′ and 3′ consensus splice site sequences in the exon-intron boundaries and branch point and polypyrimidine tract sequences. *Trans*-acting elements include spliceosomal small nuclear RNAs and proteins and various other splicing repressors and activators, many of which are still unknown [60,61]. Mutations that hamper the controlled process of splicing lead to a good number of diseases. Around 9% of all the pathogenic mutations recorded in The Human Gene Mutation Database are splicing ones [60,61]. SNPs in the splice donor and acceptor sites may break

an established splice site or create a new splice site. They may also activate cryptic sequences (sequences similar to splice sites) or affect splicing enhancers and silencers. They may even intercept the binding of spliceosomal components by making a conformational change in the mRNA secondary structure [60]. In this study, seven splice donor single nucleotide variants and seven splice acceptor single nucleotide variants were retrieved from dbSNP using NCBI Variation Viewer. Among the seven donor variants, two are annotated as 'Likely-pathogenic'. Among the seven acceptor variants, one is annotated as 'Pathogenic' and three are annotated as 'Likely-pathogenic' in the ClinVar database. Excluding them, the rest 8 SNPs were analyzed employing Human Splicing Finder (HSF) [62]. For our analysis, 'Analyze a sequence' and 'Paste your own sequence' options were chosen, and individual variants with a flanking sequence of 100 nucleotides in both 5′ and 3′ directions were used as inputs.

2.7 Prediction of the Effects of Deep Functional Intronic SNPs: Intronic regions located >100 base pairs away from the exon-intron borders are known as deep intronic regions [63]. Although they have been overlooked for a long time, they are now considered necessary, and mutations in these regions have been found in association with more than 75 diseases. Furthermore, deep intronic point mutations, deletions, and insertions are held accountable for these disease causations, with the first one being the most frequent [63].

The rs (reference SNP) IDs of all the *TBX5* intron variants were submitted to SNP Function Prediction (FuncPred) using default settings [64]. 19 SNPs were predicted by FuncPred to affect TF binding sites and were next analyzed by RegulomeDB 2.0 server. RegulomeDB 2.0 is an annotated database of SNPs in the human intergenic regions that have either established or predicted regulatory roles [65].

2.8 3D Structure Prediction of Full TBX5 Protein: Currently, there are four experimental structures of TBX5 (2X6U, 2X6V, 4SOH & 5BQD) deposited in the Protein Data Bank (PDB). Nevertheless, all of them cover less than half of the total protein. So, we decided to predict the

structure of the whole TBX5 protein by three reliable protein structure prediction tools, namely, I-TASSER [66], Phyre2 [67], and Robetta [68]. Energy minimization of the generated TBX5 models was achieved by applying the YASARA force field. YASARA force field is a combination of AMBER all-atom force field and multi-dimensional knowledge-based torsional potentials [69]. The energy minimized models were further refined by the GalaxyRefine server (http://galaxy.seoklab.org/cgi-bin/submit.cgi?type=REFINE).

2.9 Evaluation of TBX5 3D Models: Quality of the three predicted TBX5 models was evaluated by PROCHECK [70], Verify 3D [71], and SWISS-MODEL Structure Assessment Tool [72]. PROCHECK examines specific stereochemical and geometrical properties of the query protein structure and compares them against a set of ideal values of these properties obtained from well-refined high-resolution protein structures. It assesses residue-by-residue geometry and the overall structural geometry of the query structure [70]. A Ramachandran plot of φ-ψ torsion angles generated by PROCHECK is the most helpful quality indicator, and a good quality model is expected to have over 90% residues in the most favored regions. Verify 3D checks the agreement between a protein tertiary structure and its primary structure [71]. SWISS-MODEL Structure Assessment Tool provides assessments from the MolProbity and QMEAN algorithms. These algorithms evaluate a model quality at both global (i.e., for the entire structure) and local (i.e., per residue) level [72,73]. QMEAN Z-score is an indicator of the "degree of nativeness" of a model [74].

