35 **Abstract**

36 Spontaneous neuronal activity occurs at the onset of the synaptogenesis in the central Nervous
37 System and plays a major role in shaping developing neural networks. How intrinsic
38 properties of neurons evolve during this critical developmental period remains largely
39 unknown. We studied the Renshaw cells because they participate to the early-synchronized
40 neuronal activity in the embryonic spinal cord. We found that these interneurons are
41 subdivided into several functional clusters at the onset of the synaptogenesis and then display
42 a transitory involution process during which they lose their ability to sustain tonic firing. This
43 complex developmental trajectory results from the synergy between a persistent sodium
44 inward current and a delayed rectifier potassium outward current, which are present in most
45 neurons during development and in the adult. Taken together, our results reveal a core
46 mechanism producing functional heterogeneity in embryonic neurons and likely shaping the
47 ongoing of early spontaneous neuronal activity.

51

52 **Introduction**

53 The development of the central nervous system (CNS) follows complex steps, which
54 depend on genetic and environmental factors and involve interactions between multiple
55 elements of the neural tissue. Remarkably, emergent neurons begin to synchronize soon after
56 the onset of synapse formation, generating long episodes of low frequency (<0.01 Hz)
57 correlated spontaneous network activity (SNA) (Blankenship & Feller 2010, Hanson &
58 Landmesser 2003, Khazipov & Luhmann 2006, Milner & Landmesser 1999, Momose-Sato &
59 Sato 2013, Myers et al 2005, O'Donovan 1999, Saint-Amant 2010). In the mouse embryonic
60 spinal cord (SC), SNA is driven by an excitatory cholinergic-GABAergic loop between
61 motoneurons (MNs) and interneurons (INs), GABA being depolarizing before embryonic day
62 16.5 (E16.5) (Allain et al 2011). SNA emerges around E12.5 (Branchereau et al 2002,
63 Czarnecki et al 2014, Hanson & Landmesser 2003, Myers et al 2005, Yvert et al 2004), at a
64 time when functional neuromuscular junctions are not yet established (Pun et al 2002) and
65 sensory and supraspinal inputs have not yet reached the spinal motor networks (Angelim et al
66 2018, Ballion et al 2002, Marmigere & Ernfors 2007, Ozaki & Snider 1997).

67 Several studies pointed out that SNA is an essential component in neuronal networks
68 formation. (Hanson et al 2008, Katz & Shatz 1996, Moody & Bosma 2005, Spitzer 2006). In
69 the SC, pharmacologically-induced disturbances of SNA between E12.5 and E14.5 induce
70 defects in the formation of motor pools, in motor axon guidance to their target muscles and in
71 the development of motor networks (Hanson & Landmesser 2004, Hanson & Landmesser
72 2006, Hanson et al 2008, Myers et al 2005). During SNA episodes, long lasting giant
73 depolarization potentials (GDPs) are evoked in the SC, mainly by the massive release of
74 GABA onto MNs (Czarnecki et al 2014). Renshaw cells ($V1^R$) are likely the first GABAergic
75 partners of MNs in the mouse embryo (Benito-Gonzalez & Alvarez 2012, Boeri et al 2018),

76 and the massive release of GABA during SNA probably requires that many of them display
77 repetitive action potential firing or plateau potential activity (Boeri et al 2018).

78 However, little is known about the maturation of the intrinsic properties and the firing
79 pattern of embryonic $V1^R$. We recently found that $V1^R$ exhibit heterogeneous excitability
80 properties when SNA emerges in the SC (Boeri et al 2018) in contrast to adult Renshaw cells
81 that constitute a functionally homogeneous population (Bikoff et al 2016, Perry et al 2015).
82 Whether this early functional diversity really reflects distinct functional classes of embryonic
83 $V1^R$, how this diversity evolves during development, and what are the underlying biophysical
84 mechanisms remain open questions. The impact of the functional diversity of $V1^R$ on MN
85 activity during SNA episodes is also unknown. The present study addresses these issues using
86 multiple approaches, including patch-clamp recordings, cluster analysis, biophysical
87 modeling and dynamical systems theory. The firing patterns of $V1^R$ and the mechanisms
88 underlying their functional diversity are analyzed during a developmental period covering the
89 initial phase of development of SC activity in the mouse embryo (E11.5-E14.5), when SNA is
90 present, and during the critical period (E14.5-E16.5), when GABAergic neurotransmission
91 gradually shifts from excitation to inhibition and locomotor-like activity emerges
92 (Branchereau et al 2002, Myers et al 2005, Yvert et al 2004).

93 We discover that the balance between the slowly inactivating subthreshold persistent
94 sodium inward current (I_{Nap}) (Crill 1996) and the delayed rectifier potassium outward current
95 (I_{Kdr}), accounts for the heterogeneity of embryonic $V1^R$ and the changes in firing pattern
96 during development. The heterogeneity of $V1^R$ at E12.5 arises from the existence of distinct
97 functional groups. Surprisingly, and in opposition to the classically accepted development
98 scheme (Gao & Ziskind-Conhaim 1998, Gao & Lu 2008, Liu et al 2016, McKay & Turner
99 2005, Pineda & Ribera 2010, Sillar et al 1992), we show that the embryonic $V1^R$ population
100 loses its ability to support tonic firing from E13.5 to E15.5, exhibiting a transient functional

101 involution during its development. Our experimental and theoretical results provide a global
102 view of the developmental trajectories of embryonic V1^R. They demonstrate how a simple
103 mechanism, based on the synergy of two major opposing voltage-dependent currents that are
104 ubiquitous in neurons, can produce functional diversity.
105

106 **Results**

107 *The delayed potassium rectifier current I_{Kdr} is a key partner of the persistent sodium* 108 *current I_{Nap} in controlling embryonic $V1^R$ firing patterns during development*

109 We previously highlighted that $V1^R$ are spontaneously active at E12.5. Their response to a
110 2 s suprathreshold depolarizing current steps revealed four main patterns, depending of the
111 recorded interneuron (Boeri et al 2018): $V1^R$ firing only 1-3 APs at the onset depolarizing
112 pulse, which were named single spiking (SS) $V1^R$, repetitive spiking (RS) $V1^R$ (Figure 1A),
113 long-lasting sodium-dependent plateau potentials (PP) $V1^R$ and mixed events (ME) $V1^R$ that
114 shows an alternation of action potentials (APs) and plateau potentials (Boeri et al 2018).

115 We also uncovered a relationship between I_{Nap} and the ability of embryonic $V1^R$ to sustain
116 repetitive firing (Boeri et al 2018). However, the heterogeneous firing patterns of $V1^R$
117 observed at E12.5 could not be fully explained by variations in I_{Nap} (Boeri et al 2018)
118 suggesting the involvement of other voltage-gated channels, in particular potassium channels,
119 known to control firing and AP repolarization, play a role in controlling the firing pattern of
120 $V1^R$. Our voltage clamp protocol did not reveal any inward rectifying current
121 (hyperpolarizing voltage steps to -100 mV from $V_H = -20$ mV, data not shown), but we found
122 two voltage-dependent outward potassium currents, a delayed rectifier current (I_{Kdr}) and a
123 transient potassium current (I_A) in embryonic $V1^R$, whatever the firing pattern (Figures 1 B1,
124 B2 and B3). These two currents are known to control AP duration and/or firing pattern
125 (Coetzee et al 1999). The activation threshold of I_{Kdr} lied between -30 mV and -20 mV and
126 the threshold of I_A between -60 mV and -50 mV, (n = 27) (Figures 1 C1, C2 and C3).

127 It was unlikely that the heterogeneity of $V1^R$ firing patterns resulted from variations in the
128 intensity of I_A . Indeed its voltage-dependent inactivation (time constant: 23.3 ± 2.6 ms, n = 8),
129 which occurs during the depolarizing phase of an AP, makes it ineffective to control AP or
130 plateau potential durations. This was confirmed by our theoretical analysis (see Figure 10-

131 figure supplemental 1). We thus focused on I_{Kdr} . At E12.5, PP V1^R had a significantly lower
132 G_{Kdr} (2.12 ± 0.44 nS, n = 6) than SS V1^R (5.57 ± 0.56 nS, n = 9) and RS V1^R (6.39 ± 0.83 nS,
133 n = 7) (Figure 2A). In the same manner, PP V1^R at E12.5 had a significantly lower G_{Kdr} than
134 SS V1^R at E14.5 (11.11 ± 1.12 nS, n = 10). However, there was no significant difference
135 in G_{Kdr} between SS V1^R and RS V1^R at E12.5 (Figure 2A), which indicated that variations in
136 G_{Kdr} alone could not explain all the firing patterns observed at E12.5. Similarly, there was no
137 significant difference in G_{Nap} between RS V1^R (0.91 ± 0.08 nS, n = 8) and PP V1^R ($1.24 \pm$
138 0.19 nS, n = 6) at E12.5 (Figure 2B), indicating that variations in G_{Nap} alone could not
139 explain all the firing patterns of V1^R at E12.5 (Boeri et al 2018). In contrast G_{Nap} measured in
140 SS V1^R at E12.5 (0.21 ± 0.06 nS, n = 9) were significantly lower compared to G_{Nap} measured
141 in RS V1^R and in PP V1^R at E12.5 (Figure 2B).

142 Because the firing pattern of a neuron depends on the balance between outward currents
143 and inward voltage-dependent currents (Coetzee et al 1999), we then hypothesized that the
144 different firing patterns of V1^R observed at E12.5 were related to the G_{Nap} / G_{Kdr} ratio. We
145 found that this ratio was significantly lower for SS V1^R recorded at E12.5 ($G_{Nap} / G_{Kdr} =$
146 0.043 ± 0.015 , n = 9) or at E14.5 (0.012 ± 0.004 , n = 10) compared to RS V1^R (0.154 ± 0.022 ,
147 n = 8) and PP V1^R (0.66 ± 0.132 , n = 6) recorded at the same age (Figure 2C). We also found
148 that the G_{Nap} / G_{Kdr} ratio was significantly lower for RS V1^R compared to PP V1^R (Figure
149 2C).

150 Altogether, these results strongly suggest that, although the presence of I_{Nap} is required
151 for embryonic V1^R to fire repetitively or to generate plateau potentials (Boeri et al 2018), the
152 heterogeneity of the firing pattern observed between E12.5 is not determined by I_{Nap} *per se*
153 but likely by a synergy between I_{Nap} and I_{Kdr} .

154

155 ***Manipulating the balance between G_{Nap} and G_{Kdr} changes embryonic V1^R firing patterns.***

156 We previously showed that blocking I_{Nap} with riluzole converted PP $V1^R$ or RS $V1^R$ into
157 SS $V1^R$ (Boeri et al 2018). To confirm further that the balance between G_{Nap} and G_{Kdr} was
158 the key factor in the heterogeneity of $V1^R$ firing patterns, we assessed to what extent a given
159 SS $V1^R$ cell could change its firing pattern when I_{Kdr} was gradually blocked by 4-
160 aminopiridine (4-AP). We found that I_{Kdr} could be blocked by μM concentrations of 4-AP
161 (Figure 3) without affecting I_A (Figure 3-Figure supplement 1). 4-AP, applied at
162 concentrations ranging from 0.3 μM to 300 μM , specifically inhibited I_{Kdr} (Figures 3 A1 and
163 A2) with an IC_{50} of 2.9 μM (Figure 3B). These results favor the presence of the potassium
164 channel subunit $\text{K}_{V3.1}$ (Gutman et al 2005, Liu & Kaczmarek 1998), which is known to be
165 also present at postnatal stages in $V1^R$ (Song et al 2006).

166 We then determined to what extent increasing the concentration of 4-AP modified the
167 firing pattern of $V1^R$ at E12.5. Applying 4-AP at concentrations ranging from 3 μM to 300
168 μM changed the firing pattern of SS $V1^R$ recorded at E12.5 ($n = 10$) in a concentration-
169 dependent manner (Figures 4 A1, A2 and A3). In 50% of the recorded $V1^R$, increasing 4-AP
170 concentrations successfully transformed SS $V1^R$ into PP $V1^R$ with the following sequence: SS
171 \rightarrow RS \rightarrow ME \rightarrow PP (Figure 4A1). In a second group of embryonic $V1^R$ (25%), 4-AP
172 application only evoked mixed activity, with the same sequence as aforementioned (SS \rightarrow RS
173 \rightarrow ME). In the remaining SS $V1^R$ (25%), increasing 4-AP concentration only led to sustained
174 AP firing (Figure 4A2). Application of 300 μM 4-AP on RS $V1^R$ at E12.5 evoked mixed
175 events or plateau potentials (Figure 4-figure supplement 1). Plateau potentials and repetitive
176 spiking evoked in the presence of 300 μM 4-AP were fully blocked by 0.5-1 μM TTX,
177 indicating that they were generated by voltage-gated Na^+ channels (Figures 4 B and C and
178 Figure 4-figure supplement 1). It should be noted that the application of 300 μM of 4-AP
179 induced a significant 30.5 ± 12.4 % increase ($P = 0.0137$; Wilcoxon test) of the input
180 resistance (1.11 ± 0.08 $\text{G}\Omega$ versus 1.41 ± 0.12 $\text{G}\Omega$; $n = 11$).

181

182 These results show that, in addition to I_{Nap} , the delayed rectifier potassium current is also a
183 major determinant of the firing pattern of embryonic $V1^R$. They suggest that the firing pattern
184 depends on a synergy between I_{Nap} and I_{Kdr} and that the different patterns can be ordered
185 along the following sequence SS \rightarrow RS \rightarrow ME \rightarrow PP when the ratio G_{Nap}/G_{Kdr} is increased.

186

187 ***The heterogeneity of the $V1^R$ firing patterns decreases during embryonic development***

188 It was unclear whether these different firing patterns corresponded to well separated
189 classes within the E12.5 $V1^R$ population. To address this issue, we performed a hierarchical
190 cluster analysis on 163 embryonic $V1^R$, based on three quantitative parameters describing the
191 firing pattern evoked by the depolarizing pulse: the mean duration of evoked APs or plateau
192 potentials measured at half-amplitude (mean $\frac{1}{2}Ad$), the variability of the event duration
193 during repetitive firing (coefficient of variation of $\frac{1}{2}Ad$: CV $\frac{1}{2}Ad$) and the total duration of all
194 events, expressed in percentage of the pulse duration (depolarizing duration ratio: ddr) (Figure
195 5A inserts). In view of the large dispersion of mean $\frac{1}{2}Ad$ and ddr values, cluster analysis was
196 performed using the (decimal) logarithm of these two quantities (Sigworth & Sine 1987). The
197 analysis of the distribution of log mean $\frac{1}{2}Ad$, CV $\frac{1}{2}Ad$ and log ddr revealed multimodal
198 histograms that could be fitted with several Gaussians (Figure 5-Figure supplement 1 A1, B1
199 and C1). Cluster analysis based on these three parameters showed that the most likely number
200 of clusters was 5 (Figures 5 A and B), as determined by the silhouette width measurement
201 (Figure 5B). Two clearly separated embryonic $V1^R$ groups with CV $\frac{1}{2}Ad = 0$ stood out, as
202 shown in the 3D plot in figure 5C. The cluster with the largest $\frac{1}{2}Ad$ (mean $\frac{1}{2}Ad = 833.5 \pm$
203 89.99 ms) and the largest ddr (0.441 ± 0.044) contained all PP $V1^R$ ($n = 35$) (Figures 5C and
204 D and Figure 5-Figure supplement 1 A2, B2 and C2). Similarly, the cluster with the shortest

205 $\frac{1}{2}$ Ad (9.73 ± 0.66 ms) and the lowest ddr (0.0051 ± 0.0004) contained all SS $V1^R$ ($n = 46$)
206 (Figures 5 C and D and Figure 5-figure supplement 1 A2, B2 and C2).

