8 9 **Summary**

10 The *Escherichia coli* structural maintenance of chromosomes complex, MukBEF, forms axial
11 cores to chromosomes that determine their spatio-temporal organization. Here, we show
12 that axial cores direct chromosome arms to opposite poles and generate the translational
13 symmetry between newly replicated sister chromosomes. MatP, a replication terminus (*ter*)
14 binding protein prevents chromosome rotation around the longitudinal cell axis by
15 displacing MukBEF from *ter*, thereby maintaining the linear shape of axial cores. During DNA
16 replication, MukBEF action directs lagging strands towards the cell center, marked by
17 accumulation of DNA-bound β_2 -clamps in the wake of replisomes, in a process necessary for
18 the translational symmetry of sister chromosomes. Finally, the ancestral ('immortal')
19 template DNA strand, propagated from previous generations, is preferentially inherited by
20 the cell forming at the old pole, dependent on MukBEF-MatP. The work demonstrates how
21 chromosome organization-segregation can foster non-random inheritance of genetic
22 material and provides a framework for understanding how chromosome conformation and
23 dynamics shape subcellular organization.

24
25 **Keywords:** MatP/MukBEF/non-random segregation/replication/SMC

26 27 **Introduction**

28 Faithful chromosome propagation and inheritance underpin all replicative life. Organisms
29 have evolved a vast range of mechanisms to ensure timely replication and segregation of
30 genetic material. Despite this diversity, highly conserved Structural Maintenance of
31 Chromosomes (SMC) complexes play a central role in the organization of chromosomes in
32 all domains of life. Eukaryotic cells orchestrate replication and segregation in discrete stages
33 where newly replicated sister chromosomes are first individualized by condensin and held
34 together by cohesin before being pulled apart by action of the mitotic spindle and cleavage
35 of cohesin (reviewed in (Uhlmann, 2016)). In contrast, in prokaryotes, chromosome
36 replication and segregation are generally not temporally separated and occur progressively
37 (Kuzminov, 2014). Because divergent species have evolved different solutions to the same
38 problem, understanding the contributions of different mechanisms and physical constraints
39 underlying robust chromosome segregation remains a challenge (Badrinarayanan et al.,
40 2015; Surovtsev and Jacobs-Wagner, 2018; Wang et al., 2013).

41 Genetic studies have identified two major classes of proteins implicated in
42 chromosome segregation in bacteria. First, structural maintenance of chromosomes (SMC)

43 complexes, MukBEF, MksBEF and Smc-ScpAB, were initially identified in a screen for
44 *Escherichia coli* mutants that generated anucleate cells as a consequence of a failure to
45 segregate newly replicated chromosomes to daughter cells (Hiraga et al., 1989; Nolivos and
46 Sherratt, 2014). Second, studies of low copy plasmid stability identified ParABS systems,
47 which subsequently were shown to have roles in chromosome segregation in many
48 organisms (Surovtsev and Jacobs-Wagner, 2018). While many bacteria encode one or both
49 of these systems, some, for example *Pseudomonas aeruginosa*, encode two different SMCs
50 and a ParABS system (Petrushenko et al., 2011; Vallet-Gely and Boccard, 2013).
51 Nevertheless, deletion of SMC or ParAB proteins has frequently modest if any consequences
52 for chromosome segregation. Consistent with this, it has been proposed that large bacterial
53 chromosomes can utilise repelling entropic effects to facilitate separation of bacterial
54 chromosomes (Jun and Mulder, 2006), unlike much smaller low copy number plasmids that
55 require a functional ParABS system for faithful segregation (Surovtsev and Jacobs-Wagner,
56 2018). Whatever roles entropic forces may play, studies in diverse bacterial species have
57 demonstrated that chromosomal loci are not positioned randomly in cells (Fogel and
58 Waldor, 2005; Umbarger et al., 2011; Vallet-Gely and Boccard, 2013; Wang et al., 2005,
59 2006, 2014), and that in *E. coli*, MukBEF complexes play an important role in correct
60 positioning of replication origins and other loci by forming an axial core to the chromosome
61 (Danilova et al., 2007; Mäkelä and Sherratt, 2020). Absence of MukBEF leads to formation of
62 anucleate cells during growth and loss of viability at temperatures higher than 22 °C in rich
63 media (Danilova et al., 2007; Niki and Jaffe, 1991).