3. Results

3.1 SNP Information Retrieval: Searching the NCBI Variation Viewer using dbSNP as the 'source database' and single nucleotide variant (SNV) as the 'variant type', returned 14413 rsIDs associated with the *TBX5* gene as single nucleotide variants. Three hundred fifty-five rsIDs were found to be missense variants, 30 rsIDs to be nonsense (stop gained) variants, one rsID to be 'stop

lost' variant, 210 rsIDs to be synonymous variants, 11300 rsIDs to be intron variants, 821 rsIDs to be non-coding transcript variants, seven rsIDs to be splice acceptor and seven rsIDs to be splice donor variants, 689 rsIDs to be five prime UTR variants, and 345 rsIDs to be three prime UTR variants. Figure 2 is a pie chart showing different types of SNP. On further inspection, 404 missense variants with 355 rsIDs (3 nonsense variants are included in rs377649723, rs765204502, and rs903933027, and 11 synonymous variants are included in rs186780790, rs377532269, rs533581420, rs374600913, rs753688559, rs762204624, rs771883815, rs777853147, rs972633602, rs973631007, and rs769107196) and 28 nonsense variants with 28 rs IDs (27 stop gained and 1 stop lost- rs1394777873) were found. The reason behind a single rsID having more than one variant is that these variants were reported on the same chromosomal location. As per the NCBI rule, only one rsID is assigned for a specific chromosomal location [75].

Fig. 2: Pie-chart displaying the distribution of SNPs on the *TBX5* gene.

3.2 Identification and Analysis of Damaging Missense SNPs:

3.2.1 Prediction of Missense SNPs by Sequence-Homology Based Tools PROVEAN & SIFT: The retrieved 404 missense SNPs were analyzed first using PROVEAN. Out of 404 submitted substitutions, PROVEAN predicted 85 as 'Deleterious' and 301 as 'Neutral', and SIFT predicted 236 as 'Damaging' and 150 as 'Tolerated'. 242 substitutions were predicted as 'Deleterious' or 'Damaging' by either PROVEAN or SIFT, respectively, and 80 substitutions were predicted as 'Deleterious' or 'Damaging' by both tools. Results for rs571328934, rs755664220, rs756902625, rs763178387, rs769107196, rs769895888, rs777370158, rs907398622, rs945043550, rs1263504354, rs1407437475, and rs1489969947 could not be predicted by PROVEAN.

3.2.2 Prediction of Missense SNPs by Structure-Homology Based Tool PolyPhen-2: For high fidelity, the 80 SNPs predicted by PROVEAN and SIFT as 'Deleterious'/ 'Damaging' were next analyzed by PolyPhen-2. Both HumDiv and HumVar dataset trained PolyPhen-2 were used. The HumDiv model predicted 58 substitutions as 'probably damaging' (Supplementary Table 1), 16 substitutions as 'possibly damaging', and 6 substitutions as 'benign'. The HumVar model predicted 56 substitutions as 'probably damaging' (Supplementary Table 1), ten substitutions as 'possibly damaging', and 14 substitutions as 'benign'. The 58 SNPs that were predicted as 'probably damaging' by HumDiv model were also predicted as 'probably damaging by HumVar model except for rs190881877 (V205F) and rs944423586 (P337H) which were predicted as 'possibly damaging'. rs1411518530 is associated with two nucleotide variants (G>C, T), but they encode the same amino acid (D110E) and are considered a single variant in the subsequent evaluations. Predictions by PROVEAN, SIFT, and PolyPhen-2 are available in Supplementary Table 1.

3.2.3 Prediction of Pathogenic Amino Acid Substitutions by MutPred2: The threshold score of pathogenicity prediction by MutPred2 is 0.5, and a substitution having a MutPred2 score ≥0.8 can be considered highly likely to be pathogenic. All but two (K226R and P337H) of the 58 high-

confidence deleterious SNPs have a MutPred2 prediction score ≥of 0.5. Supplementary Table 2 provides MutPred2 outcomes.