207 The three other clusters corresponded to $V1^R$ with nonzero values of CV $\frac{1}{2}$ Ad (Figure 5C).
208 A first cluster regrouping all RS $V1^R$ ($n = 69$) was characterized by smaller values of $\frac{1}{2}$ Ad
209 (23.91 ± 1.43 ms), CV $\frac{1}{2}$ Ad ($27.36 \pm 1.64\%$) and ddr (0.11 ± 0.01) (Figures 5C and D and
210 figure 5-figure supplement 1 A2, B2 and C2). The last two clusters corresponded to ME $V1^R$
211 (Figures 1C and 1D). The smaller cluster, characterized by a larger CV $\frac{1}{2}$ Ad ($170.9 \pm 8.9\%$;
212 $n = 4$), displayed a mix of APs and short plateau potentials, while the second cluster, with
213 smaller CV $\frac{1}{2}$ Ad ($87.61 \pm 7.37\%$; $n = 9$), displayed a mix of APs and long-lasting plateau
214 potentials (Figure 5D and figure 5-figure supplement 1 B2). Their $\frac{1}{2}$ Ad and ddr values were
215 not significantly different (Figure 5-figure supplement 1 A2 and C2).

216 It must be noted that three embryonic $V1^R$ (1.8%) were apparently misclassified since they
217 were aggregated within the RS cluster although having zero CV $\frac{1}{2}$ Ad (Figure 5C; arrows).
218 Examination of their firing pattern revealed that this was because they generated only two
219 APs, although their ddr (0.16 to 0.2) and $\frac{1}{2}$ Ad values (31.6 to 40.3 ms) were well in the range
220 corresponding of the RS cluster.

221 These different firing patterns of $V1^R$ might reflect different states of neuronal
222 development (Belleau & Warren 2000, Gao & Ziskind-Conhaim 1998, Picken Bahrey &
223 Moody 2003, Ramoa & McCormick 1994). Single spiking and/or plateau potentials are
224 generally believed to be the most immature forms of firing pattern, repetitive spiking
225 constituting the most mature form (Spitzer 2006, Tong & McDearmid 2012). If it were so, the
226 firing patterns of embryonic $V1^R$ would evolve during embryonic development from single
227 spiking or plateau potential to repetitive spiking, this latter firing pattern becoming the only
228 one in neonates (Perry et al 2015) and at early postnatal stages (Bikoff et al 2016). However,
229 RS neurons already represent 41% of $V1^R$ at E12.5. We therefore analyzed the development

230 of firing patterns from E11.5, when $V1^R$ terminate their migration and reach their final
231 position (Alvarez et al 2013), to E16.5. This developmental period covers a first phase of
232 development (E11.5-E14.5), where lumbar spinal networks exhibit SNA, and a second phase
233 (E14.5-E16.5), where locomotor-like activity emerges (Allain et al 2010, Branchereau et al
234 2000, Myers et al 2005, Yvert et al 2004). We first analyzed changes in the intrinsic
235 properties (input capacitance C_{in} , input resistance $R_{in} = 1/G_{in}$ and spike voltage threshold)
236 of $V1^R$. C_{in} did not change significantly from E11.5 to E13.5 (Figure 6A), remaining of the
237 order of 12 pF, in agreement with our previous work (Boeri et al 2018). However, it increased
238 significantly at the transition between the two developmental periods (E13.5-E15.5) to reach
239 about 23.5 pF at E15.5 (Figure 6A). A similar developmental pattern was observed for R_{in} ,
240 which remained stable during the first phase from E11.5 to E14.5 ($R_{in} \approx 1-1.2 \text{ G}\Omega$) but
241 decreased significantly after E14.5 to reach about 0.7 $\text{G}\Omega$ at E15.5 (Figure 2B). Spike
242 threshold also decreased significantly between the first and the second developmental phases,
243 dropping from about -34 mV at E12.5 to about -41 mV at E16.5 (Figure 2C). Interestingly,
244 this developmental transition around E14.5 correspond to the critical stage at which SNA
245 gives way to a locomotor-like activity (Allain et al 2010, Branchereau et al 2000, Yvert et al
246 2004) and rhythmic activity becomes dominated by glutamate release rather than
247 acetylcholine release (Myers et al 2005).

248 This led us to hypothesize that this developmental transition could be also critical for the
249 maturation of $V1^R$ firing patterns. The distinct firing patterns observed at E12.5 were already
250 present at E11.5 (Figures 7 A and F), but the percentage of RS $V1^R$ strongly increased from
251 E11.5 to E12.5, while the percentage of ME $V1^R$ decreased significantly (Figure 7F). The
252 heterogeneity of $V1^R$ firing patterns then substantially diminished. Plateau potentials were no
253 longer observed at E13.5, and ME $V1^R$ disappeared at E14.5 (Figures 7 C and F).
254 Interestingly, the proportion of SS $V1^R$ remained high from E13.5 to E15.5 and even slightly

255 increased (91.23% at E14.5 and 93.33% at E15.5; Figure 7F). This trend was partially
256 reversed at E16.5, as the percentage of RS V1^R increased at the expense of SS V1^R (67.86 %
257 SS V1^R and 32.34% RS V1^R; Figures 7 E and F). This decrease in repetitive firing capability
258 after E13.5 was surprising in view of what is classically admitted on the developmental
259 pattern of neuronal excitability (Moody & Bosma 2005, Spitzer et al 2000). Therefore, we
260 verified that it did not reflect the death of some V1^R after E13.5. Our data did not reveal any
261 activated caspase3 (aCaspase3) staining in V1^R (FoxD3 staining) at E14.5 (n = 10 SCs)
262 (Figure 8), in agreement with previous reports showing that developmental cell death of V1^R
263 does not occur before birth (Prasad et al 2008).

264 To determine to what extent the balance between G_{Nap} and G_{Kdr} was the key factor that
265 also determined the V1^R firing patterns at E14.5 (Figures 7 C and F), we tested the effect of 4-
266 AP on single spiking V1^R at this embryonic age. G_{Kdr} in SS V1^R at E14.5 (11.11 ± 1.12 nS, n
267 = 10) was significantly high when compared to G_{Kdr} measured at E12.5 in SS V1^R (Figure
268 2A). I_{Nap} can still be observed in V1^R at E14.5 (Figure 9-Figure supplement 1). G_{Nap}
269 measured in SS V1^R at E14.5 (0.13 ± 0.05 nS, n = 10) was similar to the G_{Nap} measured at
270 E12.5 in SS V1^R (Figure 2B). At E14.5, 300 μ M 4-AP inhibited only 59.2% of I_{Kdr} .
271 Increasing 4-AP concentration to 600 μ M did not inhibit I_{Kdr} significantly more (60.2%)
272 (Figure 9-Figure supplement 2), indicating that inhibition of I_{Kdr} by 4-AP reached a plateau
273 at around 300 μ M. 600 μ M 4-AP application had no significant effect on I_A (Figure 9-Figure
274 supplement 2). The application of the maximal concentration of 4-AP tested (600 μ M)
275 converted SS V1^R (n = 13) to PP V1^R (23.1%; Figures 9 A1 and B), RS V1^R (38.5%; Figure 9
276 A2 and B) or ME V1^R (38.4%; Figure 9B), as was observed at E12.5, thus indicating that the
277 firing pattern of V1^R depends on the balance between I_{Nap} and I_{Kdr} also at E14.5. Plateau
278 potential and repetitive spiking recorded in the presence of 4-AP at E14.5 were fully blocked

279 by 0.5-1 μM TTX indicating that they were generated by voltage-gated Na^+ channels (Figures
280 9 A1 and A2), as observed at E12.5.

281

282 *Theoretical analysis: basic model*

283 As shown in Figure 10A for 26 cells, in which both G_{Nap} and G_{Kdr} were measured, the
284 three largest clusters revealed by the hierarchical clustering analysis (SS, RS and PP, which
285 account together for the discharge of more than 95% of cells, see Figure 5) correspond to well
286 defined regions of the G_{Nap} - G_{Kdr} plane. Single spiking is observed only when G_{Nap} is
287 smaller than 0.6 nS. For larger values of G_{Nap} , repetitive spiking occurs when G_{Kdr} is larger
288 than 3.5 nS, and $V1^R$ display plateau potentials when G_{Kdr} is smaller than 3.5 nS. Mixed
289 events (ME, 4.5% of the 163 cells used in the cluster analysis), where plateaus and spiking
290 episodes alternate, are observed at the boundary of RS and PP clusters. This suggested to us
291 that a conductance-based model incorporating only the leak current, I_{Nat} , I_{Nap} and I_{Kdr} (see
292 Materials and Methods) could account for the experimental observations, the observed
293 zonation being explained in terms of bifurcations between the different stable states of the
294 model.

295 A one-parameter bifurcation diagram of the model is shown in Figure 10B for two values
296 of G_{Kdr} (2.5 nS and 10 nS) and a constant injected current $I = 20$ pA. The slow inactivation of
297 I_{Nap} was not taken into account at this stage of our analysis. For $G_{Kdr} = 10$ nS, the steady-
298 state membrane voltage progressively increases (in gray) with G_{Nap} , but repetitive spiking (in
299 red, see voltage trace for $G_{Nap} = 1.5$ nS) is not achieved until G_{Nap} reaches point SN_1 , where a
300 saddle node (SN) bifurcation of limit cycles occurs. This fits with the experimental data,
301 where a minimal value of G_{Nap} is required for repetitive spiking (see also (Boeri et al 2018)),
302 and is in agreement with the known role of I_{Nap} in promoting repetitive discharge (Kuo et al

2006, Taddese & Bean 2002). Below SN_1 , the model responds to the onset of a current pulse
by firing only one spike before returning to quiescence (see voltage trace for $G_{Nap} = 0.1$ nS),
or a few spikes when close to SN_1 (not shown) before returning to quiescence. The quiescent
state becomes unstable through a subcritical Hopf bifurcation (HB) at point HB_1 , bistability
between quiescence and spiking occurring between SN_1 to HB_1 . Repetitive firing persists
when G_{Nap} is increased further and eventually disappears at point SN_2 . The firing rate does
not change much throughout the RS range (Figure 10-Figure supplement 1 B), remaining
between 11.9 Hz (at SN_1) and 17.1 Hz (at SN_2). A stable plateau appears at point HB_2 through
a subcritical HB. The model is bistable between HB_2 and SN_2 , plateau and large amplitude
APs coexisting in this range.

The model behaves very differently when G_{Kdr} is reduced to 2.5 nS (gray-blue curve in
Figure 10B). It exhibits a unique stable fixed point whatever the value of G_{Nap} is, and the
transition from quiescence to plateau is gradual as G_{Nap} is increased. No repetitive spiking is
ever observed. This indicates that the activity pattern is controlled not only by G_{Nap} but also
by G_{Kdr} . This is demonstrated further in Figure 10C, where G_{Nap} was fixed at 1.5 nS while
 G_{Kdr} was increased from 0 to 25 nS. The model exhibits a plateau potential until G_{Kdr} is
increased past point HB_2 . Repetitive spiking then sets in, *via* a supercritical HB (in contrast to
the subcritical bifurcation in Figure 10B for $G_{Kdr} = 10$ nS, see legend of Figure 10). The
amplitude of AP decays to zero at HB_2 , and no bistability occurs. When G_{Kdr} is further
increased, repetitive firing eventually disappears through a SN bifurcation of limit cycles at
point SN_1 , the quiescent state becomes stable through a subcritical HB at point HB_1 , and
bistability occurs between these two points. This behavior is in agreement with Figure 10A.

Since both G_{Nap} and G_{Kdr} control the firing pattern of embryonic V1^R cells, we computed a
two-parameters bifurcation diagram (Figure 10D), where the different possible activity states
and the transitions between them are plotted in the $G_{Nap} - G_{Kdr}$ plane. The black lines

328 correspond to the bifurcations HB_1 and HB_2 and delimit a region where only repetitive firing
329 occurs. The red lines correspond to the SN bifurcations of periodic orbits associated with the
330 transition from quiescence to firing (SN_1) and the transition from plateau to firing (SN_2). They
331 encompass a region (shaded area) where repetitive firing can be achieved but may coexist
332 with quiescence (between the HB_1 and SN_1 lines) or plateau potential (in the narrow region
333 between the HB_2 and SN_2 lines). We note that the SN_1 and SN_2 lines merge with the HB_1 and
334 HB_2 lines at points B_1 and B_2 , respectively. There, codimension-two Bautin bifurcations occur,
335 and the bifurcations HB_1 and HB_2 switch from subcritical to supercritical case.

336 Some important features of the diagram must be emphasized: 1) minimal values of both
337 G_{Nap} (to ensure sufficient excitability) and G_{Kdr} (to ensure proper spike repolarization) are
338 required for repetitive spiking, 2) quiescence and plateau can be clearly distinguished only
339 when they are separated by a region of repetitive spiking (see also Figure 10B for $G_{Kdr}=10$
340 nS), otherwise the transition is gradual (Figure 9B for $G_{Kdr}=2.5$ nS), 3) only oblique lines
341 with an intermediate slope cross the bifurcation curve and enter the RS region (see, for
342 example, the red line in Figure 10D). This means that repetitive spiking requires an
343 appropriate balance between I_{Nap} and I_{Kdr} . If the ratio G_{Nap}/G_{Kdr} is too large (blue line) or
344 too small (gray line), only plateau potentials or quiescence will be observed at steady state.
345 This is exactly what is observed in experiments, as shown by the cumulative distribution
346 function of the ratio G_{Nap}/G_{Kdr} for the different clusters of embryonic $V1^R$ in Figure 10E
347 (same cells as in Figure 9A). The ratio increases according to the sequence $SS \rightarrow RS \rightarrow ME$
348 $\rightarrow PP$, with an overlap of the distributions for $SS V1^R$ and $RS V1^R$. Note also that the ratio for
349 ME cells (around 0.25) matches the transition between repetitive spiking and plateau
350 potentials in Figure 10D (more on this below).

351 Embryonic $V1^R$ cells display voltage fluctuations of up to 5 mV, presumably due to
352 channel noise. The relatively low number of sodium and potassium channels (of the order of a

353 few thousands) led to voltage fluctuations in the stochastic version of our model comparable
354 to those seen experimentally when the cell was quiescent (top voltage trace in Figure 10D) or
355 when a voltage plateau occurred (bottom trace). Channel noise caused some jitter during
356 repetitive spiking (middle trace), with some occasionally missing spikes (not shown), and
357 induced clearly visible variations in the amplitude of APs. However, repetitive firing proved
358 to be very robust and was not disrupted by voltage fluctuations. Altogether, channel noise
359 little alters the dynamics (compare the deterministic voltage traces in Figure 10B and the
360 noisy traces in Figure 10D). This is likely because channel noise has a broad power spectrum
361 and displays no resonance with the deterministic solutions of the model.

362 The one-parameter bifurcation diagram of our model was not substantially modified when
363 we took I_A into account, as shown in Figure 10-Figure supplement 1. It just elicited a slight
364 membrane hyperpolarization, a rightward shift of the firing threshold and a decrease of the
365 firing frequency. The transition from repetitive firing to plateau was not affected because I_A is
366 inactivated by depolarization.

367 The bifurcation diagram of Figure 10D accounts qualitatively for the physiological data on
368 $V1^R$ at E12.5 presented in Figure 10A, as shown in Figure 10E where the conductance data of
369 Figure 10A were superimposed on it. Its exact position in the $G_{Nap} - G_{Kdr}$ plane actually
370 depends on the values of the passive parameters and it was computed in Figure 10D and F for
371 $G_{in} = 1$ nS and $C_{in} = 13$ pF, the median values of the input capacitance and conductance at
372 E12.5. Between E12.5 and E14.5, C_{in} , which provides an estimate of the cell size, increases
373 by 38% in average, whereas G_{in} is not significantly modified (see Figure 6). As illustrated in
374 Figure 9G the two-parameters bifurcation diagram is then shifted upward and rightward
375 compared to Figure 10F, because larger conductances are required to obtain the same firing
376 pattern. The observed regression of excitability from E12.5 to E14.5-E15.5 (see Figure 3) thus
377 comes from a decrease in G_{Nap} density (see presumable developmental trajectories indicated

378 by arrow in Figure 10F) together with a shift of the RS region as cell size increases. As a
379 result, all 9 cells shown in Figure 10G are deeply inside the SS region at E14.5.

