**Abstract**

Optogenetics at single-cell resolution can be achieved by two-photon stimulation; however, this requires intense or holographic illumination. We markedly improve stimulation efficiency by positioning fluorophores with high two-photon cross-sections adjacent to opsins. The two-photon-excited fluorescence matches the opsin absorbance and can stimulate opsins in a highly localized manner through efficient single-photon absorption. This indirect fluorescence transfer illumination allows experiments difficult to implement in the live brain such as all-optical neural interrogation and control of regional cerebral blood flow.
Introduction

Optogenetics with light-sensitive opsins has revolutionized the field of neuroscience (1). Typical experiments involve the utilization of single-photon illumination of the brain to activate opsins such as channelrhodopsin (ChR2) and others (2). While this allows temporally precise manipulation of cell ensembles, all the cells along the conical illumination light path will be activated, reducing the spatial specificity and resulting in artificially synchronized activity patterns (3). These drawbacks limit the application of optogenetics to answer important questions involving manipulation of specific cells such as neurons and other excitable cells like vascular smooth muscle cells and astrocytes within ensembles. In order to overcome these limitations, it is desirable to achieve optogenetic stimulation with single-cell level precision. One approach is to utilize two-photon absorption, which is characterized by being limited to the immediate vicinity of the focal point, thereby achieving spatially restricted activation of opsin channels (3). Several studies have demonstrated the feasibility of this approach (4–8); however, two-photon optogenetics has relatively low efficiency in eliciting a biological response, which limits its in vivo applications (Figure 1).

One of the reasons for its low efficiency is that the two-photon effect occurs in a submicron focal volume (9). Thus, only a small patch of cell membrane is illuminated at any point in time during laser scanning, which limits the number of opsin molecules that are synchronously stimulated. This limits the ion flux necessary to induce changes in membrane potential and the resulting ability to trigger action potentials. Opsin stimulation can be improved by the use of higher laser power, but unfortunately this can also have direct effects on membrane potential and cell excitability (10–12), likely due to two-photon thermal effects (13,14), which can cause confounding opsin- or activity-independent ion channel opening. Furthermore, the use of high laser power is problematic as it may induce a variety of cell signaling changes and toxicity (15–17). An alternative to improve the efficiency of two-photon illumination is to use fast laser scanning and generate spiral paths that roughly match the cell’s perimeter, which allows
simultaneous activation of a larger number of opsin channels along the cellular membrane (4,18). A related technique uses spatial light modulators to generate a hologram in the sample so that the laser can simultaneously illuminate the entire target cell (19,20) and thereby elicit a more robust cellular response. While studies have demonstrated in vivo manipulation of neural activity at single-cell resolution with both techniques (21,22), they require advanced optics and complex instrument operation that limit their implementation by most researchers. Thus, it would be of great utility to improve the efficiency by which opsins are stimulated with conventional two-photon illumination and thereby achieve reduced laser scanning times and power requirements. Here we propose a robust and practical approach to achieve in vivo optogenetic control of single cells that we termed two-photon excitation fluorescence transfer (TEFT). This approach markedly improves the efficiency of targeted brain optogenetic in the live brain and should be entirely compatible with current methodologies including spiral cell scanning and holographic illumination commonly used for studies of brain networks, cell physiology and neurovascular coupling.

Results

Two-photon excitation fluorescence transfer (TEFT) for in vivo optogenetics

In conventional two-photon optogenetics, opsins located in a small patch of membrane defined by the width of the diffraction-limited point-spread-function (PSF) (hundreds of nanometers diameter) are activated at any point in time leading relatively inefficient stimulation of opsins (18). Instead of directly activating the light-sensitive opsin channels on the cell membrane, TEFT utilizes the two-photon laser to excite fluorophores located in the vicinity of the opsins. These fluorophores have a fluorescence emission spectrum matching the optimal (single-photon) opsin absorption spectrum and the fluorescent light, instead of the two-photon laser beam, now stimulates opsins in the target cell (Figure 1). Effectively, this converts two-photon stimulation into a local single-photon point source that can be efficiently used for optogenetics (9)(Figure 2). In addition, with the TEFT strategy, densely packed fluorescent molecules
selected for a high two-photon cross section and high quantum yield (located for example in the cell cytoplasm or intravascular space) are excited throughout the volume of the PSF. Fluorescence light is emitted from the PSF volume and illuminates opsins not only within the PSF but also in the vicinity, with the intensity decaying approximately with the inverse square of the distance from the focal point. This translates into a more efficient single-photon illumination point source that can stimulate larger areas of the adjacent cell membranes, without sacrificing the focal properties of two-photon illumination necessary for single-cell optogenetic stimulation (Figure 1 and Figure 3).