64 In new-born *E. coli* cells with non-overlapping replication cycles, origins of replication
65 (*oriC*) are positioned close to the cell center, and the left and right chromosome arms are
66 linearly organized in separate cell halves. Chromosome replication-segregation leads to
67 generation of daughter cells with a chromosome organization identical to their mother cell.
68 Most cells adopt a *left-oriC-right-left-oriC-right (L-R-L-R)* translational symmetry prior to
69 division (Wang et al., 2006), which requires that either the leading or lagging strand
70 templates are symmetrically segregated to the cell poles (Toro and Shapiro, 2010; Wang et
71 al., 2005). In agreement, an elegant chromosome degradation experiment showed that the
72 leading strand templates are segregated towards the cell poles in most cells (White et al.,
73 2008). In theory, cells could also control the fate of the old template strand by non-random
74 segregation, designating the destination for each strand. During each replication cycle, there
75 is a risk of the new strand not faithfully copying the information from the template strand.
76 ‘Immortal’ (or ancestral) strand retention was originally proposed as a strategy to maintain
77 DNA purity in stem cells while the copied strands, potentially carrying mutations from
78 replication, were segregated to non-stem cell progeny (Cairns, 1975). Whether this strategy
79 is actually utilized by stem cells remains controversial (Lansdorp, 2007; Rando, 2007;
80 Wakeman et al., 2012). Ancestral strand segregation has also been tested in *C. crescentus*
81 (Marczynski et al., 1990; Osley and Newton, 1974) and *B. subtilis* (Errington and Wake,
82 1991), however, none of these studies showed any segregational strand preference
83 between daughter cells.

84 We lack a mechanistic understanding of how chromosome conformation and
85 orientation is maintained inside a bacterial cell. It also remains unknown how progressive
86 chromosome segregation facilitates non-random sister chromosome inheritance in an

87 otherwise apparently symmetrical organism. Here, we address these questions in *E. coli*
88 utilizing microfluidics culturing devices combined with time-lapse imaging, high-throughput
89 microscopy and quantitative analysis. We first demonstrate that in the absence of MukBEF,
90 anucleate cells arise predominantly from the mother cell's new pole as a consequence of
91 the failure to segregate newly replicated origins in a timely fashion. We show that nascent
92 lagging strands and their templates are directed towards cell centers, a process that is
93 required for the observed translational *L-R-L-R* segregational symmetry; and which is
94 perturbed in the absence of MukBEF. Furthermore, we show directly that the ancestral DNA
95 strand, inherited from previous generations, is preferentially segregated to the old cell pole
96 dependent on both MukBEF and its partner MatP. Lack of MatP does not perturb
97 translational *L-R-L-R* symmetry; rather it leads to flipping of chromosome orientation around
98 the longitudinal cell axis during a cell cycle, consistent with the observed loss of ancestral
99 strand retention at old poles. Taken together, the results explain how MukBEF axial cores
100 and their MatP-driven depletion from the *ter* region, lead to asymmetric strand and
101 chromosome segregation. The possible functional and evolutionary consequences of this
102 are explored.

103

104 **Results**

105 ***In the absence of MukBEF, anucleate cells arise from the newer mother cell pole***

106 To understand how anucleate *E. coli* cells form in the absence of MukBEF, we followed
107 successive cell cycles of $\Delta mukB$ cells with *oriC* and *ter* (*ori1* and *ter3*, respectively) regions
108 fluorescently labeled by FROS markers. We used a 'mother machine' microfluidics device
109 (Uphoff, 2018; Wang et al., 2010) to follow thousands of cell generations and identify
110 changes in chromosome organization that correlate with chromosome mis-segregation.
111 Under these conditions, $15.7 \pm 0.4\%$ (\pm SD) of divisions led to the formation of an anucleate
112 daughter cell (Fig. 1A, Fig. S1).