380 It is a bit trickier to explain the experiments where 4-AP changed the firing pattern of SS
381 $V1^R$ (Figure 4). This is because 4-AP decreases not only G_{Kdr} but also G_{in} and therefore the
382 rheobase current. If we take these modifications of the input conductance and rheobase into
383 account (Figure 10-Figure supplement 2), the bifurcation diagram remains qualitatively the
384 same, but it is shifted toward the origin in the G_{Nap} - G_{Kdr} plane. The bifurcation lines
385 between SS and RS (SN1) and between RS and PP (SN2) are then successively crossed when
386 G_{Kdr} is reduced, in accordance with experimental results.

387

388 ***Theoretical analysis: extended model with slow inactivation of I_{Nap}***

389 Our basic model accounts for the firing pattern of 73% of the 163 cells used in the cluster
390 analysis. However, bursting, under the form of recurring plateaus separated by brief
391 repolarization episodes (see a typical trace in Figure 11A left), was experimentally observed
392 in half of PP $V1^R$ (24 out of 46) and plateaus intertwined with spiking episodes were recorded
393 in the 13 cells of the ME cluster (8% of the total sample, see Figure 11A right for an example).
394 Recurrent plateaus indicate membrane bistability. This requires that the $I - V$ curve be S-
395 shaped, which occurs when anomalous rectification is large (large G_{Nap} and small G_{Kdr} ,
396 Figures 11B1 and 11B2). However, our basic model lacks a mechanism for switching
397 between quiescent state and plateau. Channel noise might induce such transitions, but our
398 numerical simulations showed that this is too infrequent to account for bursting (see voltage
399 trace in Figure 11B1 where the plateau state is maintained despite channel noise).

400 To explain recurrent plateaus, we incorporated a slow dynamical process, namely the
401 experimentally observed slow inactivation of I_{Nap} , in our model. The one-parameter
402 bifurcation diagram of the basic model for $G_{Kdr} = 2.5$ nS is shown in Figure 11C. The

403 injected current was reduced from the value of 20 pA used in the previous section to 8 pA, so
404 as to allow for bistability (Figure 10B2). The $G_{Nap} - V$ curve is then S-shaped, as shown in
405 Figure 11B1, with a bistability region for G_{Nap} between 1.48 and 1.87 nS. This is in contrast
406 with Figure 10B where the $G_{Nap} - V$ curve was monotonic. Adding the slow (de)inactivation
407 of I_{Nap} caused periodic transitions between up (plateau) and down (quiescent) states, and the
408 model then displayed a stable limit cycle (shown in black in Figure 11C), as illustrated by the
409 top voltage trace on the right. This mechanism is known as pseudo-plateau or plateau-like
410 bursting (a.k.a. fold-subcritical HB bursting) (Teka et al 2011). It is akin to square wave
411 bursting (Bertram et al 1995, Borisjuk & Rinzel 2005, Izhikevich 2000a, Rinzel 1985), but
412 the up-state is a stable fixed point rather than a limit cycle (Osinga et al 2012, Osinga &
413 Tsaneva-Atanasova 2010, Stern et al 2008), which is why recurrent plateaus are obtained
414 rather than bursts of APs. The duration of the plateaus and repolarization episodes depends on
415 the values of G_{Nap} , G_{Kdr} and I , but it is also largely controlled by the inactivation kinetics. A
416 voltage-independent time constant τ_s leads to up and down states of comparable durations
417 (see top voltage trace in Figure 11C), the duration of which increases with τ_s . Making
418 τ_s voltage-dependent changes the relative durations of plateaus and repolarization episodes. If
419 τ_s decreases with membrane voltage, for instance, repolarization episodes are shortened
420 (bottom voltage trace). Adding channel noise preserves bursting but introduces substantial
421 randomness in the duration of plateaus and repolarization episodes (middle voltage trace). We
422 also noted that adding the I_A current lengthened the repolarizing phase (Figure 10-Figure
423 supplement 1).

424 Slow inactivation of I_{Nap} also provides an explanation for mixed patterns, where plateaus
425 alternate with spiking episodes (Figure 11A, right). They take place in our model near the
426 transition between repetitive spiking and plateau, as in experiments (Figure 10A). Slow

427 inactivation ($V_s = -30$ mV, $k_s = -5$ mV) can lead to elliptic bursting (Izhikevich 2000b, Su et
428 al 2004) when the bifurcation HB_2 is subcritical and located near the Bautin bifurcation B_2 ,
429 which is the case here (Figure 10D). The model then displays a stable limit cycle with
430 alternating plateaus and spiking episodes, arising from crossing the bifurcation points HB_2
431 and SN_2 back and forth (see bifurcation diagram in Figure 11D and top voltage trace). We
432 note that sufficient deinactivation of I_{Nap} for triggering a new plateau is difficult to be
433 achieved during spiking episodes, because voltage oscillates over a large range and variations
434 of the inactivation level are largely averaged out. Therefore, we had to choose a shallower
435 inactivation curve than for pseudo-plateau bursting together with a more depolarized half-
436 inactivation voltage to achieve elliptic bursting. Otherwise, the model keeps on spiking
437 repetitively without returning to the plateau state. This is probably why it is difficult in many
438 recorded cells to elicit plateaus by increasing the injected current, an experimental
439 observation that was not explained by our basic model.

440 When τ_s is voltage-dependent and small enough in the subthreshold voltage range, there is
441 not enough time for APs to be fired between plateaus (see bottom voltage trace in Figure
442 11D). One then observes successive plateaus with superimposed voltage oscillations that
443 decay at plateau onset and grow at offset. Both types of plateaus, with voltage oscillations
444 (elliptic bursting) and without (pseudo-plateau bursting) were observed in the embryonic $V1^R$
445 we recorded. Finally, we note that bistability between plateau and repetitive spiking is not
446 necessary for elliptic bursting, which may also be due to the slow passage through HB_2 when
447 this Hopf bifurcation is supercritical (Baer et al 1989, Holden & Erneux 1993). Slow
448 inactivation of I_{Nap} then leads to a delayed destabilization of the plateau after HB_2 is crossed,
449 while deinactivation during repetitive spiking leads to the crossing of HB_2 in the opposite
450 direction and a delayed restabilization of the plateau (not shown).

451 Altogether, our study shows that a model incorporating the slow inactivation of
452 I_{Nap} accounts for all the firing patterns displayed by cells of the PP and ME clusters.

453

454 ***4-AP increased GABAergic inputs on MNs at E12.5***

455 During SNA, MNs receive massive inputs from GABAergic INs and, to a lesser extent,
456 from glutamatergic INs. This leads to the occurrence of Giant Depolarizing Potential (GDPs)
457 (Czarnecki et al 2014). $V1^R$ are likely the first INs to release GABA at E12.5 (Boeri et al
458 2018). However, it is unclear how the heterogeneity of the activity patterns observed in $V1^R$
459 shapes GABA-evoked current in MNs, even though I_{Nap} appears essential for the occurrence
460 of GDPs and SNA in the SC at E12.5 (Boeri et al 2018). To address this issue, we took
461 advantage of the ability of 4-AP to change the activity pattern of $V1^R$. We focused our
462 analysis on the evoked GABAergic Giant Inward Currents (GICs) (voltage clamp recordings;
463 $E_{Cl} = -30$ mV) and GABAergic GDPs (current clamp recordings). GICs and GDPs were
464 induced by a 1 ms stimulation applied at the cervical level of the SC while recording lumbar
465 MNs (Figure 12A) in the presence of the broad-spectrum glutamate receptor antagonist
466 kynurenic acid (4 mM). At E12.5, 4-AP increased the amplitude of GABAergic GICs ($155 \pm$
467 86 pA vs 191 ± 112 at 30 μ M, and 206 ± 115 pA at 300 μ M, $n = 6$) and the GICs half-width
468 (0.57 ± 0.28 s vs 1.01 ± 0.34 s at 30 μ M, and 1.32 ± 0.34 s at 300 μ M, $n = 6$) (Figures 12 B1
469 and B2). When analyzing GDPs, we observed a strong increase of their half-width in the
470 presence of 4-AP (1.9 ± 0.4 s vs 3.8 ± 1.3 s at 30 μ M, and 3.6 ± 1.1 s at 300 μ M, $n = 8$) but no
471 significant change in their amplitude (30.5 ± 7.2 mV vs 32.6 ± 6.4 mV at 30 μ M and $33.4 \pm$
472 7.2 mV at 300 μ M, $n = 8$), nor in the firing rate of MNs (Figures 12 C1 and C2). Increasing
473 the proportion of GABAergic INs that sustain repetitive firing or plateau potential activity
474 likely enhances the release of GABA on MNs as exemplified by the increased evoked
475 GABAergic current on MNs. However, the lack of effects on GDP amplitude and on MN

476 firing indicates that the biophysical properties of MNs buffer variations in the intensity of
477 their GABAergic inputs. This is likely due to a combination of the depolarized equilibrium
478 potential of chloride at this embryonic age ($E_{Cl} = -30$ mV; (Allain et al 2011)) and the
479 relatively high input resistance of E12.5 MNs (0.3-1 G Ω) (Czarnecki et al 2014)), allowing
480 relatively small changes in GABAergic conductance to evoke a voltage response with
481 maximum amplitude. Such a process probably contributes to the robustness of MN activity
482 during episodes of SNA.

483 **Discussion**

484 $V1^R$ constitute a homogeneous population in terms of their transcription factor program
485 during development (Benito-Gonzalez & Alvarez 2012, Stam et al 2012), their physiological
486 function (Eccles et al 1956) and their firing pattern at postnatal stages (Bikoff et al 2016).
487 Surprisingly, our electrophysiological recordings and our cluster analysis clearly indicate that
488 distinct functional classes of $V1^R$ are transiently present during development at the onset of
489 the SNA (E11.5-E12.5). Five different groups of embryonic $V1^R$ were defined using cluster
490 analysis, according to their firing properties.

491

492 *Development of the firing pattern of embryonic $V1^R$ during SNA*

493 It is generally assumed that, during early development, newborn neurons cannot sustain
494 repetitive firing (Pineda & Ribera 2010, Spitzer et al 2000). Later on, neurons progressively
495 acquire the ability to fire repetitively, APs become sharper, and neurons eventually reach their
496 mature firing pattern, due to the progressive appearance of a panoply of voltage-gated
497 channels with different kinetics (Moody & Bosma 2005, Pineda & Ribera 2010, Spitzer et al
498 2000). Our results challenge the general view that single spiking is a more immature form of
499 excitability (Pineda & Ribera 2010). Indeed, we show that repetitive firing and plateau
500 potentials dominated at early stages (E11.5-E12.5), single spiking prevailing only later
501 (E13.5- E16.5).

502 The different $V1^R$ firing patterns observed at E11.5-E12.5 might reflect variability in the
503 maturation level between $V1^R$ at a given developmental stage, as suggested for developing
504 MNs (Durand et al 2015, Vinay et al 2000). However, this is unlikely since $V1^R$ transiently
505 lose their ability to sustain tonic firing or plateau potential after E13.5. The heterogeneous
506 discharge patterns of $V1^R$ observed before E13.5 contrasts with the unique firing pattern of
507 $V1^R$ at postnatal age (Bikoff et al 2016). Accordingly, the transient functional heterogeneity

508 of $V1^R$ rather reflects an early initial developmental stage (E11.5-E13.5) of intrinsic
509 excitability-

510 The physiological meaning of the transient functional involution of $V1^R$ that follows, after
511 E12.5, is puzzling. To our knowledge, such a phenomenon was never described in vertebrates
512 during CNS development. So far, a functional involution was described only for inner hair
513 cells between E16 and P12 (Marcotti et al 2003a, Marcotti et al 2003b) and cultured
514 oligodendrocytes (Sontheimer et al 1989), and it was irreversible. Because most $V1^R$ cannot
515 sustain tonic firing after E12.5, it is likely that their participation to SNA is limited to the
516 developmental period before other GABAergic interneuron subtypes mature and start to
517 produce GABA and glycine (Allain et al 2004). Interestingly, embryonic $V1^R$ begin to
518 recover their capability to sustain tonic firing when locomotor-like activity emerges (Myers et
519 al 2005, Yvert et al 2004), a few days before they form their recurrent synaptic loop with
520 MNs (around E18.5 in the mouse embryos, (Sapir et al 2004)). One possible function of the
521 transient involution between E12.5 and E15.5 could be to regulate the growth of $V1^R$ axons
522 toward their targets. It is indeed known that low calcium fluctuations within growth cones are
523 required for axon growth while high calcium fluctuations stop axon growth and promote
524 growth cone differentiation (Henley & Poo 2004).

525

526 ***Ion channels mechanisms underlying the functional heterogeneity of embryonic $V1^R$***

527 Blockade of I_{Nap} leads to single spiking (Boeri et al 2018), which emphasizes the
528 importance of this current for the occurrence of repetitive firing and plateau potentials in $V1^R$
529 at early development stages. But these neurons can also switch from one firing pattern to
530 another, when G_{Kdr} is decreased by 4-AP, which emphasizes the importance of I_{Kdr} . We
531 found that the main determinant of embryonic $V1^R$ firing pattern is the balance between
532 G_{Nap} and G_{Kdr} .

533 A Hodgkin-Huxley-like model incorporating a persistent sodium current I_{Nap} provided a
534 parsimonious explanation of all the firing patterns recorded in the $V1^R$ population at E12.5,
535 even in details. It provided a mathematical interpretation for the clustering of embryonic $V1^R$
536 shown by the hierarchical analysis and accounted for the effect of 4-AP and riluzole (Boeri et
537 al 2018) on the discharge. Remarkably, it highlights how a simple mechanism involving only
538 the two opposing currents I_{Nap} and I_{Kdr} can produce functional diversity in a population of
539 developing neurons. The model explains why minimal G_{Nap} and G_{Kdr} are required for firing,
540 how a synergy between G_{Nap} and G_{Kdr} controls the firing pattern, and it accounts for the
541 zonation of the $G_{Nap} - G_{Kdr}$ plane that is observed experimentally.

542 Adding the slow inactivation of I_{Nap} to the model allowed us to account for the bursting
543 patterns displayed by cells of the PP and ME clusters. We showed, in particular, that mixed
544 events arose from elliptic bursting at the repetitive spiking-plateau transition and that smooth
545 repetitive plateaus could be explained by a pseudo-plateau bursting mechanism (Osinga &
546 Tsaneva-Atanasova 2010, Teka et al 2011). Such bursting scenario has been previously
547 studied in models of endocrine cells (Stern et al 2008, Tagliavini et al 2016, Tsaneva-
548 Atanasova et al 2010) and adult neurons (Oster et al 2015), but rarely observed in experiments.

549 Heterogeneity of the discharge pattern of pacemaker neurons has also been observed in the
550 embryonic pre-Bötzing network (Chevalier et al 2016). However, it is related there to the
551 gradual change of balance between two inward currents, I_{Nap} and the calcium-activated
552 nonselective cationic current I_{CAN} , during neuronal maturation, which leads to the progressive
553 replacement of pseudo-plateau bursting by elliptic bursting. Such a scenario cannot account
554 for the variety of discharge patterns observed in embryonic $V1^R$ at the E11.5-12.5 stage of
555 development (Boeri et al 2018). Our theoretical analysis and our experimental data clearly
556 indicate that competition and synergy between two opposing currents are necessary to explain
557 all the firing patterns of $V1^R$. We also note that our model is not restricted to embryonic $V1^R$,

558 but may also apply to any electrically compact cell, the firing activity of which is dominated
559 by sodium and delayed rectifier potassium currents. This is the case of many classes of
560 embryonic cells in mammals at an early stage of their development.

561 Altogether our experimental and theoretical results provide a global view of the
562 developmental trajectories of embryonic $V1^R$ (see Figures 9F and 9G). At E12.5,
563 conductances of embryonic $V1^R$ are widely spread in the $G_{Nap} - G_{Kdr}$ plane, which explains
564 the heterogeneity of their firing patterns. This likely results from the random and uncorrelated
565 expression of sodium and potassium channels from cell to cell at this early stage. Between
566 E12.5 and E14.5-15.5 cell size increases, and G_{Kdr} with it, while the density of sodium
567 channels decreases (see Figures 6 and 9). The functional involution displayed by $V1^R$ between
568 E12.5 and E15.5 thus mainly results from a decrease of G_{Nap} coordinated with an increase of
569 G_{Kdr} . How these synergistic processes are controlled during this developmental period
570 remains an open issue.