In vivo optogenetic control of vascular smooth muscle cells with TEFT stimulation

Guided by the abovementioned TEFT optogenetics principles, we tested the feasibility of two-photon optogenetic stimulation of vascular smooth muscle cells (vSMC) in the live mouse brain to locally control cerebral blood flow (23). Optogenetic control of the brain vasculature has recently been implemented as a powerful tool for dissecting mechanisms of neurovascular coupling and its control by different vascular mural cell types (24,25). We hypothesized that TEFT may improve the efficiency and reliability of vascular optogenetics, and thus investigated this method with various combinations of opsins and intravascular fluorescent dyes. We first tested the ability to induce vessel constriction in Cspg4-Ai32 mice, in which the perivascular vSMCs express the excitatory ChR2. In order to provide the fluorescence emission that matches the optimal absorption of ChR2, we intravascularly injected cascade blue-conjugated albumin. We then scanned a region of interest (ROI) over the selected vessel segment using the femtosecond laser tuned to 800 nm, a wavelength that is unable to directly excite ChR2 (26) and therefore cannot induce adequate vSMC contraction (Figure 4). As predicted, we observed a robust vessel constriction that was only elicited when we implemented the stimulation in the presence of intravascular cascade blue (Figure 4a, Supplementary Movie 1). In contrast, we did not observe any vessel constriction when we used an unconjugated control albumin, albumin conjugated with a dye not optimally matched to ChR2 absorption (Figure 4d) or when we used a 950-nm wavelength, which does not excite the cascade blue dye (Figure
Importantly, the stimulation only induced constriction of the targeted vessel segments, while the diameter of adjacent segments or vessels in the nearby region remained unchanged (Figure 4g). Next, we used archaerhodopsin (Arch)-expressing mice (Cspg4-ArchT (Ai40D)) to induce vSMC hyperpolarization and determine the efficiency of TEFT to induce vSMC-relaxation and consequent vasodilation. To achieve the optimal single-photon activation wavelength of Arch (~545 nm, (27)), we utilized an intravascular Alexa514-conjugated albumin and 900-nm two-photon illumination. This resulted in efficient and focal vessel dilation (Supplementary Movie 2), which did not occur in the absence of the intravascular dye (Figure 5a and b). For both ChR2 and ArchT activation, we found that many other dyes with similar emissions were capable of inducing opsin activation. For example, all three blue-emitting fluorescent dyes, Cascade-blue, Alexa 405 and AMCA (aminomethylcoumarin acetate), were able to trigger vessel contraction in Cspg4-ChR2 mice (Figure 4f), while the two yellow-emitting dyes, Alexa 514 and Lucifer yellow, produced vessel dilation in Cspg4-ArchT mice (Figure 5e). Together, these results demonstrate that the fluorescence generated from these intravascular dyes by two-photon excitation was a potent indirect light source for highly efficient and specific optogenetic control of vSMCs in vivo.