113 In $\Delta mukB$ cells *ori1* was often mis-localized towards the old pole at birth, rather
114 than at midcell (Fig. 1B), as previously observed for wild type (WT) cells (Wang et al., 2006).
115 As the cell cycle progressed, *ori1* localized preferentially towards the old cell pole, with
116 newly replicated sister *ori1* loci frequently remaining in close proximity. In contrast, *ter3*
117 migrated from the new-born cell pole to midcell similar to what has been previously
118 reported (Fig. 1B)(Wang et al., 2005). ~80% of anucleate cells were generated when
119 duplicated *ori1* loci in mother cells remained together in the region of the old pole prior to
120 cell division (Fig. 1C). In contrast, in ~70% of mother cells where chromosome segregation
121 was faithful, *ori1* loci were visible as separate foci (Fig. 1C). Delayed separation of newly
122 replicated *ori1* loci could be a consequence of delayed decatenation, since the decatenase
123 TopoIV, is no longer recruited by MukBEF to *oriC*-proximal regions (Zawadzki et al., 2015).
124 Indeed, modest over-expression of TopoIV leads to a reduction in cohesion time of newly
125 replicated *oriC* from ~14 min to ~5 min (Wang et al., 2008). Delayed *ori1* decatenation of
126 $\Delta mukB$ cells might explain non-viability under fast growth conditions, while slow growth
127 conditions allow sufficient time for chromosome decatenation and segregation in most cells.
128 In anucleate cell divisions, daughter cells that inherited two chromosomes divided normally
129 after a modest increase in generation time (Fig. S1). However, the probability of these cells

130 forming an anucleate cell in subsequent division was $9.1 \pm 2\%$ (\pm SD), significantly lower than
131 for cells born with a single chromosome.

132 Prior to anucleate cell formation, mother cells divided nearly symmetrically (2.1 ± 0.2
133 μm and $2.4 \pm 0.2 \mu\text{m}$, respectively (\pm SD); two-sample t-test p-value 0.17), with the divisome
134 being placed close to midcell. While the average anucleate cell length at birth did not
135 significantly differ from that of the sister, the growing sister was systematically longer than
136 the anucleate sister at birth (Fig. S1), the bias for the longer growing sister increasing with
137 mother cell division size. Importantly, we showed that anucleate cells formed preferentially
138 at the newer mother cell pole ($74.4 \pm 1.8\%$ (\pm SD), Fig. 1D). Therefore, anucleate cell
139 formation is associated with the nucleoid being preferentially retained at the old pole of
140 ΔmukB mother cells, while in the case of WT cells the nucleoid is localized closer to the
141 newer pole of the dividing cell (Fisher et al., 2013). We conclude that mis-localization of *ori1*
142 towards the old pole, accompanied by delayed segregation of newly replicated *ori1* loci,
143 directs the formation of anucleate cells to the mother cell's new pole.

144

145 ***MukBEF and MatP direct left-oriC-right chromosome organization***

146 Next we investigated how MukBEF orchestrates chromosome organization and segregation
147 in growing cells. MukBEF and MatP have been proposed to be major factors in dictating *left-*
148 *oriC-right* (L-R) chromosome organization in *E. coli* (Mäkelä and Sherratt, 2020; Wang et al.,
149 2006). MukBEF complexes form axial cores that linearly organize the chromosome outside
150 the 800 kb *ter* region, from where MatP bound to *matS* sites displaces MukBEF (Fig.
151 2A)(Mäkelä and Sherratt, 2020). Complete axial cores were most easily visualized in cells in
152 which MukBEF occupancy on the chromosome was increased ~ 3.5 -fold, while cells with WT
153 MukBEF abundance on chromosomes exhibited more granular structures (Mäkelä and
154 Sherratt, 2020). To characterize how MukBEF axial cores influence chromosome
155 organization during the cell cycle, we used strains that allowed us to test the requirements
156 for *left* and *right* chromosome arm organization in relation to *oriC* and *ter* in MatP⁺ and
157 ΔmatP cells with WT levels of MukBEF, and in ΔmukB cells (Fig. 2). The *left* and *right*
158 chromosome arms were labeled at *L3* and *R3* (-128° and 122° from *oriC*, respectively) with
159 FROS markers, as were *ori1* and *ter3* loci (Fig. 2A, B).