571

572 ***Physiological implications of the $G_{Nap} - G_{Kdr}$ synergy in $V1^R$ at the onset of the SNA***

573 The increase in GABA-ergic GIC amplitude and duration in the presence of 4-AP suggests
574 that 4-AP, by changing the G_{Nap} / G_{Kdr} ratio and the input conductance increases embryonic
575 $V1^R$ excitability, which in turn augments GABA release onto MNs. This fits with the view
576 according to which repetitive firing is more efficient than single spiking at evoking calcium
577 entry and promoting vesicular release at presynaptic terminals, plateau potentials being even
578 more efficient (Hallermann & Silver 2013, Tibbs et al 1989, Wang & Kaczmarek 1998). It
579 must however be noted that although 4-AP increased GDP duration, this potassium blocker
580 had little effect on GDP amplitude and on MN firing, indicating that MN activity is poorly
581 affected by variations in GABA release. This can be explained by the depolarized equilibrium
582 potential of chloride ions at this developmental age (-30 mV) (Delpy et al 2008) and by the

583 high input resistance of MNs, which limits the number of activated GABA_A receptors needed
584 for generating a GDP of maximal amplitude. In addition, most MNs are not able to sustain
585 tonic firing during a GDP at E12.5 (Czarnecki et al 2014), which prevents increase in GDP
586 duration from increasing MN firing rate.

587 Due to their functional involution V1^R must become less efficient to generate GABAergic
588 GICs on MNs after E12.5. However, this is unlikely to impact SNA on MNs since V1^R lose
589 their ability to sustain tonic firing at a time when other interneurons begin to produce GABA
590 (Allain et al 2011). We cannot completely rule out that some other INs than V1^R were also
591 affected by 4-AP application already at E12.5, but it is important to note that V1^R are the first
592 INs contacting MNs and producing GABA at this age in the embryonic SC (Boeri et al 2018),
593 which makes them the best candidates to explain the effect of 4-AP.

594 Our model is not restricted to embryonic V1^R. It may also apply to any electrically
595 compact cell or to the axon initial segment where G_{Nap} and G_{Kdr} play a major role in the
596 occurrence of repetitive firing (Kole & Stuart 2012). It is noteworthy that, even though the
597 nature of the firing pattern is determined only by the synergy of G_{Nap} and G_{Kdr} in our model,
598 its quantitative features also depend on the input conductance. This implies that changes in
599 G_{input} evoked by local synaptic activity may alter the firing pattern of the postsynaptic neurons.
600 Interestingly, the initial segment of cortical and hippocampal pyramidal neurons receive
601 GABAergic inputs (Kole & Stuart 2012).

602

603 ***Conclusions***

604 In conclusion, our results indicate for the first time that a single mechanism involving two
605 classes of ubiquitous voltage-gated channels with opposite functions that are ubiquitous in
606 neurons is sufficient to produce functional diversity between neurons. It accounts for the

607 unusual developmental pattern of immature V1^R during the important time window where
608 SNA is expressed in the embryonic spinal cord.

609

610 **Materials and Methods**

611 *Isolated spinal cord preparation.*

612 Experiments were performed in accordance with European Community guiding principles
613 on the care and use of animals (86/609/CEE, CE Off J no. L358, 18 December 1986), French
614 decree no. 97/748 of October 19, 1987 (J Off République Française, 20 October 1987, pp.
615 12245-12248). All procedures were carried out in accordance with the local ethics committee
616 of local Universities and recommendations from the CNRS. We used GAD67eGFP knock-in
617 mice to visualize putative GABAergic INs (Tamamaki et al 2003), as in our previous study
618 (Boeri et al 2018). To obtain E12.5-E16.5 transgenic GAD67-eGFP embryos, 8 to 12 weeks
619 old wild-type Swiss female mice were crossed with GAD67-eGFP Swiss male mice.

620 Isolated mouse SCs from 420 embryos were used in this work and obtained as previously
621 described (Delpy et al 2008, Scain et al 2010). Briefly, pregnant mice were anesthetized by
622 intramuscular injection of a mix of ketamine and xylazine and sacrificed using a lethal dose of
623 CO₂ after embryos of either sex were removed. Whole SCs were isolated from eGFP-positive
624 embryos and maintained in an artificial cerebrospinal fluid (ACSF) containing 135 mM NaCl,
625 25 mM NaHCO₃, 1 mM NaH₂PO₄, 3 mM KCl, 11 mM glucose, 2 mM CaCl₂, and 1 mM
626 MgCl₂ (307 mOsm/kg H₂O), continuously bubbled with a 95% O₂-5% CO₂ gas mixture.

627 In the lumbar SC of GAD67eGFP mouse embryos, eGFP neurons were detected using 488
628 nm UV light. They were localized in the ventro-lateral marginal zone between the motor
629 columns and the ventral funiculi (Stam et al 2012). Embryonic V1^R identity was confirmed by
630 the expression of the forkhead transcription factor Foxd3 (Boeri et al 2018).

631

632 *Whole-cell recordings and analysis*

633 The isolated SC was placed in a recording chamber and was continuously perfused (2

634 ml/min) at room temperature (22-26°C) with oxygenated ACSF. Whole-cell patch-clamp
635 recordings of lumbar spinal embryonic V1^R were carried out under direct visualization using
636 an infrared-sensitive CCD video camera. Whole-cell patch-clamp electrodes with a resistance
637 of 4-7 MΩ were pulled from thick-wall borosilicate glass using a P-97 horizontal puller
638 (Sutter Instrument Co., USA). They were filled with a solution containing (in mM): 96.4 K
639 methanesulfonate, 33.6 KCl, 4 MgCl₂, 4 Na₂ATP, 0.3 Na₃GTP, 10 EGTA, and 10 HEPES
640 (pH 7.2; 290 mOsm/kg-H₂O). This intracellular solution led to an equilibrium potential of
641 chloride ions, E_{Cl} , of about -30 mV, close to the physiological values measured at E12.5 in
642 spinal MNs (Delpy et al 2008). The junction potential (6.6 mV) was systematically corrected
643 offline.

644 Signals were recorded using Multiclamp 700B amplifiers (Molecular Devices, USA). Data
645 were low-pass filtered (2 kHz), digitized (20 kHz) online using Digidata 1440A or 1550B
646 interfaces and acquired using pCLAMP 10.5 software (Molecular Devices, USA). Analyses
647 were performed off-line using pCLAMP 10.5 and Axograph 1.7.2 (Molecular devices;
648 RRID:SCR_014284) software packages.

649 In voltage-clamp mode, voltage-dependent K⁺ currents (I_{Kv}) were elicited by 500 ms
650 depolarizing voltage steps (10 mV increments, 10 s interval) after a prepulse of 300 ms at V_H
651 = -100 mV. To isolate I_{Kdr} , voltage steps were applied after a 300 ms prepulse at V_H = -30
652 mV that inactivated the low threshold transient potassium current I_A . I_A was then obtained by
653 subtracting offline I_{Kdr} from the total potassium current I_{Kv} . Capacitance and leak current
654 were subtracted using on-line P/4 protocol provided by pCLAMP 10.5.

655 In current-clamp mode, V1^R discharge was elicited using 2 s depolarizing current steps
656 (from 0 to ≈ 50 pA in 5-10 pA increments, depending on the input resistance of the cell) with
657 an 8 s interval to ensure that the membrane potential returned to V_H . When a cell generated a

658 sustained discharge, the intensity of the depolarizing pulse was reduced to the minimal value
659 compatible with repetitive firing.

660 I_{Nap} was measured in voltage-clamp mode using a 70 mV/s depolarizing voltage ramp
661 (Huang & Trussell 2008). This speed was slow enough to preclude substantial contamination
662 by the inactivating transient current and fast enough to avoid substantial inactivation of I_{Nap} .
663 Subtraction of the current evoked by the voltage ramp in the presence of 1 μ M tetrodotoxin
664 (TTX) from the control voltage ramp-evoked current revealed I_{Nap} .

665

666 ***Pharmacological reagents***

667 During patch-clamp recordings, bath application of TTX (1 μ M, Alomone, Israel) or 4-AP
668 (0.3 - 600 μ M, Sigma) was done using 0.5 mm diameter quartz tubing positioned, under direct
669 visual control, 50 μ m away from the recording area. The quartz tubing was connected to 6
670 solenoid valves linked with 6 reservoirs *via* a manifold. Solutions were gravity-fed into the
671 quartz tubing. Their application was controlled using a VC-8 valve controller (Warner
672 Instruments, USA).

673 4-aminopyridine (4-AP; Sigma Aldrich, USA) was used to block I_{Kdr} . To determine the
674 concentration–response curve, $I - V$ curves of I_{Kdr} for different concentrations of 4-AP (0.3
675 to 300 μ M) were compared to the control curve obtained in the absence of 4-AP. The
676 percentage of inhibition for a given concentration was calculated by dividing the peak
677 intensity of I_{Kdr} by the peak value obtained in control condition. The obtained normalized
678 concentration–response curves were fitted using the Hill equation:

$$679 \frac{100 - I_{min}}{1 + ([4-AP]/IC_{50})^{n_H}} + I_{min} ,$$

680 where [4-AP] is the 4-AP concentration, I_{min} is the residual current (in percentage of the peak
681 I_{Kdr}), $100 - I_{min}$ is the maximal inhibition achieved for saturating concentration of 4-AP,

682 IC_{50} is the 4-AP concentration producing half of the maximal inhibition, and n_H is the Hill
683 coefficient. Curve fitting was performed using KaleidaGraph 4.5 (Synergy Software, USA).

684

685 ***Immunohistochemistry and confocal microscopy***

686 E14.5 embryos were collected from pregnant females. Once dissected out of their yolk sac,
687 SCs were dissected and immediately immersion-fixed in phosphate buffer (PB 0.1 M)
688 containing 4% paraformaldehyde (PFA; freshly prepared in PB, pH 7.4) for 1 h at 4°C. Whole
689 SCs were then rinsed out in 0.12 M PB at 4°C, thawed at room temperature, washed in PBS,
690 incubated in NH_4Cl (50 mM), diluted in PBS for 20 min and then permeabilized for 30 min in
691 a blocking solution (10% goat serum in PBS) with 0.2% Triton X-100. They were incubated
692 for 48 h at 4°C in the presence of the following primary antibodies: guinea pig anti-FoxD3
693 (1:5000, gift from Carmen Birchmeier and Thomas Müller of the Max Delbrück Center for
694 Molecular Medicine in Berlin) and rabbit anti-cleaved Caspase-3 (1:1000, Cell Signaling
695 Technology Cat# 9661, RRID:AB_2341188). SCs were then washed in PBS and incubated
696 for 2 h at RT with secondary fluorescent antibodies (goat anti-rabbit-conjugated 649; donkey
697 anti-guinea pig-conjugated Alexa Fluor 405 [1:1000, ThermoFisher]) diluted in 0.2% Triton
698 X-100 blocking solution. After washing in PBS, SCs were dried and mounted in Mowiol
699 medium (Millipore, Molsheim, France). Preparations were then imaged using a Leica SP5
700 confocal microscope. Immunostaining was observed using a 40X oil-immersion objective
701 with a numerical aperture of 1.25, as well as with a 63X oil-immersion objective with a
702 numerical aperture of 1.32. Serial optical sections were obtained with a Z-step of 1 μm (40X)
703 and 0.2-0.3 μm (63X). Images (1024x1024; 12-bit color scale) were stored using Leica
704 software LAS-AF and analyzed using ImageJ 1.5 (N.I.H., USA; <http://rsb.info.nih.gov/ij/>) and
705 Adobe Photoshop CS6 (Adobe, USA) software.

706

707 ***Cluster analysis***

708 To classify the firing patterns of embryonic $V1^R$, we performed a hierarchical cluster
709 analysis on a population of 163 cells. Each cell was characterized by three quantitative
710 measures of its firing pattern (see legend of Fig 1). After normalizing these quantities to zero
711 mean and unit variance, we performed a hierarchical cluster analysis using the `hclust` function
712 in R software (version 3.3.2, <https://cran.r-project.org/>) that implements the complete linkage
713 method. The intercluster distance was defined as the maximum Euclidean distance between
714 the points of two clusters, and, at each step of the process, the two closest clusters were
715 merged into a single one, thus constructing progressively a dendrogram. Clusters were then
716 displayed in data space using the `dendromat` function in the R package ‘squash’ dedicated to
717 color-based visualization of multivariate data. The best clustering was determined using the
718 silhouette measure of clustering consistency (Rousseeuw 1987). The silhouette of a data point,
719 based on the comparison of its distance to other points in the same cluster and to points in the
720 closest cluster, ranges from -1 to 1. A value near 1 indicates that the point is well assigned to
721 its cluster, a value near 0 indicates that it is close to the decision boundary between two
722 neighboring clusters, and negative values may indicate incorrect assignment to the cluster.
723 This allowed us to identify an optimal number k of clusters by maximizing the overall
724 average silhouette over a range of possible values for k (Rousseeuw 1987), using the
725 silhouette function in the R package ‘cluster’.

726

727 ***Biophysical modeling***

728 To understand the relationship between the voltage-dependent membrane conductances
729 and the firing patterns of embryonic $V1^R$, we relied on a single compartment conductance
730 based model that included the leak current, the transient and persistent components of the

731 sodium current, I_{Nat} and I_{Nap} , and a delayed rectifier potassium current I_{Kdr} . Voltage
732 evolution then followed the equation

$$733 \quad C_{in} \frac{dV}{dt} = G_{in}(V_H - V) + G_{Nat}m^3h(E_{Na} - V) + G_{Nap}m_p^3(E_{Na} - V) + G_{Kdr}n^3(E_K - V) + I \quad (1),$$

734 where C_{in} was the input capacitance; G_{in} the input conductance; G_{Nat} , G_{Nap} , G_{Kdr} the
735 maximal conductances of the aforementioned currents; m , m_p and n their activation variables;
736 h the inactivation variable of I_{Nat} ; V_H the baseline potential imposed by *ad hoc* current
737 injection in current-clamp experiments; E_{Na} and E_K the Nernst potentials of sodium and
738 potassium ions, and I the injected current. All gating variables satisfied equations of the form:

$$739 \quad \tau_x \frac{dx}{dt} = x_\infty(V) - x,$$

740 where the (in)activation curves were sigmoid functions of the form:

$$741 \quad x_\infty = \frac{1}{1 + \exp(-(V - V_x)/k_x)}$$

742 with k_x being positive for activation and negative for inactivation. The time constant τ_x was
743 voltage-independent except for the inactivation variable h .

744 To take into account the inactivating potassium current I_A revealed by experiments, we
745 also considered a model with the additional term $G_A m_A h_A (E_K - V)$ added to the right-hand-
746 side of equation (1). The activation variable m_A of I_A was assumed to follow any voltage
747 change instantaneously while its inactivation variable evolved more slowly.

748 To explain the more complex activity patterns observed in 27 % of the cells, we added a
749 slow inactivation variable s to I_{Nap} , which became $G_{Nap} m_p^3 s (V_{Na} - V)$. We considered that
750 the corresponding time constant τ_s could be voltage-dependent.

751 The effect of channel noise was investigated with a stochastic realization of the model,
752 where channels kinetics were described by Markov-type models, assuming a unitary channel
753 conductance of 10 pS for all channels.

754 Most model parameters were chosen on the basis of experimental measurements (see S1
755 File). Parameters that could not be constrained from our experimental data were chosen from
756 an experimentally realistic range of values.