High spatial resolution TEFT control of neuronal activity in the live brain

Having demonstrated the effectiveness of TEFT using intravascular dyes to activate vSMCs, we next explored the feasibility of applying this method to neurons in the live brain. Due to the difficulty of introducing organic fluorescent dyes into cells in vivo, we instead overexpressed fluorescent proteins in the target neurons. We used in utero electroporation of neurons in the mouse brain to first co-express the red-emitting fluorescent protein tdTomato and the opsin ReaChR (peak absorption 595 nm), as well as the calcium sensor GCaMP6 to detect neuronal activity changes. Co-expression of tdTomato, ReaChR and GCaMP6 was confirmed by observing calcium responses triggered by direct ReaChR activation upon red LED illumination. Cells that demonstrated robust responses were then targeted for two-photon stimulation. To test the feasibility of implementing TEFT in neurons, we scanned these cells by two-photon
illumination of a ROI covering the entire cell body using a wavelength of 920 nm (Figure 6a), which is not optimal for ReaChR excitation (28). This focused scanning triggered a rapid rise in GCaMP6 fluorescence (Figure 6b). Furthermore, whole-cell patch-clamp recording in acute brain slices obtained from the same batch of mice showed that these calcium transients were associated with changes in membrane potential including action potentials (Figure 6c).

We next compared this optogenetic-induced calcium rise in cells with and without tdTomato co-expression. While two-photon scanning can directly stimulate ReaChR at relatively high powers (28), co-expression with tdTomato markedly increased the efficiency, and enabled activation at laser powers that are normally too low for ReaChR stimulation (Figure 6d). We observed ~50% reduction of the laser power required to reach 50% probability of activation using the TEFT method (20% rise of GCaMP6 fluorescence used as arbitrary threshold) (Figure 6e). Importantly, when cells were individually stimulated, we could elicit a robust calcium rise in the targeted cell, without any calcium changes in the immediately adjacent one (Figure 7). Together these observations demonstrate that two-photon excitation of tdTomato can efficiently induce ReaChR activation with a high degree of spatial specificity.

Fluorophore/opsin constraints critical for optimal TEFT efficiency

In contrast to the tdTomato/ReaChR pair for TEFT optogenetic stimulation, we were not able to elicit two-photon activation of ChR2 when pairing it with genetically encoded blue fluorescent proteins or SNAPtag-targeted organic dyes co-expressed in the same neurons (Figure 8). This contrasts with the highly efficient activation we observed when ChR2 in vSMCs was stimulated in the presence of blue intravascular organic dyes (Figure 2). As an explanation for this phenomenon, we hypothesized that the number of photons emitted by the donor fluorophores in the vicinity of opsins is a critical variable that determines their efficient activation. To better understand this relationship, we calculated the theoretical number of photons emitted after two-photon excitation of various well-known fluorescent proteins (29,30) (Figure
2 and 8c). With these data, we determined that the mTagBFP/ChR2 pair that we used experimentally for neurons, was not suitable for TEFT optogenetics, given that for laser powers of ~10 mW, typical of most intravital applications, the calculated emitted fluorescence of mTagBFP was only of the order of 0.01 mW/mm², which is two orders of magnitude lower than the reported power needed for ChR2 activation (31). In contrast, with the tdTomato/ReaChR pair, using 10 mW for two-photon illumination, yielded around 0.15 mW/mm² (Figure 8d), which is known to be sufficient to elicit strong ReaChR photo currents (32). One way to overcome the low two-photon cross section of most genetically encoded blue fluorescent proteins, would be to increase their intracellular concentration to achieve greater net photon emissions. However, it is difficult to increase their intracellular concentrations beyond ~10 micromolar (33). This contrasts with the concentration of intravascular dyes that we used for stimulation of ChR2 in vSMCs (~500 micromolar), which can be further increased as needed, thereby achieving highly efficient TEFT optogenetic stimulation.

Discussion

We report a novel approach to improve the limited efficiency of two-photon illumination for opsin stimulation in vivo. By positioning organic dyes or genetically encoded fluorescent proteins in the cytoplasm or immediate vicinity of opsins (intravascular), and using two-photon illumination to excite them, a focal source of single-photon emissions is generated, which efficiently activates adjacent opsins. The TEFT technique retains the focal illumination properties (given the rapid intensity decay as a function of distance from the single-photon light source, see Figure 3), which allows opsin stimulation at cellular and possibly subcellular resolution. We demonstrate that TEFT allows in vivo experiments otherwise not easily achievable such as targeted opsin stimulation of vSMCs and neurons with widely available standard two-photon microscopy setups. The lowered laser power requirements achieved by this method could be critical for reducing thermal injury (34) and unwanted laser-induced electrophysiological effects independent of opsin activation (10,11). TEFT can be further optimized in the future by improving the
quantum yield of the paired fluorescent proteins utilized or by developing more efficient methods for targeting bright organic dyes to specific cellular compartments, thereby achieving higher concentrations, \textit{in vivo}. Finally, this method is entirely compatible and should also improve the efficiency of other methods for two-photon optogenetic stimulation such as the use of fast spiral scanning paths (4,18) or scanless holographic approaches (19,20). Together our data demonstrates a significant improvement in the methodologies for targeted cell optogenetics stimulation that are critical for experiments requiring precise spatial and temporal single-cell stimulation for investigation of cellular physiology and neural networks \textit{in vivo}.