3.2.4 Scrutinization of Predicted Pathogenicity by Meta-predictors: The pathogenicity of the aforementioned substitutions was further examined by five deleteriousness meta-predictors whose predictions are based on various ensemble methods. Forty-eight substitutions were predicted 'Damaging' by all the meta-servers, and the rest were predicted 'Damaging' by at least two meta-servers. The results are shown in Table 1.

Table 1: Prediction of amino acid substitution and disease relation by five meta servers.

AAS=Amino Acid Substitution, [†]D=Deleterious/Damaging/Disease, [‡]T=Tolerated, [§]N=Neutral

3.2.5 Prediction of Conserved Amino Acid Residues by ConSurf and Solvent Accessibility of Residues and TBX5 Secondary Structure by NetSurfP-2.0: ConSurf provided position-specific amino acid conservation scores of TBX5 residues. It also ranked the amino acid residues in a color-

coded scale of integers ranging from 1 to 9, where one indicates a highly variable and 9 indicates the most conserved residue. It was found that most of the substitutions are located in highly conserved positions. NetSurfP-2.0 predicted solvent accessibility (exposed or buried) of the amino acids and provided each residue's relative and total accessible surface area. 37 substitutes were found to occur in buried residues, and 21 substitutes were found to be in exposed residues. Table 2 summarizes ConSurf and NetSurfP-2.0 outcomes. Figures 3 and 4 are graphical presentations of these results.

3.2.7 Prediction of the Effects of Amino Acid Substitutions on the Structural Integrity of TBX5 Protein by Missense3D and Normal Mode Analysis:

The amino acid substitutions were subsequently analyzed by Missense3D to see how these amino acid substitutions would affect protein tertiary structure. 15 substituted structures were predicted to be 'Damaging' by Missense3D

(Table 3). Details of Missense3D predictions can be found in Supplementary Figures 3-17. DynaMut predicted 37 substitutions as destabilizing for the protein. Among the 15 substitutions predicted to be detrimental by Misssense3D, 13 were also predicted as damaging by either iStable2.0 or DynaMut, and 5 were predicted to be destabilizing by both (Figure 5). Table 3 provides predictions by these tools.

Fig. 5: Close-up views of the 5 substitutions predicted to be damaging by iStable 2.0, Missense3D, and DynaMut. These 5 substitutions are A) P85S, B) W121R, C) V153D, D) E208D, and E) I222N. Native amino acids are shown in green and mutated amino acids are shown in red in this figure.

3.2.8 Molecular Dynamics Simulation: Differences between the Cα RMSD profile of native structure (5BQD_A) and that of mutant structures (downloaded from Missense3D) are visible in Figure 6 (A). RMSD profiles of the mutant structures showed more deviations than the native structure. From the Cα RMSF profiles (Figure 6 (B)), it can be found that residue-wise RMSF values of the mutant structures were greater for all residues than the native structure (residue N192 is an exception). Comparing RMSF values of specific mutant residues with their native counterparts (Figure 6 (C)) it was found that W121R, V153D, and E208D showed considerably greater fluctuation. Fluctuation of P85S and I222N was close to their respective native residues. Greater deviations in the RMSD and RMSF profiles support unstable nature of the TBX5 mutant proteins and thus their likelihood to cause disease.

Fig. 6: (A) Cα RMSD values of the native and mutant TBX5 proteins. (B) Residue-wise Cα RMSF values of native and mutant TBX5 proteins. (C) Comparison between the Cα RMSF values of native and mutant residues.