757

758 ***Choice of model parameters***

759 V_H was set to -60 mV. C_{in} (average 13.15 pF, 50% between 11.9 and 15.1 pF, only 18
760 cells out of 246 in the first quartile below 7.2 pF or in the fourth quartile above 19 pF) and
761 G_{in} (50% of cells between 0.71 and 1.18 nS, only 7 out of 242 with input conductance above
762 2 nS) were not spread much in the cells recorded at E12.5, showing that most embryonic V1^R
763 were of comparable size. Interestingly, C_{in} and G_{in} were not correlated, which indicated that
764 the input conductance was determined by the density of leak channels rather than by the sheer
765 size of the cell. Moreover, no correlation was observed between the passive properties and the
766 firing pattern (Boeri et al 2018). Therefore, we always set G_{in} and C_{in} to 1 nS and 13 pF in
767 the model (except in Figure 10-Figure supplement 2), close to the experimental medians (0.96
768 nS and 13.15 pF, respectively). The membrane time constant C_{in}/G_{in} was then equal to 13
769 ms, which was also close to the experimental median (13.9 ms, N=241).

770 E_{Na} was set to a standard value of 50 mV. The activation curve of I_{Nap} was obtained by
771 fitting experimental data, leading to a mid-activation of -33 mV and a steepness of 11 mV.
772 The experimentally measured values of G_{Nap} were in the range 0-2.2 nS. We assumed that the
773 activation curve of I_{Nat} was shifted rightward by 6 mV in comparison to I_{Nap} . No
774 experimental data was available for the inactivation of I_{Nat} . We chose a mid-inactivation
775 voltage $V_h = -45$ mV and a steepness $k_h = -5$ mV. We also assumed that the activation time
776 constant of both I_{Nat} and I_{Nap} was 1.5 ms, and that the inactivation time constant was
777 voltage-dependent: $\tau_h(V) = 16.5 - 13.5 \tanh((V + 20)/15)$, decreasing by one order of
778 magnitude (from 30 ms down to 3 ms) with the voltage increase. This enabled us to account

779 for the shape of the action potentials recorded in experiments, showing a slow rise time and
780 rather long duration. The conductance G_{Nat} was not measured experimentally. When
781 choosing a reasonable value of 25 nS for G_{Nat} , the model behaved very much as recorded
782 embryonic V1^R: similar current threshold (typically 10-20 pA) and stable plateau potential
783 obtained for the largest values of G_{Nap} .

784 When investigating how repetitive plateaus were generated (see Fig 10C), we chose $V_s = -$
785 30 mV for the mid-inactivation of I_{Nap} and set the steepness k_s at -5 mV (as for the
786 inactivation of I_{Nat}). To account for mixed events (and oscillatory plateaus, see Fig 10D), we
787 had to shift the inactivation curve ($V_s = -20$ mV) and make it less steep ($k_s = -15$ mV), so as
788 to ensure sufficient de-inactivation of I_{Nap} during spiking episodes.

789 E_K was set to a standard value of -80 mV. The activation parameters of I_{Kdr} were obtained
790 by fitting the experimental data: $V_n = -20$ mV, $k_n = 20$ mV, $\tau_n = 10$ ms and an activation
791 exponent of 3. The activation and inactivation properties of I_A were also chosen based on
792 experimental measurements. Accordingly, $V_{m_A} = -30$ mV, $k_{m_A} = -12$ mV, $V_{h_A} = -70$ mV,
793 $k_{h_A} = -7$ mV, and $\tau_{h_A} = 23$ ms. We assumed that $G_A = G_{Kdr}$, consistently with experimental
794 data (see S8 Fig A).

795

796 *Numerical simulations and dynamical systems analysis*

797 We integrated numerically the deterministic model using the freeware XPPAUT
798 (Ermentrout 2002) and a standard fourth-order Runge-Kutta algorithm. XPPAUT was also
799 used to compute one-parameter and two-parameters bifurcation diagrams. The stochastic
800 version of the model was also implemented in XPPAUT and computed with a Gillespie's
801 algorithm (Gillespie 1976).

802 To investigate the dynamics of the model with slow inactivation of I_{Nap} , we relied on
803 numerical simulations together with fast/slow dynamics analysis (Witelski & Bowen 2015).

804 In this approach, one distinguishes slow dynamical variables (here only s) and fast dynamical
805 variables. Slow variables vary little at the time scale of fast variables and may therefore be
806 considered as constant parameters of the fast dynamics in first approximation. In contrast,
807 slow variables are essentially sensitive to the time average of the fast variables, much more
808 than to their instantaneous values. This separation of time scales allows one to conduct a
809 phase plane analysis of the full dynamics.

810

811 *Statistics*

812 All values were expressed as mean \pm SEM. Statistical significance was assessed by non-
813 parametric Kruskal-Wallis test with Dunn's post hoc test, Mann-Whitney test or Wilcoxon
814 matched pairs test (GraphPad Prism 5.0 Software, USA). Significant changes in the
815 proportions of firing patterns with age were assessed by chi-square test for large sample and
816 by Fisher's exact test for small sample. Significance was determined at $P < 0.05$.

817 **Acknowledgments**

818 We thank Susanne Bolte, Jean-François Gilles and France Lam for assistance with confocal
819 imaging (IBPS imaging facility) and IBPS rodent facility team for animal care and
820 production. We thank University Paris Descartes for hosting Yulia Timofeeva as an invited
821 professor. This work was supported by INSERM, CNRS, Sorbonne Université (Paris),

1054 **Figure captions**

1055 **Figure 1. Delayed Rectifier and A-Type potassium currents are present in embryonic**
1056 **V1^R at E12.5**

1057 (A) Representative traces of voltage responses showing single-spiking activity (left trace),
1058 repetitive action potential firing (middle trace) and plateau potential activity (right trace). (B1,
1059 B2 and B3) Representative examples of the total outward K⁺ currents obtained from $V_H = -$
1060 100 mV (left traces), of I_{Kdr} ($V_H = -30$ mV, middle traces) and of isolated I_A (left traces)
1061 recorded at E12.5 in SS V1^R (A1), RS V1^R (A2) and PP V1^R (B3). Voltage-dependent
1062 potassium currents were evoked in response to 10 mV membrane potential steps (200 ms)
1063 from -100 or from -30 mV to +40 mV (10 s interval between pulses). V1^R were voltage
1064 clamped at $V_H = -60$ mV. A prepulse of -40 mV (300 ms) was applied to activate both I_A and
1065 I_{Kdr} . I_{Kdr} was isolated by applying a prepulse of 30 mV (300 ms) to inactivate I_A (B1 insert).
1066 I_A was isolated by subtracting step-by-step the currents obtained using a prepulse of 30 mV
1067 ($V_H = -30$ mV) from the currents obtained using a prepulse of -40 mV ($V_H = -100$ mV). (C1,
1068 C2 and C3) Current-voltage relationship ($I - V$ curves) of I_{Kdr} (filled circles) and of I_A (open
1069 circles) recorded in SS V1^R (C1), RS V1^R (C2) and PP V1^R (C3). $I - V$ curves were obtained
1070 from currents shown in A1, A2 and A3. Note that the $I - V$ curves are similar between SS
1071 V1^R, RS V1^R, PP V1^R.

1072

1073 **Figure 2. Maximal G_{Kdr} , G_{Nap} values and G_{Nap}/G_{Kdr} ratio in embryonic V1^R recorded at**
1074 **E12.5 and at E14.5**

1075 (A) Bar graph showing maximal G_{Kdr} value (Max G_{Kdr}) in SS V1^R at E12.5 (n = 9; gray bar)
1076 and at E14.5 (n = 10; gray bar), and in RS V1^R (n = 7; red bar), ME V1^R (n = 3; purple bar)
1077 and PP V1^R at E12.5 (n = 7; blue bar). G_{Kdr} was calculated from I_{Kdr} at $V_H = +20$ mV,
1078 assuming a K⁺ equilibrium potential of -96 mV. There is no significant difference

1079 in G_{Kdr} between SS V1^R and RS V1^R, while G_{Kdr} is significantly smaller in PP V1^R as
1080 compared to SS V1^R and RS V1^R. G_{Kdr} was significantly higher in SS V1^R at E14.5 than in SS
1081 V1^R, RS V1^R and PP V1^R at E12.5. (Kruskall-Wallis test $P < 0.0001$; SS V1^R versus RS V1^R
1082 at E12.5, $P = 0.5864$; SS V1^R versus PP V1^R at E12.5, $P = 0.0243$; RS V1^R versus PP V1^R at
1083 E12.5, $P = 0.0086$; E14.5 SS V1^R versus E12.5 SS V1^R, $P = 0.0048$; E14.5 SS V1^R versus
1084 E12.5 RS V1^R, $P = 0.0384$, E14.5 SS V1^R versus E12.5 PP V1^R, $P < 0.0001$). The increase in
1085 G_{Kdr} between E12.5 and E14.5 is likely to be due to the increase in neuronal size (input
1086 capacitance; Figure 2A). Indeed there was no significant difference (Mann Whitney test, $P =$
1087 0.133) in G_{Kdr} density between SS V1^R at E12.5 (408.5 ± 42.95 pS/pF, $n = 9$) and at E14.5
1088 (522.6 ± 49.6 pS/pF, $n = 10$). (B) Bar graph showing the maximal G_{Nap} value (Max G_{Nap}) in
1089 SS V1^R at E12.5 ($n = 9$; gray bar) and E14.5 ($n = 10$; green bar), and in RS V1^R ($n = 8$; red bar),
1090 ME V1^R ($n = 3$; purple bar) and PP V1^R ($n = 6$; blue bar) at E12.5. Max G_{Nap} was calculated
1091 from maximal I_{Nap} value measured on current evoked by assuming a Na⁺ equilibrium
1092 potential of +60 mV. There was no difference in G_{Nap} between RS V1^R and PP V1^R. On the
1093 contrary, G_{Nap} measured in SS V1^R at E12.5 or at E14.5 was significantly smaller as
1094 compared to G_{Nap} measured at E12.5 in RS V1^R or in PP V1^R. G_{Nap} measured at E12.5 and
1095 E14.5 in SS V1^R were not significantly different (Kruskall-Wallis test $P < 0.0001$; E12.5 SS
1096 V1^R versus E12.5 RS V1^R, $P = 0.0034$; E12.5 SS V1^R versus E12.5 PP V1^R, $P = 0.0006$;
1097 E12.5 RS V1^R versus E12.5 PP V1^R, $P = 0.5494$; E14.5 SS V1^R versus E12.5 SS V1^R, $P =$
1098 0.5896; E14.5 SS V1^R versus E12.5 RS V1^R, $P = 0.0005$; E14.5 SS V1^R versus E12.5 PP V1^R,
1099 $P < 0.0001$). (C) Histograms showing the G_{Nap} / G_{Kdr} ratio in SS V1^R at E12.5 ($n = 9$; gray
1100 bar) and E14.5 ($n = 10$; green bar) and in RS V1^R ($n = 8$; red bar), ME V1^R ($n = 3$; purple bar)
1101 and PP V1^R ($n = 6$; blue bar) at E12.5. Note that the G_{Nap} / G_{Kdr} ratio differs significantly
1102 between SS V1^R, RS V1^R and PP V1^R at E12.5, while it is not different between SS V1^R
1103 recorded at E12.5 and at E14.5 (Kruskall-Wallis test $P < 0.0001$; SS V1^R versus RS V1^R at

1104 E12.5, $P = 0.0367$; SS $V1^R$ versus PP $V1^R$ at E12.5, $P < 0.0001$; RS $V1^R$ versus PP $V1^R$ at
1105 E12.5, $P = 0.0159$; E14.5 SS $V1^R$ versus E12.5 SS $V1^R$, $P = 0.2319$; E14.5 SS $V1^R$ versus
1106 E12.5 RS $V1^R$, $P = 0.0017$; E14.5 SS $V1^R$ versus E12.5 PP $V1^R$ $P < 0.0001$). Data shown in A
1107 and B were used to calculate G_{Nap} / G_{Kdr} ratio shown in C. ($*P < 0.05$, $**P < 0.01$, $***P <$
1108 0.001).

1109

1110 **Figure 3. Delayed Rectifier potassium current was inhibited by low concentrations of 4-**
1111 **aminopyridine in embryonic $V1^R$ recorded at E12.5**

1112 Example of voltage-dependent potassium currents evoked in response to 10 mV membrane
1113 potential steps (200 ms) from -100 mV or from -30 mV to +40 mV (10 s interval between
1114 pulses). $V1^R$ were voltage clamped at $V_H = -60$ mV. A prepulse of -40 mV (300 ms) was
1115 applied to activate both I_A and I_{Kdr} . I_{Kdr} was evoked in response to 10 mV membrane
1116 potential steps (200 ms) from -100 mV to +40 mV. $V1^R$ were voltage clamped at $V_H = -60$
1117 mV. A prepulse of 30 mV ($V_H = -30$ mV) was applied to isolate I_{Kdr} . (A1) Representative
1118 example of the effect of 300 μ M 4-AP application on I_{Kdr} recorded from embryonic $V1^R$ at
1119 E12.5. (A2) Curves showing current-voltage relationships of I_{Kdr} in control and in the
1120 presence of 300 μ M 4-AP. Measurements were performed on traces shown in A1. (B) Dose-
1121 response relationship of 4-AP-evoked I_{Kdr} inhibition (mean + SE). Data were normalized to
1122 I_{Kdr} amplitude measured in the absence of 4-AP ($V_H = 40$ mV) and fitted as explained in
1123 Materials and Methods. Note that 4-AP IC_{50} is in μ M range (2.9 μ M). 0.3 μ M 4-AP n = 3, 1
1124 μ M 4-AP n = 3, 3 μ M 4-AP n = 9, 10 μ M 4-AP n = 13, 30 μ M 4-AP n = 7, 100 μ M 4-AP n =
1125 7, 300 μ M 4-AP n = 7.

1126 **Figure 4. Increasing 4-AP concentration changed the firing pattern of single spiking**
1127 **embryonic $V1^R$ recorded at E12.5**

1128 The firing pattern of embryonic $V1^R$ was evoked by 2 s suprathreshold depolarizing current
1129 steps. (A1-A2) Representative traces showing examples of the effect of increasing
1130 concentration of 4-AP (from 3 to 300 μM) on the firing pattern of a SS $V1^R$ recorded at E12.5.
1131 Note that in this case increasing 4-AP concentration converted single spiking (black trace) to
1132 repetitive spiking (red trace), repetitive spiking to a mixed event pattern (purple trace) and
1133 mixed events to plateau potential (blue trace). (A2) Example of SS $V1^R$ in which increasing 4-
1134 AP concentration converted single spiking to repetitive spiking only. (A3) Bar plots showing
1135 the change in the firing pattern of SS $V1^R$ according to 4-AP concentrations (control $n = 10$, 3
1136 μM 4-AP $n = 8$, 10 μM 4-AP $n = 10$, 30 μM 4-AP $n = 10$, 100 μM 4-AP $n = 10$, 300 μM 4-AP
1137 $n = 8$). (B) Representative traces showing the effect of 0.5 μM TTX on a plateau potential
1138 evoked in a SS $V1^R$ in the presence of 300 μM 4-AP. (C) Representative traces showing the
1139 effect of 0.5 μM TTX on repetitive AP firing evoked in a SS $V1^R$ in the presence of 300 μM
1140 4-AP. In both cases, the application of TTX fully blocked the responses evoked in the
1141 presence of 4-AP, indicating that they were underlain by the activation of voltage-gated Na^+
1142 channels.