160 New-born WT cells exhibited the distinctive *left-oriC-right* (L3-R3) chromosome
161 organization (Fig. 2C, D and E, Fig. S2), where *oriC* remained at the cell center and the
162 chromosome arms (*L3* and *R3*) resided in opposite cell halves ($97.8 \pm 0.6\%$ (\pm SD), Fig. 2F and
163 G) (Nielsen et al., 2006; Wang et al., 2006). During replication-segregation, the pattern was
164 extended into a translationally symmetric *left-oriC-right-left-oriC-right* (L3-R3-L3-R3) pattern
165 in $73.1 \pm 3.9\%$ (\pm SD) of WT cells (Fig. 2G). In the absence of MukBEF, we expected
166 chromosome organization to be more 'relaxed' as lengthwise chromosome compaction is
167 relieved (Mäkelä and Sherratt, 2020). Indeed, the localization of all four chromosomal
168 markers was less precise, with a wide distribution of *L3-R3* distances (Fig. 2F), fewer *L3* and
169 *R3* foci localized in opposite cell halves ($56.6 \pm 3.2\%$ (\pm SD), Fig. 2G), and a random chance of
170 observing the *L3-R3-L3-R3* organization ($47.7 \pm 0.2\%$ (\pm SD)), versus *L3-R3-R3-L3* or *R3-L3-L3-*
171 *R3*. The impaired chromosome organization in ΔmukB cells is frequently accompanied by
172 the chromosome arms being aligned together along the long cell axis with *ori1* towards the

173 old cell pole (Fig. 2B and D)(Danilova et al., 2007), an organization reminiscent of the
174 situation in wild-type *C. crescentus* (Wang et al., 2013). We conclude that absence of
175 lengthwise compaction by MukBEF axial cores causes loss of both the distinctive *L-R*
176 chromosome organization prior to replication and the *L-R-L-R* organization after replication.

177 Absence of MatP leads to the formation of circular MukBEF axial cores, rather than
178 linear ones (Fig. 2A). We observed that $\Delta matP$ cells exhibited chromosome locus localization
179 patterns strikingly different from that of WT and $\Delta mukB$ cells (Fig. 2 C and E). The average
180 distance between *L3* and *R3* was reduced two-fold (Fig. 2F), consistent with MukBEF-
181 mediated lengthwise compaction of *ter* in the absence of MatP (Mäkelä and Sherratt, 2020).
182 Lengthwise compaction of *ter* reduced the efficiency of *L3* and *R3* being directed into
183 opposite cell halves ($65.7 \pm 0.8\%$ ($\pm SD$), Fig. 2G). Concomitantly, it also led to *L3* and *R3* foci
184 being preferentially localized closer to the cell center than in WT cells where *L3* and *R3*
185 localize towards the cell poles (Fig. 2E). Surprisingly, despite these substantial perturbations,
186 the normal *L3-R3-L3-R3* organization was retained in $\Delta matP$ cells prior to cell division ($80.2 \pm$
187 1.9% ($\pm SD$)).

188 Because the circular MukBEF axial cores of $\Delta matP$ cells lead to rotational
189 chromosome symmetry (Mäkelä and Sherratt, 2020), we hypothesized that non-replicating
190 chromosomes in new born cells are free to rotate around the longitudinal axis of the cell.
191 This would switch the configuration from *L3-R3* to *R3-L3* (or *vice versa*); while bi-lobed
192 replication intermediates could prevent the rotation as replication progresses. To test this
193 hypothesis, we followed $\Delta matP$ cells under the microscope to observe how often the *L3-R3-*
194 *L3-R3* orientation flips to *R3-L3-R3-L3* (or *vice versa*) in consecutive generations (Fig. S2).
195 Indeed, $\Delta matP$ cells retained the chromosome orientation only in $32.2 \pm 4.6\%$ ($\pm SD$) of
196 daughter cells, while WT cells predominantly retained the orientation ($91.4 \pm 5.2\%$ ($\pm SD$),
197 Fig. 2H). The $\Delta matP$ daughter cells with flipped chromosome orientation were initially born
198 with the same orientation as in the mother cell ($88.4 \pm 2.8\%$ ($\pm SD$), Fig. S2E), indicating that
199 the chromosome rotation generally occurs after division but prior to duplication of the
200 chromosome. We propose that the *L3-R3-L3-R3* organization arises from an interplay
201 between bidirectional replication and the action of MukBEF axial cores.

202

203 ***DnaN marks lagging strand segregation to the cell center***

204 Translational symmetry of sister chromosomes arises at least in part during DNA replication
205 from the symmetric segregation of lagging strands towards midcell (and leading strands
206 towards the cell poles), as shown using an elegant genetic system (White et al., 2008). Here,
207 we sought directly to visualise the positioning of lagging strands in WT, $\Delta matP$ and $\Delta mukB$
208 cells.