**Figure 1:** Diagram depicting the principle of two-photon excitation fluorescence transfer (TEFT). (a) Direct two photon illumination of light gated ion channels (opsins) induces photocurrents mainly at focal points on the cell membrane as the laser scans the field of view (left diagram). Jablonski diagram depicting standard two photon excitation of opsins and resulting photocurrent (Middle diagram). Raster scanning showing opsin activation at site of focal membrane illumination by two-photon laser (Right diagram). (b) Expression of fluorescent proteins or presence of organic dyes in the immediate vicinity of opsins (i.e. cell cytoplasm or intravascular space) allows indirect two-photon illumination (Left diagram) by scanning the entire area and exciting fluorophores all along the path instead of just at sites of opsins on the membrane (Right diagram). The two-photon excitation of adjacent fluorophores generates single photon emissions that are less focal and can indirectly activate the adjacent membrane opsins and generate photocurrents. This can improve the efficiency of opsin activation because it generates a larger number of exciting photons, thereby more efficiently stimulating the adjacent opsins.
Figure 2: Theoretical estimation of fluorescence irradiance with two-photon excitation. (a) Schematic diagram of fluorescence transfer mediated two-photon optogenetics and the Jablonski diagram for the principle of two-photon excitation. Two-photon excitation generates fluorescence that can be absorbed by opsins expressed on the cell membrane. Two prerequisites for efficient fluorescence transfer optogenetics: 1, matching the spectrum between fluorophore emission and opsin absorption; and 2, sufficient irradiance of the fluorescence to generate photocurrents. (f) Quantifications of vessel diameters with different experimental conditions. Data are presented as mean ± standard deviation, with individual datapoints provided (N=10 to 20 vessels per group). One sample Wilcoxon tests were used for each group to compare to 1, with additional Bonferroni’s correction for multiple comparisons (*: p<0.05). (g) Two-photon time-lapse images of vessel constriction in a Cspg4-cre:Ai32 mouse with intravascular blue dye. White dashed boxes indicated the stimulation scanning region of interest. Notice the restriction of the constricted area to the illumination ROI only.
Figure 5: Fluorescence transfer-mediated two-photon optogenetic inhibition of vascular smooth muscle cells in vivo. (a) Two-photon time-lapse images of vessel dilation in archaerhodopsin expressing mouse (Cspg4:ArchT-GFP). (b) Representative two-photon time-lapse images of the same vessel segment with yellow intravascular dye. White and blue dashed lines show site where diameter was measure overtime in a and b. Scanning parameters in a and b: 25 Hz, 900 nm laser, 10 µs dwell time, 10mW. (c) Vessel cross-section line profiles depicted overtime during scanning at the locations of dashed lines in a and b. (d) Quantification of normalized vessel diameters with and without yellow intravascular dye. Data are represented as mean ± standard deviation. N=10 vessels per group. Yellow, red and blue segments indicate statistically significant timepoints between groups (*: p<0.05; **: p<0.01 and ***: p<0.001, respectively, Student’s t-test between groups for each time point, with Bonferroni’s correction for multiple comparison). (e) Quantification of vessel diameters with different experimental conditions. Data are presented as mean ± standard deviation, with individual datapoints provided. N=10 to 20 vessels per group. One sample Wilcoxon tests were used for each group to compare to 1, with additional Bonferroni’s correction for multiple comparison (**: p<0.01).