1143

1144 **Figure 5. Cluster analysis of embryonic $V1^R$ firing pattern in the embryonic spinal cord**
1145 **at E12.5**

1146 (A, inserts) Cluster analysis of embryonic $V1^R$ firing pattern was performed using three
1147 parameters that describe the firing pattern during a 2 s suprathreshold depolarizing pulses: the
1148 mean of the half-amplitude event duration (mean $\frac{1}{2}\text{Ad}$), the coefficient of variation of $\frac{1}{2}\text{Ad}$
1149 ($\text{CV } \frac{1}{2}\text{Ad}$) allowing to quantify the AP variation within a train (CV was set to 0 when the
1150 number of spikes evoked by a depolarizing pulse was ≤ 3) and the duration ratio $\text{ddr} = \Sigma \frac{1}{2}\text{Ad}$
1151 Ad/Pw , obtained by dividing the sum of $\frac{1}{2}\text{Ad}$ by the pulse duration Pw , that indicates the
1152 total time spent in the depolarized state. For example, $\text{ddr} = 1$ when a plateau potential lasts as

1153 long as the depolarizing pulse. Conversely, its value is low when the depolarizing pulse
1154 evokes a single AP only. A. Dendrogram for complete linkage hierarchical clustering of 163
1155 embryonic V1^R according to the values of log mean $\frac{1}{2}Ad$, of CV $\frac{1}{2}Ad$ and of log ddr. The
1156 colored matrix below the dendrogram shows the variations of these three parameters for all
1157 the cells in the clusters (colored trees) extracted from the dendrogram. (B) The number of
1158 clusters was determined by analyzing the distribution of silhouette width values (see Material
1159 and Methods). The boxplots show the distribution of silhouette width values when the number
1160 of clusters k varies from 2 to 12. The mean silhouette width values (red diamond shaped
1161 points) attained their maximum when the estimated cluster number was 5. (C) 3D plot
1162 showing cluster distribution of embryonic V1^R according to log mean $\frac{1}{2}Ad$, CV $\frac{1}{2}Ad$ and log
1163 ddr. Each cluster corresponds to a particular firing pattern as illustrated in D: V1^R that cannot
1164 sustain repetitive firing of APs (1 to 3 AP/pulse only, gray), V1^R that can fire tonically (red),
1165 V1^R with a firing pattern characterized by a mix of APs and relatively short plateau potentials
1166 (dark purple), V1^R with a firing pattern characterized by a mix of APs and relatively long
1167 plateau potentials (light purple) and V1^R with evoked plateau potentials only (blue). The
1168 arrow in D indicates 3 misclassified V1^R that could not sustain repetitive firing although they
1169 were assigned to the cluster of repetitively firing V1^R (see text).

1170

1171 **Figure 6. Changes in the input capacitance, the input resistance and the threshold values**
1172 **of embryonic V1^R from E11.5 to E16.5**

1173 (A) Graph showing how the input capacitance C_{in} of V1^R changes with embryonic age. C_{in}
1174 significantly increased between E12.5 or E13.5 and E14.5 (Kruskall-Wallis test $P < 0.0001$;
1175 E12.5 versus E11.5 $P = 0.258$, E12.5 versus E13.5 $P = 0.904$, E12.5 versus E14.5 $P < 0.0001$,
1176 E12.5 versus E15.5 $P < 0.0001$, E12.5 versus E16.5 $P < 0.0001$, E13.5 versus E14.5 $P <$
1177 0.0001 , E13.5 versus E15.5 $P < 0.0001$, E13.5 versus E16.5 $P < 0.0001$; E11.5 $n = 31$, E12.5

1178 $n = 267$, E13.5 $n = 43$, E14.5 $n = 61$, E15.5 $n = 16$, E16.5 $n = 30$). (B) Graph showing how the
1179 input resistance R_{in} of $V1^R$ changes with embryonic age. R_{in} significantly increased between
1180 E12.5 or E14.5 and E15.5 (Kruskall-Wallis test $P < 0.0001$; E12.5 versus E11.5 $P > 0.999$,
1181 E12.5 versus E13.5 $P = 0.724$, E12.5 versus E14.5 $P > 0.999$, E12.5 versus E15.5 $P = 0.0004$,
1182 E12.5 versus E16.5 $P = 0.0005$, E14.5 versus E15.5 $P = 0.0019$, E14.5 versus E16.5 $P <$
1183 0.0058 ; E11.5 $n = 31$, E12.5 $n = 261$, E13.5 $n = 43$, E14.5 $n = 60$, E15.5 $n = 16$, E16.5 $n = 30$).
1184 (C) Graph showing how the threshold of regenerative events (APs and plateau potentials) of
1185 $V1^R$ changes with embryonic age. The average threshold became significantly more
1186 hyperpolarized after E12.5 (Kruskall-Wallis test $P < 0.0001$; E12.5 versus E11.5 $P = 0.676$,
1187 E12.5 versus E13.5 $P = 0.0039$, E12.5 versus E14.5 $P < 0.0001$, E12.5 versus E15.5 $P <$
1188 0.0001 , E12.5 versus E16.5 $P < 0.0001$, E13.5 versus E14.5 $P > 0.999$, E13.5 versus E15.5 P
1189 $= 0.1398$, E13.5 versus E16.5 $P = 0.0013$; E14.5 versus E15.5 $P > 0.999$, E14.5 versus E16.5
1190 $P = 0.0634$, E15.5 versus E16.5 $P > 0.999$; E11.5 $n = 20$, E12.5 $n = 162$, E13.5 $n = 31$, E14.5
1191 $n = 30$, E15.5 $n = 16$, E16.5 $n = 30$). Yellow and purple bars below the graphs indicate the
1192 two important phases of the functional development of spinal cord networks. The first one is
1193 characterized by synchronized neuronal activity (SNA) and the second one is characterized by
1194 the emergence of a locomotor-like activity (see text). Note that changes in C_{in} and
1195 R_{in} occurred at the end of the first developmental phase. ($*P < 0.05$, $** P < 0.01$, $*** P <$
1196 0.001 ; control, E12.5).

1197

1198 **Figure 7. Developmental changes of embryonic $V1^R$ firing patterns from E11.5 to E16.5**

1199 The intrinsic activation properties were analyzed using 2 s suprathreshold depolarizing
1200 current steps. (A-E) Representative traces of voltage responses showing SS $V1^R$ (black), RS
1201 $V1^R$ (red), ME $V1^R$ (purple) and PP $V1^R$ (blue) at E11.5 (A), E13.5 (B), E14.5 (C) E15.5 (D)
1202 and E16.5 (E). (F) Bar graph showing how the proportions of the different firing patterns

1203 change from E11.5 to E16.5 (E11.5 n = 22, E12.5 n = 165, E13.5 n = 32, E14.5 n = 57, E15.5
1204 n = 15, 16.5 n = 28). Yellow and purple bars below the graphs indicate the first and the
1205 second phase of functional embryonic spinal cord networks. The proportions of the different
1206 firing patterns significantly changed between E11.5 to E12.5 (Fisher's exact test, $P = 0.0052$)
1207 with a significant increase in the proportion of RS V1^R (Fisher's exact test, $P = 0.0336$) and a
1208 significant decrease in the proportion of ME V1^R (Fisher's exact test, $P = 0.01071$) at E12.5.
1209 Only two firing patterns (SS and RS) were observed after E13.5 and most embryonic V1^R lost
1210 their ability to sustain tonic firing after E13.5. However, at E16.5 the proportion of RS V1^R
1211 significantly increased at the expense of SS V1^R when compared to E14.5 (Fisher's exact test,
1212 $P = 0.0112$), indicating that embryonic V1^R began to recover the ability to sustain tonic firing
1213 after E15.5.

1214

1215 **Figure 8. Activated caspase-3 is not observed in embryonic V1^R at E14.5**

1216 Representative confocal image of the ventral part of an isolated lumbar spinal cord of E14.5
1217 GAD67-eGFP mouse embryo showing immunostainings using antibodies against eGFP (A),
1218 FoxD3 (B) and activated Caspase 3 (aCaspase 3, C). (D) Superimposition of the three
1219 stainings shows that embryonic V1^R (eGFP+ and FoxD3+) were not aCaspase 3
1220 immunoreactive. (A1, B1, C1 and D1) Enlarged images from A, B and C showing that
1221 aCaspase 3 staining is localized in areas where eGFP and Foxd3 stainings were absent. (A2,
1222 B2, C2 and D2) Enlarged images from A, B and C showing that aCaspase 3 staining is absent
1223 in the area where V1^R (eGFP+ and FoxD3+) are located. aCaspase 3 staining that did not co-
1224 localize with GAD67eGFP likely indicates MN developmental cell death (Rigato et al 2011).

1225

1226 **Figure 9. 600 μ M 4-AP changed the firing pattern of single spiking embryonic V1^R**
1227 **recorded at E14.5**

1228 The firing pattern of embryonic $V1^R$ was evoked by 2 s suprathreshold depolarizing current
1229 steps. (A1, A2) Representative traces showing the effect of 4-AP application (600 μ M) on the
1230 firing pattern of single SS $V1^R$ recorded at E14.5. Note that the applications of 600 μ M 4-AP
1231 evoked either a plateau potential (A1) or repetitive AP firing (A2), both fully blocked by TTX.
1232 (B) Bar plots showing the proportions of the different firing patterns observed in the presence
1233 of 600 μ M 4-AP versus control recorded in SS $V1^R$ at E14.5 (n = 14).

1234

1235 **Figure 10. Embryonic $V1^R$ firing patterns predicted by computational modeling**

1236 (A) Firing patterns of 27 recorded cells, in which both G_{Nap} and G_{Kdr} were measured. Gray:
1237 SS, red: RS, blue: PP. The three purple points located at the boundary between the RS and PP
1238 regions correspond to mixed events (ME) where plateau potentials alternate with spiking
1239 episodes. Note that no cell exhibited low values of both G_{Nap} and G_{Kdr} (lower left), or large
1240 values of both conductances (upper right). (B) Bifurcation diagram of the deterministic model
1241 when G_{Kdr} is kept fixed to 2.5 nS or 10 nS while G_{Nap} is varied. $G_{in} = 1$ nS and $I = 20$ pA.
1242 For $G_{Kdr} = 10$ nS (i.e. in the top experimental range), the red curves indicate the maximal and
1243 minimal voltages achieved on the stable limit cycle associated with repetitive firing (solid
1244 lines) and on the unstable limit cycle (dashed lines). The fixed point of the model is indicated
1245 by a gray solid line when it corresponds to the stable quiescent state, a gray dashed line when
1246 it is unstable and a solid blue line when it corresponds to a stable plateau potential. The two
1247 HB corresponding to the change of stability of the quiescence state (HB₁, $G_{Nap} = 0.95$ nS) and
1248 of the voltage plateau (HB₂, $G_{Nap} = 3.04$ nS) are indicated, as well as the two SN bifurcations
1249 of limit cycles associated with the onset (SN₁, $G_{Nap} = 0.58$ nS) and offset (SN₂, $G_{Nap} = 3.14$
1250 nS) of repetitive spiking as G_{Nap} is increased. For $G_{Kdr} = 2.5$ nS, the model does not display
1251 repetitive firing; it possesses a unique fixed point, which is always stable (blue-gray curve).
1252 The transition from quiescence to plateau is gradual with no intervening bifurcation.

1253 Representative voltage traces of the three different activity patterns are shown: single spiking
1254 in response to a 2 s current pulse (gray, $G_{Nap} = 0.1$ nS, $G_{Kdr} = 10$ nS), repetitive spiking
1255 (red, $G_{Nap} = 1.5$ nS, $G_{Kdr} = 10$ nS) and plateau potential (blue, $G_{Nap} = 1.5$ nS, $G_{Kdr} = 2.5$ nS).
1256 Note that the plateau never outlasts the current pulse. (C) Bifurcation diagram when G_{Nap} is
1257 kept fixed at 1.5 nS and G_{Kdr} is varied ($I = 20$ pA). Same conventions as in B. Plateau
1258 potential is stable until point HB₂ ($G_{Kdr} = 5.05$ nS), repetitive firing can be observed between
1259 HB₂ and SN₁ ($G_{Kdr} = 21.05$ nS). The quiescent state is stable from point HB₁ ($G_{Kdr} = 15.76$
1260 nS) onward. Increasing G_{Nap} by merely 10% from 1.5 to 1.65 nS makes the bifurcation HB₂
1261 subcritical (not shown). This is because the RS-PP transition of the model occurs near a
1262 Bautin bifurcation (a.k.a. generalized HB) bifurcation, where the supercritical HB, subcritical
1263 HB and the SN bifurcation of limit cycles merge as shown in D (point B₂). (D) Two-
1264 parameters bifurcation diagram of the model in the $G_{Nap} - G_{Kdr}$ plane ($I = 20$ pA). The black
1265 lines indicate the bifurcations HB₁ and HB₂. The red lines indicate the SN bifurcations of
1266 limit cycles SN₁ and SN₂. The shaded area indicates the region where repetitive firing can
1267 occur. The black squares B₁ and B₂ correspond to Bautin bifurcations where supercritical HB
1268 (occurring between B₁ and B₂), subcritical HB (occurring on the rest of the HB₁ and HB₂ lines)
1269 and the SN bifurcations of limit cycles SN₁ and SN₂ coalesce. Because the model is near a
1270 Bautin bifurcation, its behavior is little affected by the nature of the bifurcation HB₂. When
1271 HB₂ is subcritical, the bistability region between HB₂ and SN₂ is narrow (see Fig 9, B and D)
1272 and action potentials keep a large amplitude until their disappearance at point HB₂ (see Fig
1273 9B). When HB₂ is supercritical, the spike amplitude vanishes at HB₂ but the decay is very
1274 steep (see Fig 9C). Taking into account channel noise further softens the distinction between
1275 these two cases. The oblique lines correspond to three different values of the ratio G_{Nap}/G_{Kdr} :
1276 0.03 (gray), 0.2 (red) and 0.5 (blue). Voltage traces on the right display the response to a 2 s
1277 current pulse when channel noise is taken into account for the three regimes: quiescence (top,

1278 gray trace and dot in the diagram), repetitive firing (middle, red) and plateau potential (bottom,
1279 blue). They correspond to the three deterministic voltage traces shown in B. Note that the
1280 one-parameter bifurcation diagrams shown in B correspond to horizontal lines through points
1281 1 and 2 ($G_{Kdr} = 10$ nS) and through point 3 ($G_{Kdr} = 2.5$ nS), respectively. The bifurcation
1282 diagram in C corresponds to a vertical line through point 2 and 3 ($G_{Nap} = 1.5$ nS). (E)
1283 Cumulative distribution function of the ratio G_{Nap}/G_{Kdr} for the four clusters shown in A,
1284 showing the sequencing SS (gray) \rightarrow RS (red) \rightarrow ME (purple, 3 cells only) \rightarrow PP (blue)
1285 predicted by the two-parameters bifurcation diagram in D. The wide PP range, as compared to
1286 SS and RS, merely comes from the fact that G_{Kdr} is small for cells in this cluster. (F) The data
1287 points in A are superimposed on the two-parameters bifurcation diagram shown in D,
1288 demonstrating that our basic model accounts well for SS, RS and PP clusters (indicated with
1289 the same color code as in A). The bifurcation diagram is simplified compared to A, only the
1290 region where repetitive spiking is possible (i.e. between the lines SN_1 and SN_2 in A) being
1291 displayed (shaded area). Notice that 3 ME cells (purple dots) are located near the transition
1292 between the RS and PP regions (indicated here by the purple fringe along the SN_2 bifurcation
1293 line). The four arrows indicate the presumable evolution of G_{Nap} and G_{Kdr} for SS, RS, ME
1294 and PP cells between E12.5 and E14.5-15.5. G_{Nap} eventually decreases while G_{Kdr} keeps on
1295 increasing. G. Distribution of a sample of cells in the $G_{Kdr} - G_{Kdr}$ plane at E14.5. All the cells
1296 are located well within the SS region far from bifurcation lines because of the decreased G_{Nap}
1297 compared to E12.5, the increased G_{Kdr} , and the shift of the RS region (shaded) due to
1298 capacitance increase (18 versus 13 pF).