209 During replication, ~ 40 DNA-bound β_2 -clamps, which ensure DNA polymerase III
210 processivity, have a ~ 3 min residence time on DNA before they are unloaded (Moolman et
211 al., 2014). The DNA-bound clamps are expected to accumulate largely on the lagging strand
212 and its template because new clamps are loaded during synthesis of each Okazaki fragment
213 (Fig. 3A). We reasoned that since β_2 -clamps could potentially cover >100 kb of newly
214 replicated lagging strand DNA, they could serve as a marker to monitor lagging strand
215 segregation (Fig. 3B). As a reference, for the localization of replication forks, we imaged

216 fluorescent DNA polymerase III ϵ -subunits (DnaQ). Indeed, while DnaQ foci were more
217 spread towards cell poles as previously described (Reyes-Lamothe et al., 2008), DnaN foci
218 localized closer to the cell center cell center, consistent with the lagging strands being
219 directed to the cell center (Fig. 3C). By directly measuring the distance from each DnaQ
220 focus to the closest DnaN focus, we found that $41.2 \pm 5\%$ (\pm SD) of DnaQ foci do not
221 colocalize with DnaN foci during replication (Fig. 3D). Differential location of bulk DnaN and
222 replication forks was confirmed by measurement of the distances from replicative helicase
223 (DnaB) foci to their closest DnaN focus ($47.1 \pm 6.1\%$ (\pm SD) not colocalizing) (Fig. S3B, C).
224 Since DnaN and DnaQ colocalize during early and late replication, when sister replisomes
225 are necessarily close together, we also analysed the localization patterns in mid-replication
226 cycle (Fig. 3E), when independently tracking replication forks are more frequently spatially
227 separate. The pattern of DnaQ foci that did not colocalize with DnaN foci (Fig. S3F)
228 underlines the conclusion that spatially separate sister replisomes in opposite cell halves
229 have a different cellular location from DnaN. Our results are consistent with previous
230 independent measurements of DnaQ and DnaN localization, and the observation that DnaN
231 foci of sister replisomes often do not spatially separate (Mangiameli et al., 2017; Reyes-
232 Lamothe et al., 2008; Wallden et al., 2016). Here we provide the first direct evidence that
233 the replisome and β_2 -clamps frequently do not colocalize during replication.

234 Our direct visualization of the segregation of lagging strands during replication,
235 supports the previously shown symmetric segregation of leading strands towards the cell
236 poles (White et al., 2008). To analyze how MukBEF and MatP contribute to lagging strand
237 segregation, we measured DnaN localization in $\Delta matP$ and $\Delta mukB$ cells. The DnaN
238 distribution in $\Delta matP$ cells was much broader than in WT cells (Fig. 3E and F), indicative of
239 spatially less precise lagging strand segregation, but still directed towards cell centers, as
240 predicted by the *L3-R3-L3-R3* organization. The DnaQ distribution in mid-cycle $\Delta matP$ cells
241 was more central than that of DnaN ($50.8 \pm 1.3\%$ (\pm SD) colocalization with DnaN, Fig. 3E),
242 most likely because of less separated chromosome arms. Both DnaQ and DnaN exhibited a
243 broader distribution at shorter cell lengths (Fig. 3F), presumably because of a more random
244 chromosome conformation (Fig. 2). $\Delta mukB$ cells showed a bimodal distribution of DnaN and
245 DnaQ localizations towards cell poles, with almost identical patterns for both markers (Fig.
246 3G). This shows that lagging strands and their templates cannot be directed to cell centers in
247 a timely manner in the absence of MukBEF function, a result consistent with impaired *L-R*
248 and *L-R-L-R* organization in $\Delta mukB$ cells. By measuring the distance from each DnaQ focus to
249 the closest DnaN focus, we found that lagging strands did not leave the vicinity of the
250 replisome during the DnaN dwell time on chromosomes of ~ 3 min ($78.4 \pm 0.5\%$ (\pm SD) of foci;
251 Fig. S3G). We hypothesize that this is a consequence of delayed decatenation by TopoIV in
252 the absence of MukBEF (Zawadzki et al., 2015), since lagging strand templates can only be
253 segregated from the leading strands once decatenation has occurred.