Figure 6: In vivo optogenetics of single neurons using fluorescence transfer-mediated two-photon stimulation. (a) Two-photon raster scanning in a live mouse brain of ROI (white dashed square) covering a neuron that is co-expressing ReaChR, GCaMP6 and tdTomato, induces robust calcium transients (ROI scan parameters: pixel size: 0.42 µm/pixel, 50 Hz, 5 s, 920 nm laser, 4 µs dwell time, 8.6 mW). Time-lapse images (bottom panel, green) show rapid increase in calcium levels following two-photon illumination. (b) GCaMP6 calcium response of a neuron coexpressing ReaChR, GCaMP6 and tdTomato using the same scanning parameters as in a (ROI scanning interval indicated by the orange bar). (c) Brain slice whole cell patch-clamp recording on a tdTomato and ReaChR positive neuron. The orange bar indicates ROI scanning (scanning parameters: 0.42 µm/pixel, 20 Hz, 5 s, 920 nm laser, 4 µs dwell time, 1.9 to 4.7 mW). (d) Comparison of two-photon optogenetics in ReaChR/GCaMP6 positive neurons with and without tdTomato expression (N=37 for tdTomato positive; N=28 for tdTomato negative). Data are represented as mean ± standard error (*: p<0.05, Student’s t-test comparison between groups for each time point). (e) Cumulative Ca²⁺ responses measured with GCaMP6 comparing stimulation of cells with and without expression of tdTomato using 920nm excitation. Curve fitting showed that tdTomato-expressing neurons are more efficiently activated than tdTomato-negative neurons at various laser powers (20% rise of GCaMP6 fluorescence used as arbitrary threshold of neuronal activation) (p=0.0015 comparing differences between fitted curves, see methods for statistical details).
Figure 7: Fluorescence transfer-mediated two-photon stimulation retains single neuron resolution in vivo. (a) Sequential two photon stimulation (920nm) of single neuron out of two adjacent ReaChR, GCaMP6 and tdTomato coexpressing cells (top-left). (b) Heat maps of individual cell GCaMP6 responses immediately after excitation of a ROI positioned on the stimulated neuron (orange dashed box; middle and -right panels). (c) Calcium response curves of these two neurons (Dotted line indicates interval without scanning, see methods for detail) using stimulation parameters as in a, show that despite their proximity, the tdTomato emission within the illuminated ROI from either cell is unable to activate the immediately adjacent cell, highlighting the preservation of spatial specificity when using two photon florescence transfer optogenetics.
Figure 8: Ineffective excitation of ChR2 in neurons using blue fluorescent proteins reveal critical constraints for optimal TEFT efficiency. (a) Calcium response of ChR2, jRCaMP and tagBFP positive neurons (N=34) shows no response when scanned with two-photon (780 nm for tagBFP excitation, 1045 nm for jRCaMP calcium imaging, 4 μs dwell time, ~15 mW); ROI scanning (48x48 pixels, 20 Hz, for 5 s) performed on the neuron soma. Data are represented as mean ± standard error. (b) Quantification of calcium response during two-photon scanning (similar to a) with CellTracker Blue CMHC, SNAP-cell 430, and tagBFP in ChR2 and jRCaMP co-expressing neurons (N=3, N=7, N=34). Data are represented as mean ± standard error. An important note is that none of the organic dyes or SNAP-cell 430 labeling strategies achieved sufficiently bright labeling in vivo, potentially limiting the overall stimulation efficiency. (c) Theoretical calculations of two-photon fluorescence photon generation for selected fluorescent proteins using the equation in Figure 2. Two-photon excitation wavelengths used in calculations corresponded to the peak cross-section of each protein. Laser power was kept at 10 mW with a 1.0 numerical aperture lens. (d) Estimations of two-photon excitation fluorescence irradiance of tdTomato and tagBFP, with various objectives (air or water immersion, numerical aperture from 0.05-1.0). Laser power was kept at 10 mW, fluorescent protein concentration was set at 10 μM, and a target cell was 5 μm in diameter. Based on these calculations the blue-emitting proteins have a theoretical low efficiency for exciting the opsins, consistent with our experimental data.
Supplementary Movie 1: Fluorescence transfer-mediated two-photon optogenetic activation of ChR2 in vascular smooth muscle cells leads to vessel constriction. Time-lapse videos of the same vessel segment in a Cspg4-Ai32 mouse with (right panel, 800nm excitation) and without (left panel, 925nm excitation) the excitation of the intravascular blue-emitting dye. Scanning parameters in both: 25 Hz, 10 µs dwell time, 10mW laser power.