1299

1300 **Figure 11. Effects of the slow inactivation of I_{Nap} on firing patterns predicted by**
1301 **computational modeling**

1302 (A) Examples of repetitive plateaus (left) and mixed events (right) recorded in $V1^R$ at E12.5
1303 during a 2 s current pulse. (B1) Current-voltage curve of the basic model (without slow
1304 inactivation of I_{Nap} , and without I_A or channel noise) for $G_{Kdr} = 2.5$ nS and for $G_{Nap} = 1.7$ nS
1305 (lower curve) and 2.5 nS (upper curve). $G_{in} = 2.5$ nS. Solid lines denote stable fixed points
1306 and dashed lines unstable ones. For $G_{Nap} = 1.7$ nS, bistability between quiescence and plateau
1307 occurs between the SN bifurcations SN_1 ($I = 2.1$ pA) and SN_2 ($I = 8.3$ pA). When G_{Nap} is
1308 increased to 2.5 nS, that bistability region extends to the negative current range, which
1309 implies that once a plateau has been elicited, the model will stay in that stable state and not
1310 return to the resting state, even though current injection is switched off (see insert). B1 Insert.
1311 Voltage response to a 2 s current pulse of 8 pA for $G_{Nap} = 2.5$ nS. The resting state (gray dot
1312 on the lower curve in B1) is destabilized at pulse onset and a plateau is elicited (blue dot on the
1313 upper curve in B1). At pulse offset, the plateau is maintained, even though the injected current
1314 is brought back to zero, and channel noise is not sufficient to go back to the resting state. (B2)
1315 Domain of bistability between quiescence and plateau (shaded) in the $I - G_{Nap}$ plane for $G_{Kdr} =$
1316 2.5 nS. It is delimited by the two lines SN_1 and SN_2 where SN bifurcations of fixed points
1317 occur. Bistability requires that G_{Nap} exceeds 1.35 nS, and the domain of bistability enlarges as
1318 G_{Nap} is increased further. The two horizontal lines correspond to the two cases shown in
1319 B1: $G_{Nap} = 1.7$ nS and 2.5 nS. (C) Behavior of the model when slow inactivation is
1320 incorporated (half-inactivation voltage $V_s = -30$ mV, steepness $k_s = -5$ mV). The bifurcation
1321 diagram of the basic model (without slow inactivation) for $I = 8$ pA (compared to 20 pA in
1322 Fig 9) and $G_{Kdr} = 2.5$ nS (same conventions as in Fig 9B) and the stable limit cycle (black
1323 solid curve) obtained when slow inactivation is added (voltage-independent time constant: 1 s)
1324 are superimposed. The limit cycle is comprised of four successive phases (see labels): 1) long
1325 plateau during which I_{Nap} slowly inactivates, 2) fast transition to the quiescent state, 3)
1326 repolarization episode during which I_{Nap} slowly deinactivates, 4) fast transition back to the

1327 plateau. Each plateau starts with a full blown action potential (or a series of rapidly decaying
1328 spikelets). Note that the bifurcation HB is subcritical here (unstable limit cycle in red), at
1329 variance with square wave bursting (supercritical bifurcation and stable limit cycle); this is a
1330 characteristic feature of pseudo-plateau bursting. Voltage responses to a 2 s current pulse are
1331 shown on the right for different kinetics of slow inactivation. Top: voltage-independent time
1332 constant of 1 s, Middle: same with channel noise added to fast and slow gating variables,
1333 Bottom: time constant increases with membrane voltage from 100 ms to 1 s (midpoint: -30
1334 mV, steepness: 15 mV). (D) Mixed events. The bifurcation diagram of the basic model
1335 for $G_{K_{dr}} = 2.5$ nS and $I = 10$ pA and the stable limit cycle obtained in the presence of slow
1336 inactivation ($G_{Nap} = 2.5$ nS, $V_s = -20$ mV, $k_s = -15$ mV, voltage-independent time constant: 1
1337 s) are superimposed. Here again, the limit cycle is comprised of four successive phases (see
1338 labels): 1) slow inactivation of I_{Nap} that leads to the crossing of the bifurcation point HB₂ and
1339 the destabilization of the plateau potential, 2) fast transition to the spiking regime, 3)
1340 repetitive spiking during which I_{Nap} slowly de-inactivates, which leads to the crossing of the
1341 bifurcation point SN₂ and terminates the spiking episode, 4) fast transition back to the stable
1342 plateau potential. Voltage traces for a constant injected current (10 pA) are shown on the right
1343 and in the absence of any channel noise. Top: voltage-independent time constant of 1 s,
1344 Bottom: time constant increases with membrane voltage from 200 to 800 ms (same V_s and k_s
1345 as in C). Note that in C and D the first plateau lasts longer than the following ones, as in
1346 electrophysiological recordings of embryonic V1^R cells displaying repetitive plateaus. This
1347 form of adaptation is caused by the slow inactivation of the persistent sodium current.

1348

1349 **Figure 12. Effect of 4-AP application on evoked GABAergic GICs or GDPs recorded in**
1350 **MNs at E12.5.**

1351 (A) Drawing showing the cervical position of the stimulation electrode and the lumbar
1352 position of the recording electrode. (B1) Evoked Giant Inward Current (GIC) in the presence
1353 of 4 mM kynurenic acid in control condition, in the presence of 30 μ M 4-AP and 300 μ M 4-
1354 AP. (B2) Bar graph showing GIC amplitude (pA) and half-width (s) ($*P < 0.05$). 4-AP
1355 applied at concentrations of 30 μ M or 300 μ M significantly increased the amplitude
1356 (Wilcoxon test, $P = 0.016$ and $P = 0.047$ respectively) and half-width (Wilcoxon test, $P =$
1357 0.016 and $P = 0.018$ respectively) of GABAergic GIC. (C1) Evoked Giant Depolarizing
1358 Potential (GDP) in the presence of 4 mM kynurenic acid in control condition, in the presence
1359 of 30 μ M 4-AP and 300 μ M 4-AP. (C2) Bar graph showing GDPs amplitude (mV) and half-
1360 width (s). 4-AP applied at concentrations of 30 μ M or 300 μ M significantly increased
1361 GABAergic GDPs half-width (Wilcoxon test $P = 0.004$ and $P = 0.007$ respectively), but it did
1362 not significant change the amplitude (Wilcoxon test $P = 0.07$ and $P = 0.07$ respectively).

SUPPLEMENTARY FIGURES

Figure 3-Figure supplement 1. I_A is insensitive to 4-AP in embryonic $V1^R$.

I_A was obtained as the difference between currents evoked from $V_H = -100$ mV and currents evoked from $V_H = -30$ mV (10 mV voltage step). (A1) Representative example of the effect of 300 μ M 4-AP on I_A in $V1^R$ recorded at E12.5. (A2) I_A Current-voltage ($I - V$) relationship in control conditions and in the presence of 300 μ M 4-AP. The $I - V$ curves were obtained from the traces shown in A1. (B) Bar graph showing the percentage of I_A block elicited by 4-AP. Note that 4-AP did not significantly block I_A (Wilcoxon test $P = 0.065$, $n = 10$).

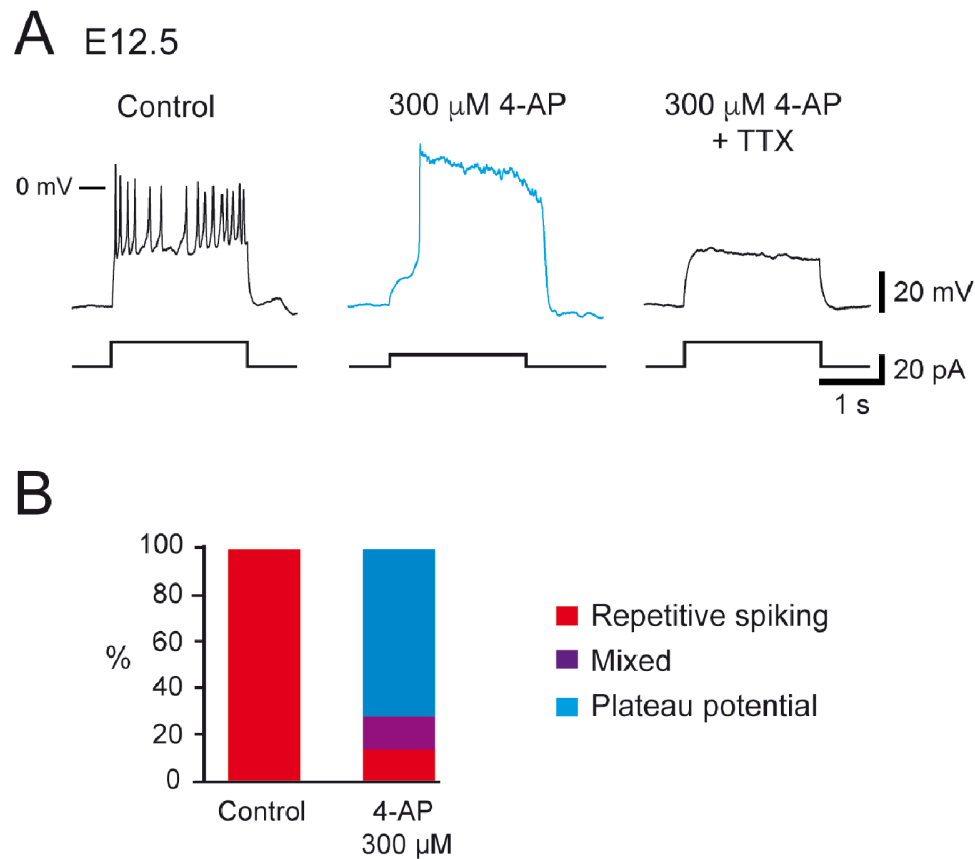

Figure 4-Figure supplement 1. Effect of 4-AP application in repetitively spiking V1^R at E12.5.

(A) Representative traces showing the effect of 4-AP application (300 μ M) on RS V1^R at E12.5. Note that plateau potential activity evoked in the presence of 4-AP (middle trace) was blocked by 0.5 μ M TTX (right trace). (B) Bar plots showing the changes in the firing pattern of RS V1^R evoked by 300 μ M 4-AP application (n = 14). 4-AP application evoked a plateau potential in 71.4 % of the recorded neurons (10/14) and mixed events in 14.3% of the recorded neurons (2/14). The excitability pattern was not modified in 2 neurons.

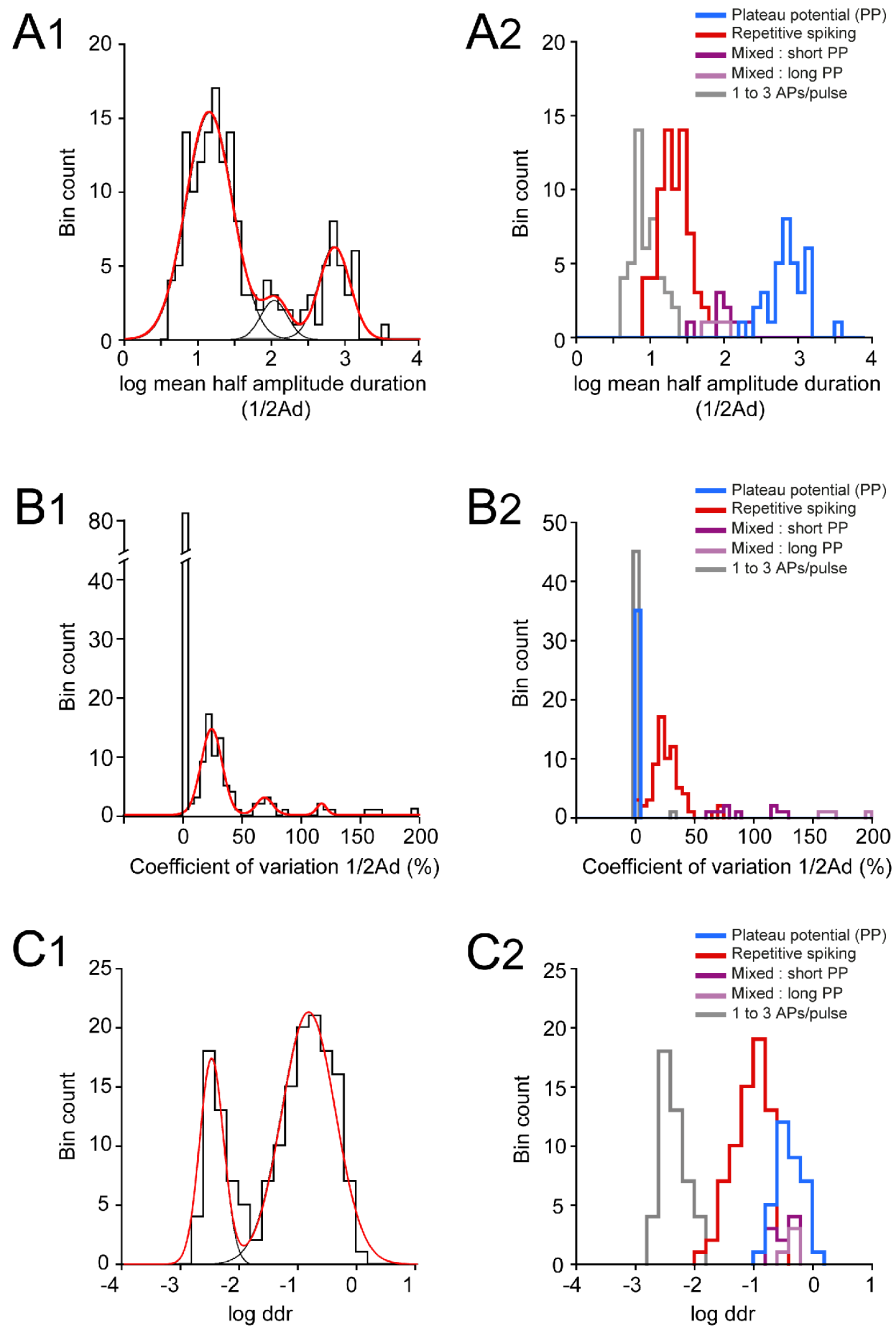

Figure 5-Figure supplement 1 : Distributions of log $1/2Ad$, CV $1/2Ad$ and log ddr values related to the cluster analysis of embryonic $V1^R$ firing patterns.

(A1) Histogram of log mean $1/2Ad$ (mean half amplitude event duration) for the whole $V1^R$ population at E12.5 ($n=164$; bin width 0.1). The histogram was well fitted by the sum of three Gaussian curves with means and SDs of 1.135, 2.046 & 2.84, and 0.316, 0.181 & 0.21, respectively. (A2) Histogram of the values of log mean $1/2Ad$ sorted after cluster analysis showing SS $V1^R$ (black), RS $V1^R$ (red), ME $V1^R$ with short plateau potentials ($ME_s V1^R$, light purple), ME $V1^R$ with long plateau potentials ($ME_l V1^R$, dark purple) and PP $V1^R$ (blue). log