254 Finally, a dynamin-like protein CrfC (aka YjdA) has been proposed to bind β_2 -clamps
255 and tether the nascent strands of sister-chromosomes together (Ozaki et al., 2013).
256 However, upon deletion of *crfC*, we observed no changes to DnaN localization along the
257 long cell axis, or any decrease in the frequency of the *L3-R3-L3-R3* configuration (Fig. S3G,
258 H). This result indicates that CrfC is not necessary for WT chromosome conformation and
259 segregation.

260

261 ***Ancestral DNA strands are preferentially retained at older cell poles***

262 Previously it has been hypothesized that a symmetrical segregation of lagging strands to the
263 cell center leads to sister chromosomes' translational symmetry and, in consequence, the
264 ancestral ('immortal') template DNA strand is not randomly segregated to daughter cells
265 over subsequent generations but preferentially retained in the daughter with the older cell
266 pole (discussed in (Toro and Shapiro, 2010)). Cell division generates two new cell poles at
267 the division septum, while the other ends of the daughter cells are the older poles that were
268 created in an earlier division. To address this theory directly, we have developed a novel
269 pulse-chase assay. It allowed us to visualize relative age of DNA strands between sister
270 chromosomes and relate their position to the age of the pole without the need for cell
271 synchronization or tracking (Fig. 4A).

272 The assay comprises pulse labelling of newly replicated DNA and identifying relative
273 pole age by chemoreceptor accumulation at cell poles. The newly synthesized DNA was
274 labelled by a 15 min EdU (5-Ethynyl-2'-deoxyuridine) pulse, after which cells were washed,
275 and allowed to grow for 3 h (generation time ~150 min). To avoid EdU-mediated growth
276 defects, thymidine was added to the medium to outcompete EdU. We observed no
277 detrimental effects on growth rate or cell size from the low concentration of EdU used in
278 the pulse (Fig. S4). After the growth period, which was longer than a single generation time,
279 most cells have completed an additional round of replication resulting in only one of the
280 two sister chromosomes remaining EdU-labelled (Fig. 4A). Cells were fixed and EdU was
281 visualized by click-chemistry using Alexa 488 azide. In cells with segregated chromosomes
282 just before division, the chromosome with new strand was fluorescently labeled, while the
283 one with the ancestral strand was not.

284 To identify the older cell pole, we exploited the fact that the serine chemoreceptor,
285 Tsr, accumulates approximately linearly with time at the cell poles (Ping et al., 2008). Hence
286 the older pole can be distinguished from the new pole by a higher quantity of fluorescently
287 labeled Tsr. Because imaging the Tsr-GFP fusion used before (Ping et al. 2008) was
288 incompatible with EdU staining, we devised an alternative labeling method. To this end, a
289 functional HaloTag fusion of the endogenous *tsr* gene was labeled with synthetic TMR dye
290 (Fig. 4B). Furthermore, nucleoids were stained by DAPI. This allowed us to determine if the
291 older strand chromosome was segregated towards the older or newer pole in each cell (Fig.
292 4C). We limited analysis only to cells with segregated chromosomes (i.e. two visibly separate
293 nucleoid regions) only one of which displayed EdU fluorescence. Note that this does not bias
294 the analysis towards a specific pole. In a control experiment we confirmed that the intensity
295 of Tsr-mYpet foci was higher at the older pole in $99.2 \pm 0.5\%$ (\pm SD) of cells.

296 We observed that $71.3 \pm 3.9\%$ (\pm SD) of WT cells contained EdU foci in the
297 chromosome closer to the new pole (Fig. 5A). Because EdU was incorporated into the new
298 template strand, this indicates that the ancestral strand is preferentially retained at the
299 older pole. The result deviates significantly from random retention, where the older pole
300 would have a 50% chance of inheriting either strand (binomial two-tailed test p-value $< 10^{-5}$).
301 We also compared the dispersion (SD) of our data to a binomial distribution with
302 different sample sizes to estimate reliability of our experiment (Fig. 5B). We found excellent

303 agreement showing that our measurements are robust for the given sample size, with no
304 additional noise sources, and increasing data sample size would give diminishing returns.