Supplementary Movie 2: Fluorescence transfer-mediated two-photon optogenetic activation of ArchT in vascular smooth muscle cells leads to vessel dilation. Time-lapse videos of the same vessel segment in a Cspg4-Ai40D mouse with (right panel, 900nm excitation) and without (left panel, 930nm excitation) the excitation of the intravascular yellow-emitting dye. Scanning parameters in both: 25 Hz, 10 µs dwell time, 10mW laser power.
Materials and Methods

Mice

All rodent procedures were approved by the Yale University Institutional Animal Care and Use Committee. For vascular studies, transgenic mice that express the Cre recombinase under the mural cell NG2 (Cspg4) promoter, and reporter lines with cre-dependent channelrhodopsin-2 (Ai32) or Archaerhodopsin-3 (Ai40D) were purchased from The Jackson Laboratory (JAX# 008533, JAX# 021188, JAX# 012569). Cre-expressing strains were crossbred with the reporter strains and the offspring were used for all experiments. For neuronal studies, wild type mice were used for electroporation of various constructs (JAX# 000651). For all experiments, 2-3-month-old mice from both sexes were used.

Reagents

Purified albumin (Sigma-Aldrich, 05470) was used for fluorescent dye conjugation. Reactive esters were used for labeling (Thermo Fisher Scientific, C-2284, A6118, A30000, L-1338) according to the manufacturer’s instruction. The labeled albumin was diluted so that 5mg reactive dyes constituted 1mL of injection stock. 100μl of labeled albumin was injected intravenously before imaging, final dye concentration in blood was estimated to be ~0.5mM. In all conjugations, albumin was used at concentrations greater than the number of fluorophores to eliminate the need for free fluorophore purification.

To express constructs by in Utero electroporation we obtained and modified the following plasmid constructs from Addgene: CAG-tdTomato, CAG-ReaChR (#50954), Syn-GCaMP6f (#100837), CAG-tagBFP (#49151), Syn-ChR2 (#58880), CAG-jRCaMP (#61562). See Supplement for maps of modified plasmids.

In utero electroporation

In utero electroporation was done as previously described (36). Briefly, Plasmids were used at the final concentration of 1.0 µg/µl (for each plasmid), mixed with 2 mg/ml Fast Green for visualization during plasmid injection and electroporation. Electroporation was performed around embryonic day 13 to 15 (E13 to E15). Mice were anesthetized with ketamine/xylazine (100mg/kg and 10mg/kg i.p.). Buprenorphine was administered (i.p.) every 12 hours for 2 more days following surgery. After exposing the uterine horns, ~1 µl of plasmid mixture was pressure injected into the lateral ventricle of each embryo via a pulled glass microelectrode (tip size 10~20 um) using Picospritzer II (General Valve, 20 psi). 50 V current pulses generated by a BTX 8300 pulse generator (BTX Harvard Apparatus) were used for electroporation. Mice were allowed to age to 1 month prior to utilization in all experiments.