3.2.8 Prediction of Post-translational Modification Site Missense SNPs by AWESOME: Among the 58 high-confidence deleterious SNPs, AWESOME predicted P108T, D111Y, and A143T substitutions could create new phosphorylation sites (AWESOME scores are -0.711, -1.458 and -

0.05, respectively), and S261C substitution can cause loss of a phosphorylation site (AWESOME score 2.752). R237P, R237Q, R237W, and R375W can cause loss of methylation sites (AWESOME scores are 0.834, 0.834, 0.834, and 0.768, respectively). S261C substitution can cause loss of serine mediated O-linked N-acetylgalactosamine (AWESOME score 0.8291) and O-linked N-acetylglucosamine formation (AWESOME score 0.4322). P108T and A143T substitutions can cause a gain of threonine mediated O-linked N-acetylglucosamine formation (AWESOME scores are -0.3507 and -0.354, respectively).

3.3 Evidence of Deleteriousness from *in vitro* Experiments: Among our identified 58 missense SNPs, G80R [76], G125R [77], T223M [78], R237P [79], R237Q, and R237W [76] have been confirmed experimentally to be responsible for HOS. G80R, R237P, R237Q, and R237W cause loss of function, whereas G125R leads to function [79].

3.4 Identification and Analyzing Nonsense and Stop Lost SNPs by PredictSNP2: 2 stop gained (Nonsense), and 1 stop PredictSNP2 analyzed lost SNPs. It predicted the nonsense mutations as deleterious, and the stop lost mutation as neutral. Q156Ter nonsense mutation is significant because it disrupts the highly conserved T-box (amino acid position 58-238). Table 4 shows the results from PredictSNP2 server.

Table 4: Prediction about Nonsense and Stop Lost SNPs by PredictSNP2.

3.5 Prediction of the effects of UTR SNPs by UTRdb & MirSNP: UTR SNPs that could affect transcriptional motifs were retrieved from the UTRdb server. Three SNPs in the 3′ UTR

(rs28730760, rs28730761, and rs883079) were found to be present in the polyadenylation (poly-A) sites and hence, may result in pathogenicity. In addition, UTRdb output returned six transcriptional motif matches in the 5′ UTR and three transcriptional motif matches in the 3′ UTR. Table 5 provides analysis from the UTRdb server.

3′ UTR SNPs that might create or break a miRNA target site or enhance or decrease miRNA binding to mRNA were predicted by the MirSNP server. A total number of 86 SNPs in the 3′ untranslated region of the *TBX5* gene were predicted to alter miRNA-mRNA binding. Supplementary Table 3 shows the results from the MirSNP server.

Table 5: Transcriptional Motifs Present in *TBX5* Untranslated Regions.

3.6 Predicting the effects of SNPs located in splice sites by HSF: Human Splicing Finder (HSF) web tool was employed to predict the effects of SNPs located in 5′ and 3′ splice sites. A total number of 11 splice site SNPs were subjected to assessment. All were found to have 'probably no impact on splicing' by HSF. Table 6 shows the predictions obtained from the HSF.

Table 6: Prediction about Splice Site SNPs by HSF.

rsIDs	Alleles	Predicted Signal	Interpretation
Splice Acceptor Variant			
rs1555226330	C>A	No significant splicing motif alteration detected	This mutation has probably no impact on splicing
rs1031873727	G>A	ESS Site broken	Alteration of an intronic ESS site, Probably no impact on splicing
rs1031873727	G>T	ESS Site broken	Alteration of an intronic ESS site, Probably no impact on splicing
rs891464399	G>A	New ESE Site	Creation of an intronic ESE site, Probably no impact on splicing

rs181078973	A>C	No significant splicing motif alteration detected	This mutation has probably no impact on splicing
rs181078973	A>G	No significant splicing motif alteration detected	This mutation has probably no impact on splicing
rs374919751	C>G	New ESE Site	Creation of an intronic ESE site, Probably no impact on splicing
rs374919751	C>T	No significant splicing motif alteration detected	This mutation has probably no impact on splicing
rs1288475235	C>A	No significant splicing motif alteration detected	This mutation has probably no impact on splicing
rs1015550731	T>C	ESS Site broken	Alteration of an intronic ESS site, Probably no impact on splicing

3.7 Prediction about Deep Functional Intronic SNPs: 19 among all the *TBX5* intron variants were predicted to affect transcription factor binding sites by FuncPred. These 19 SNPs were further analyzed by RegulomeDB 2.0 server, and only two among these SNPs (rs12827969 and rs61931002) can be considered functionally important RegulomeDB 2.0 score. Table 7 summarizes results from SNP FuncPred and RegulomeDB.