mean $\frac{1}{2}Ad$ was significantly different between SS $V1^R$, PP $V1^R$, the whole ME $V1^R$ population (ME_s and ME_l $V1^R$) and PP $V1^R$ (Kruskall-Wallis test $P < 0.0001$; SS $V1^R$ versus RS $V1^R$, $P < 0.0001$; SS $V1^R$ versus ME $V1^R$, $P < 0.0001$; SS $V1^R$ versus PP $V1^R$, $P < 0.0001$; RS $V1^R$ versus ME $V1^R$, $P = 0.0004$; RS $V1^R$ versus PP $V1^R$, $P < 0.0001$; ME $V1^R$ versus PP $V1^R$, $P = 0.018$; SS $V1^R$ $n = 46$, RS $V1^R$ $n = 69$, ME_s $V1^R$ $n = 9$, ME_l $V1^R$ $n = 4$, PP $V1^R$ $n = 35$). (B1) Histogram of CV $\frac{1}{2}Ad$ for the whole $V1^R$ population at E12.5 ($n = 164$; bin width 5%). Note that a large population of $V1^R$ had zero CV $\frac{1}{2}Ad$ ($n = 83$). The histogram for CV $\frac{1}{2}Ad \neq 0$ was fitted by the sum of three Gaussian curves with means and SDs of 23.4, 68.4 & 117 (%) and 8.9, 6.8 & 4.1, respectively. (B2) Histograms of the values of CV $\frac{1}{2}Ad$ sorted after cluster analysis showing SS $V1^R$ (black), RS $V1^R$ (red), ME_s $V1^R$ (light purple), ME_l $V1^R$ (dark purple) and PP $V1^R$. CV $\frac{1}{2}Ad$ was not significantly different between SS $V1^R$ and PP $V1^R$ (CV $\frac{1}{2}Ad$ of SS $V1^R$ and PP $V1^R$ = 0.682 % and 0% respectively: only one of the 46 SS $V1^R$ displayed 3 PA and had a CV $\frac{1}{2}Ad$ of 31.37). CV $\frac{1}{2}Ad$ was significantly different between RS $V1^R$ and the whole ME $V1^R$ population and also between SS $V1^R$ or PP $V1^R$ and RS $V1^R$ or ME $V1^R$ (Kruskall-Wallis test $P < 0.0001$; SS $V1^R$ versus RS $V1^R$ $P < 0.0001$, SS $V1^R$ versus ME $V1^R$ $P < 0.0001$, SS $V1^R$ versus PP $V1^R$ $P = 0.846$, RS $V1^R$ versus ME $V1^R$ $P = 0.0003$, RS $V1^R$ versus PP $V1^R$ $P < 0.0001$, ME $V1^R$ versus PP $V1^R$ $P < 0.0001$). (C1) Histogram of log ddr (sum of $\frac{1}{2}Ad$ divided by pulse duration) for the whole $V1^R$ population at E12.5 ($n = 164$; bin width 0.2). The histogram was fitted by the sum of two Gaussian curves with means and SDs of -2.51 & -0.851, and 0.2 & 0.46, respectively. (C2) Histograms of the values of log ddr sorted after cluster analysis showing SS $V1^R$ (black), RS $V1^R$ (red), ME_s $V1^R$ (light purple), ME_l $V1^R$ (dark purple) and PP $V1^R$. log (ddr) was not significantly different between ME $V1^R$ and PP $V1^R$, while it was significantly different between SS $V1^R$ and RS $V1^R$, SS $V1^R$ and the whole ME $V1^R$ population, SS $V1^R$ and PP $V1^R$, RS $V1^R$ and the whole ME $V1^R$ population, RS $V1^R$ and PP $V1^R$ (Kruskall-Wallis test $P < 0.0001$; SS $V1^R$ versus RS $V1^R$, $P < 0.0001$; SS $V1^R$ versus ME $V1^R$, $P < 0.0001$; SS $V1^R$ versus PP $V1^R$, $P < 0.0001$; RS $V1^R$ versus ME $V1^R$, $P < 0.0001$; RS $V1^R$ versus PP $V1^R$, $P < 0.0001$; ME $V1^R$ versus PP $V1^R$, $P = 0.977$). ME_s $V1^R$ and ME_l $V1^R$ differed only by their CV $\frac{1}{2}Ad$ (Mann-Whitney test, log mean $\frac{1}{2}Ad$ for ME_s $V1^R$ versus log mean $\frac{1}{2}Ad$ for ME_l $V1^R$, $P = 0.26$; CV $\frac{1}{2}Ad$ for ME_s $V1^R$ versus CV $\frac{1}{2}Ad$ ME_l $V1^R$, $P = 0.0028$ and log ddr for ME_s $V1^R$ versus log ddr for ME_l $V1^R$, $P = 0.1483$). It is noteworthy that the distribution of the values of each metric was multimodal thus indicating that each of them could partially discriminate different groups of embryonic $V1^R$ according to their firing pattern.

Figure 9-Figure supplement 1. I_{Nap} is present in embryonic $V1^R$ recorded at E14.5.

Representative trace of I_{Nap} evoked by a slow depolarizing voltage ramp (70 mV/s, upper insert) in SS embryonic $V1^R$ (lower insert). I_{Nap} was isolated by subtracting currents evoked by depolarizing ramps in the presence of 1 μ M TTX to the control current evoked in the absence of TTX (upper insert).

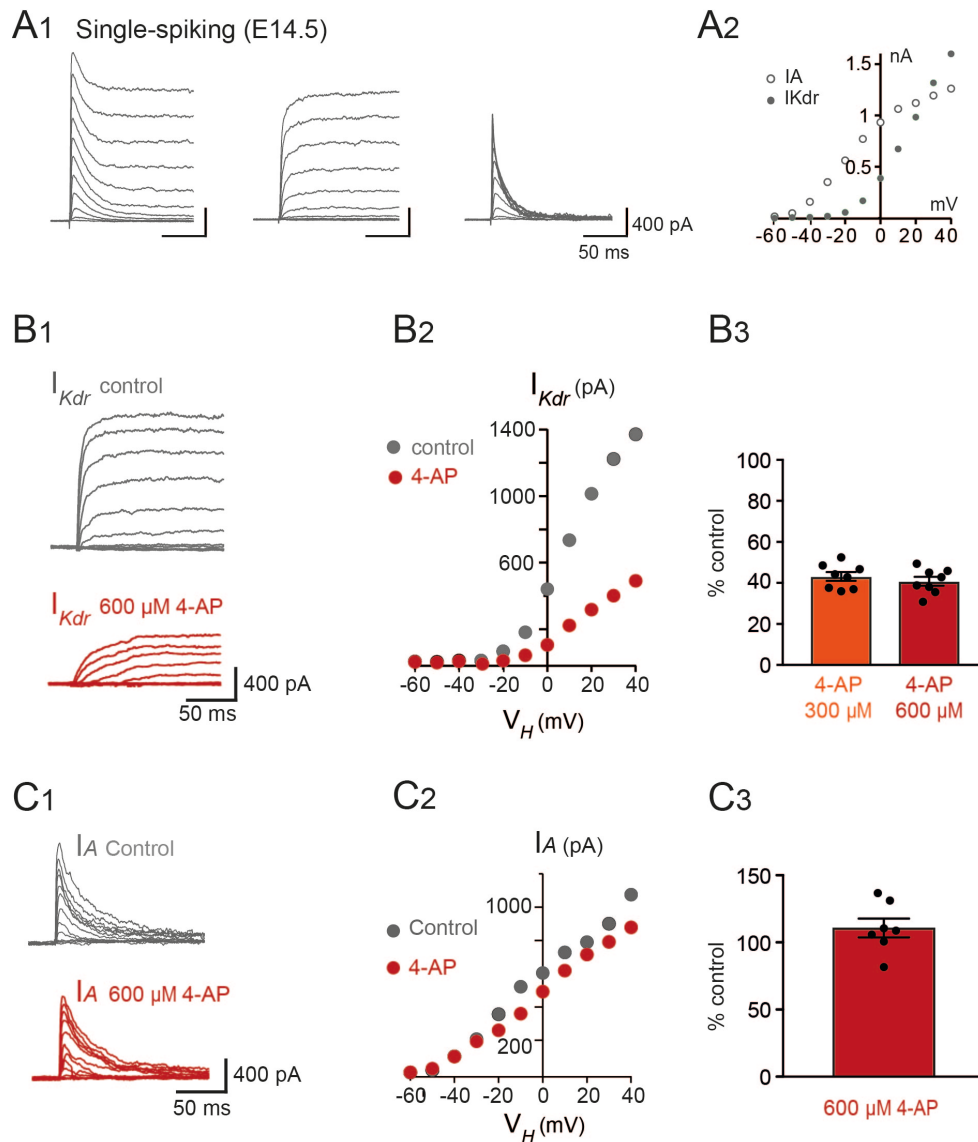

Figure 9-Figure supplement 2. I_{Kdr} was inhibited by 4-AP in $V1^R$ recorded at E14.5.

(A1) Representative examples of the total outward K^+ currents obtained from $V_H = -100$ mV (left traces), of I_{Kdr} ($V_H = -30$ mV, middle traces) and of isolated I_A (left traces) recorded in SS $V1^R$ at E14.5. (A2) Current-voltage relationship of I_{Kdr} (filled circle) and of I_A (open circle) in SS $V1^R$ at E14.5. $I - V$ curves were obtained from currents shown in A1. (B1) Representative example of the effect of 4-AP at 600 μ M in $V1^R$ at E14.5. (B2) Current-voltage curves in control condition and in the presence of 600 μ M 4-AP. (B3) Bar plots showing the percentage of I_{Kdr} inhibition evoked by 300 μ M 4-AP application ($n = 8$) and by 600 μ M 4-AP application ($n = 7$). The percentages of I_{Kdr} inhibition evoked by 300 μ M 4-AP and by 600 μ M 4-AP applications were not significantly different ($P = 0.574$). (C1) Representative example of the effect of 600 μ M 4-AP on I_A in $V1^R$ recorded at E14.5. (C2) $I - V$ curves in control conditions and in the presence of 600 μ M 4-AP. These curves were obtained from the traces shown in B1. (C3) Bar graph showing the percentage of I_A block elicited by 4-AP. 4-AP did not significantly block I_A (Wilcoxon test $P = 0.11$, $n = 6$).

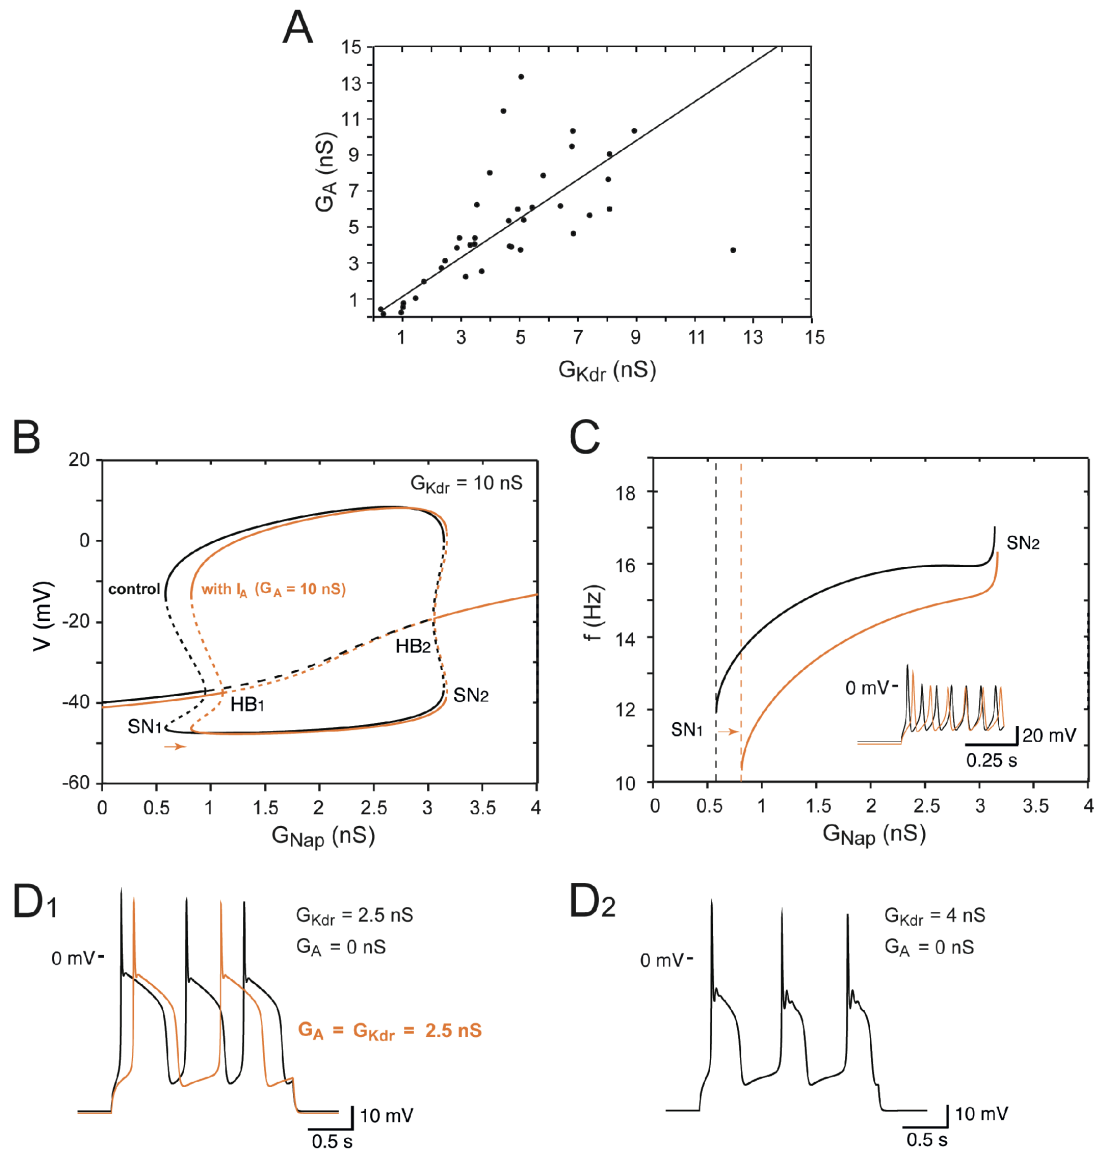

Figure 10-Figure supplement 1. Effects of I_A on embryonic $V1^R$ firing patterns predicted by computational modeling.

(A) The maximal conductances of I_{Kdr} and I_A at E12.5 are linearly correlated. Best fit: $G_A = 1.09 G_{Kdr}$ ($R^2 = 0.81$, $N=44$). (B) Effect of I_A on the dynamics of the basic model. The one-parameter bifurcation diagrams in control condition (black, $G_{Kdr} = 10$ nS, no I_A , same as in Fig 9B) and with I_A added (orange, $G_A = 10$ nS) are superimposed. The I_A current shifts the firing threshold SN_1 to the right by 0.234 nS (from $G_{Nap} = 0.582$ nS to $G_{Nap} = 0.816$ nS, see also C) as indicated by the orange arrow, without affecting the amplitude of action potentials (see also insert in C). In contrast, I_A shifts SN_2 by only 0.025 nS because it is inactivated by depolarization. (C) I_A also slows down the discharge frequency, as shown by comparing the $G_{Nap} - V$ curves without I_A (black) and with I_A (orange). For $G_{Nap} = 1$ nS, for instance, the firing frequency is reduced by 16.7%, from 14.19 to 11.82 Hz. Here again, the effect of I_A progressively decreases as G_{Nap} increases because of the membrane depolarization elicited by I_{Nap} . For $G_{Nap} = 3$ nS, for instance, the firing frequency is reduced by 5% only, from 15.96 to 15.16 Hz. The frequency reduction elicited by I_A does not merely result from the increased firing threshold; when shifted to the right by 0.234 nS, the control $G_{Nap} - V$ curve still does not overlap with the $G_{Nap} - V$ curve obtained for $G_A = 10$ nS (not shown). Note that

the latency of the first spike is increased (see voltage trace in insert), which is a classical effect of I_A . (D) In the pseudo-plateau bursting regime, the I_A ($G_A = 10$ nS) lengthens the repolarizing phase without affecting the duration of plateaus much, as shown by the comparison of the voltage traces obtained without I_A (control, black) and with I_A (orange) in D1. This is because I_A is activated near rest but inactivated during voltage plateaus. In the example shown, only two plateaus occur during the 2 s current pulse, instead of three in the control condition. Note also that the latency of the first plateau is increased. Increasing G_{Kdr} to 4 nS, in the absence of I_A , similarly lengthens repolarization episodes, as shown in D2. However, plateaus are shortened and display some spikelets, at variance with D1. This is because I_{Kdr} does not inactivate (or does it only very slowly), in contrast to I_A .

Figure 10-Figure supplement 2. Influence of input conductance changes on the bifurcation diagram.

The RS region of the basic model is displayed in the $G_{Nap} - G_{Kdr}$ plane in control condition for E12.5 V1^R ($C_{in} = 13$ pF, $G_{in} = 1$ nS, $I = 20$ pA, shaded area), and when G_{in} and I were both reduced by 10% (middle curve) or by 20% (left curve). The reduced I accounts for the decrease in rheobase following the decrease in G_{in} . If 4-AP reduced only G_{Kdr} (as indicated by a downward arrow) the firing pattern of SS V1^R would not change, the control RS region being too far to the right to be visited. In contrast, when the effects of 4-AP on the input resistance and rheobase are taken into account, the bifurcation diagram moves closer to the origin of the $G_{Nap} - G_{Kdr}$ plane, and the RS and PP regions are then successively entered as G_{Kdr} is reduced. The same explanation holds at E14.5.