Craniotomy surgery, window implantation and in vivo two-photon imaging

Mice were anesthetized with an intraperitoneal injection of Ketamine/Xylazine mixture, with final concentration of 100mg/kg and 10mg/kg, respectively. The status of anesthesia was assessed periodically with hind paw pinch. The mouse was head-fixed to a custom-made headplate by gluing the skull to it. A craniotomy of about 4mm diameter was made (AP -1.5mm, ML 2.0 mm) with a dental drill, with dura mater carefully removed. A coverslip was put to cover the craniotomy opening and secured with cyanoacrylate glue. The mouse was kept anesthetized during subsequent imaging sessions, and immediately euthanized after finalizing the experiment.
Two-photon imaging was carried out with a commercial system (Bruker Ultima Investigator), controlled through Prairie View software. A tunable Ti:Sapphire laser was used to generate two-photon excitation with its wavelength and mode-locking tuned through MaiTai software. In the case of RCaMP imaging, a 1045nm fixed wavelength laser (MaiTai InSight X3) was used. A poch cell was used to modulate laser power; and the laser power on the sample was measured with a power meter (Thorlabs PM100D). The point scanning was achieved by galvanometer scanners with various dwell times. The full frame rate was kept at 0.5 Hz, and for stimulation, the scanning within regions of interests (ROIs) was at 20 Hz or 50 Hz frequencies. During ROI scanning, the regions outside the ROI were not scanned nor imaged (represented by the dashed portion of the GCaMP6 response curved in Figure 7). Fluorescence emission was collected with gallium arsenide phosphide photo-multiplier tubes. A 20x water immersion 1.0 numerical aperture objective (Zeiss) and a 10x air 0.4 numerical aperture objective (Leica) were used for most experiments.

**Single cell patch clamp and two-photon optogenetics**

Acute brain slices of the in utero electroporated mice (P30-P40) were prepared following a N-methyl-D-glucamine (NMDG) protective recovery method (37). Whole cell patch clamp and two-photon optogenetics were then performed in slices in an ASCF containing (in mM) 120 NaCl, 3.1 KCl, 1.1 CaCl2, 1.2 MgCl2, 1.25 MgSO4, 26 NaHCO3, 0.5 L-glutamine, 0.1 ascorbic acid, 0.1 Na-pyruvate, and 20 glucose; saturated with 95% O2 - 5% CO2 at 35°C. To target fluorescent cells, we used a two-photon microscope system (Ultima; Prairie Technologies) equipped with a Ti:Sapphire pulsed laser (MaiTai), configured on an Olympus upright microscope (BX51WI) with a 20x, 0.5 NA objective lens (LUMPlanFL/IR) and a 60x, 1.0 NA objective lens (LUMPLANFL/IR). Cells were patched under 60x objective lens with pipette solutions as follows (in mM): (1) for voltage clamp, 105 CsMeSO4, 0.5 CaCl2, 10 HEPES, 5 EGTA, 5 Na2-phosphocreatine, 2 ATP-Mg, 0.5 GTP-2Na, 2 ascorbic acid, and 8 QX314-Cl (pH 7.2), with 20–30 CsOH; (2) for current clamp, 105 potassium gluconate, 5 KCl, 0.5 CaCl2, 2 MgCl2, 5 EGTA, 10 HEPES, 5 Na2-phosphocreatine, 2 ATP-2Na, 0.5 GTP-2Na, and 2 ascorbic acid (pH 7.2) with 5 NaOH and 15 KOH. Liquid junction potential was calculated with pCLAMP software and corrected (Molecular Devices, Union City, CA). Once whole cell patch clamp was achieved, 20x objective lens was switched for two-photon optogenetics. A single ROI (48 x 48 pixel, 10 x 10 µm) including only the cell soma was chosen for raster scan, with 920nm wavelength, 12 µs dwell time, and laser intensity less than 20 mW, which shows no clear photo damage to cell membranes. An external voltage was used to trigger the two-photon image scan, so that the timing of laser scanning and cell voltage/current can be accurately matched for later analysis.

**Statistics**

Statistical analyses were carried out using GraphPad Prism (8.4.1). Data were presented in mean ± standard deviation in Figure 4e, 4f, 5d and 5e, and in mean ± standard error in Figure 6d. For comparing normalized vessel diameter time-lapse traces (Figure 4e and 5d), Student’s t-test was performed with each timepoint, with Bonferroni correction for multiple comparison. For comparing the two-photon mediated vessel motility in different conditions (Figure 4f and 5e), one-sample Wilcoxon tests were used for each group to compare to a value of 1, with additional Bonferroni’s correction for multiple comparison. For comparing the efficacy of neuronal optogenetics with and without fluorescence transfer (Figure 6e), we fit the response probability from each group to the following exponential equation: \( Y = 1 - \exp(-K*(X-L)) \), in which the parameter L indicates the minimal power to elicit calcium responses and K indicates the change rate of the curve. Extra sum-of-squares F test was used to determine whether two sets of parameters were statistically different.