Table 7: Predictions Regarding Deep Intronic SNPs.

RegulomeDB ranks: 1a-1f: likely to affect binding and linked to the expression of a gene target, 2a-2c: likely to affect binding, 3a-3b: less likely to affect binding, 4,5,6: minimal binding evidence.

3.8 3D Structure prediction of Full TBX5 Protein: Due to the unavailability of a TBX5 full-length protein crystal structure, full-length 3D models of TBX5 were created employing three different protein structure prediction algorithms, which were later energy minimized and refined. Supplementary Figure 1 shows cartoon presentations of the energy minimized and refined models.

3.9 Evaluation of TBX5 3D Models: 3D Model evaluation is indispensable for checking the credibility of the generated model. PROCHECK assessed the 3D models generated in the current study, Verify 3D, and SWISS-MODEL Structure Assessment Tool. Ramachandran plot is a reliable qualitative indicator of protein structure [70]. PROCHECK calculated Ramachandran plots for the created models. A model is considered reasonable by PROCHECK if >90% residues are present in the most favored regions of the Ramachandran plot. Only one model (generated by Robetta and later energy minimized and refined) was found to fulfill this criterion. It has 94.5% of residues in the most favored regions. Supplementary Figure 2 shows the Ramachandran plots calculated by PROCHECK. Verify 3D is another tool that approves a model if its 80% or more amino acid residues score ≥ 0.2 in the 3D/1D profile. However, none of the models could fulfill this

requirement. MolProbity score and QMEAN Z-score for our models were obtained from the SWISS-MODEL Structure Assessment Tool. A low MolProbity score and a high QMEAN Z-score are preferred. A negative QMEAN Z-score indicates instability in a protein structure [71]. All of our models have a negative QMEAN Z-score. This disagreement can be explained by the fact that presently available *ab initio* protein modeling tools predict poorly for proteins having more than 120 residues [80], and for our protein models, 279 residues (5BQD-A chain extends from 1-239 residues and the full-length protein has 518 residues) do not have any template. However, among the models, the energy minimized and refined Robetta model has the lowest MolProbity score and the least negative QMEAN Z-score. Considering Ramachandran plot results, MolProbity scores, and QMEAN Z-scores, it can be decided that Robetta outperformed two other protein structure prediction tools used in this study. Supplementary Table 4 summarizes the results obtained from PROCHECK, Verify 3D, and SWISS-MODEL Structure Assessment Tool, and Supplementary Figure 2 shows the Ramachandran plots obtained from PROCHECK.

4. Discussion

Recently bioinformatics approaches have become popular for identifying different human gene SNPs and predicting their structural and functional consequences. In the past few years, damaging SNPs of *CCR6* gene [81], *SMPX* gene [82], human aldehyde oxidase gene [83], *PTEN* gene [84], folate pathway genes [85], human bone morphogenetic protein receptor type 1A gene [86], *SKP2* gene [87], human adiponectin receptor 2 gene [88], *MMP9* gene [89], etc. have been identified with the help of different computational biology tools. With the rapid development of genomics, the number of reported SNPs in different databases is continuously increasing for the last few years. However, determining the SNPs that result in diseases is challenging. Various pathogenicity prediction tools can narrow this number to a list of high-confidence deleterious deleterious SNPs [90]. *TBX5* gene is an essential regulator of cardiac and upper limb development, and mutations in this gene are responsible for Holt-Oram syndrome, especially missense mutations. It is estimated

that 1 in 100,000 neonates are born with Holt-Oram syndrome, and male and female children are affected equally. Since HOS is an autosomal dominant condition, it is imperative that all individuals with HOS and their parents and siblings get genetic counseling [91]. In the past years, some mutations, including SNPs, have been reported in association with the *TBX5* gene. However, most of the SNPs of this gene have not been characterized yet. In this study we have tried to fill this gap.

In our current study, we have analyzed all currently available *TBX5* SNPs. Since results from a single bioinformatics tool may be inconclusive, we have appointed 9 highly reliable prediction tools for identifying deleterious missense SNPs. The 58 deleterious missense SNPs that were initially identified by concordance among PROVEAN, SIFT, and PolyPhen-2 results were also damaged by 6 other tools (PredictSNP1, PredictSNP2, MetaLR, MetaSVM, and REVEL) with few exceptions. Among these 58 missense SNPs, 5 missense SNPs (G80R, G125R, T223M, R237P, R237Q, and R237W) have been experimentally found to be responsible for HOS [76-79].

The conservation analysis found that 55 among the 58 missense SNPs cause amino acid substitution in highly conserved positions (ConSurf score 7-9). This further corroborates the importance of these SNPs. Furthermore, 8 of these 58 missense SNPs (P108T, D111Y, A143T, R237P, R237Q, R237W, S261C, and R375W) were found to have the ability to modify post-translational sites.

We have also analyzed the effects of these 58 SNPs on the stability of native TBX5 protein. 15 SNPs were predicted to cause structural damage by Missense3D. G80R, T72K, and V153D substitutions introduce buried charges. V153D and I22N mutations substitute buried hydrophobic residues with hydrophilic residues. G80R and G145W replace a buried glycine, P85L, P85S, and P142S replace a *cis* proline, D105N breaks a buried salt bridge, and E208D disrupts a side-chain / side-chain H-bond and a side-chain / main-chain H-bond. W121R, S261C, and W401C cause an expansion in the internal protein cavity and thus make protein structure unstable. G80R, G145W, and C323Y substitutions trigger clash alerts. These three substitutions lead to a MolProbity clash

score ≥30, and the increase in clash score is >18 compared to the wild-type. G80R and G125R mutations induce disallowed phi/psi alerts. 5 of these 15 substitutions (P85S, W121R, V153D, E208D, and I222N) were predicted to destabilize native protein structure by the consensus of Missense3D, DynaMut, and iStable 2.0. These SNPs which have not yet been reported [rs1565941579 (P85S), rs1269970792 (W121R), rs772248871 (V153D), rs769113870 (E208D), and rs1318021626 (I222N)] are most likely to cause HOS.

We have also employed 6 other tools to identify deleterious non-coding SNPs on the *TBX5* gene. 86 SNPs in the 3′ UTR of the *TBX5* gene were identified that could affect miRNA-mRNA binding. No significant SNP was identified in the splice sites of *TBX5,* and 2 deep intronic SNPs were identified that could affect transcription factor binding and gene expression.

Due to the unavailability of a full-size experimental TBX5 protein structure, 3D models were also predicted employing I-TASSER, Phyre2, and Robetta. Later, the 3D structures were evaluated by PROCHECK, Verify 3D, and SWISS-MODEL Structure Assessment Tool. A model is considered good if >90% of residues are present in the most favored regions of the Ramachandran plot. In the case of our *TBX5* models, only Robetta generated model passed this requirement (94.5%). On the other hand, verify 3D results and QMEAN Z-scores indicate poor quality of the generated models. This can be explained by the inability of the available *ab initio* protein modeling tools to predict correct structure of proteins having more than 120 residues [80]. These template-less regions are responsible for the deviations of our models from an ideal one.

5. Conclusion

This extensive *in silico* study attempts to find putatively most damaging *TBX5* SNPs. Our obtained results can guide further wet-lab studies of *TBX5* gene-related diseases and may potentiate finding cures in the future.