305 How is ancestral strand retention related to chromosome organization? To address
306 this question, we tested the contributions of MukBEF and MatP to ancestral strand
307 retention. Upon deletion of *mukB*, we observed a random segregation of the ancestral
308 strand ($48.5 \pm 3.8\%$ (\pm SD), Fig. 5A), demonstrating that functional MukBEF is required for
309 ancestral strand retention at older poles. Deletion of *matP* also abolished the preferential
310 segregation of the ancestral strand ($46.2 \pm 1.1\%$ (\pm SD), Fig. 5A). While MatP has not been
311 implicated in early chromosome segregation, when the segregation pattern(s) emerge, the
312 influence of MatP on MukBEF action is crucial as it prevents longitudinal chromosome
313 rotation (Fig. 2H), which would disrupt the association of the ancestral strand with the older
314 pole. MatP-*matS* also interacts with the divisome through ZapB and this interaction has
315 been proposed to partially anchor *ter* to the inner cell membrane (Espéli et al., 2012). This
316 interaction could plausibly contribute to the ancestral strand retention by anchoring the
317 chromosome and thereby preventing chromosome rotation. However, upon replacing the
318 native *matP* with a non-divisome interacting *matP* Δ C20 mutant or deleting *zapB*, we did not
319 observe any difference to WT with regard to ancestral strand retention ($71.0 \pm 3.1\%$ and
320 $71.8 \pm 1.0\%$, respectively (\pm SD); Fig. 5A). This confirms that the loss of ancestral strand
321 retention in Δ *matP* cells is related to the proposed longitudinal rotation of the chromosome
322 over generations.

323 Finally, since MukBEF and MatP have co-evolved with a group of proteins (including
324 Dam and SeqA) that are related to Dam DNA methyltransferase activity (Brézellec et al.,
325 2006), we tested the influence of these proteins on the retention of the ancestral strand.
326 Dam methylates adenines in the sequence GATC, which transiently distinguishes strands
327 after replication because of delayed methylation of the newly replicated strands. Prior to
328 Dam methylation, SeqA binds to hemimethylated GATC sites, negatively regulating
329 replication initiation and possibly contributing to chromosome segregation (reviewed in
330 (Waldminghaus and Skarstad, 2009)). Deletion of either *dam* or *seqA* did not influence
331 ancestral strand retention at older poles ($69.9 \pm 1.5\%$ and $67.6 \pm 3.3\%$, respectively (\pm SD);
332 Fig. 5A), indicating GATC methylation patterns do not affect the observed asymmetry and
333 consequently, overall *L-R* chromosome organization.

334

335 Discussion

336 Our results demonstrate how MukBEF axial cores direct nucleoid organization and non-
337 random segregation of sister chromosomes in *E. coli*. This work extends that describing
338 chromosome organization by MukBEF axial cores (Mäkelä and Sherratt, 2020), and uncovers
339 important principles of nucleoid organization and replication-segregation, as illustrated in
340 Fig. 6 and outlined below.

341

- 342 1. MukBEF axial cores, linearized by *matS*-MatP-mediated depletion of MukBEF from
343 *ter*, are required for *left-oriC-right* chromosome locus organization along the long
344 cell axis.

- 345 2. The linearity of axial cores prevents longitudinal nucleoid rotation, thereby retaining
346 the *left-oriC-right* chromosome orientation over generations.
- 347 3. Translational symmetry of the sister chromosomes results from the axial core
348 structures together with the segregation of lagging strands towards the cell center.
- 349 4. The ancestral DNA strand is preferentially segregated to the older pole cell over
350 generations, a process dependent on MukBEF and MatP.
- 351 5. Absence of MukBEF leads to anucleate cell formation predominantly at the newer
352 mother cell pole, largely because of failure to segregate newly replicated origins
353 from the vicinity of the older pole.

354

355 Our analyses provide molecular mechanisms underlying the *E. coli* chromosome
356 organization and segregation, and complement previous studies that have rigorously
357 quantified the nucleoid dynamics in mechanical terms (Cass et al., 2016; Fisher et al., 2013;
358 Fritsche et al., 2012). The model succinctly explains previous observations and provide a
359 conceptual foundation for understanding how nucleoid conformation and dynamics shape
360 the subcellular organization.

361

362 ***E. coli* chromosome organization**

363 Stiff nucleoid ‘bundles’ that are radially confined by cell dimensions and exhibit a contour
364 length of the scale of cell dimensions were characterized in live-imaging studies of WT *E. coli*
365 (Fisher et al., 2013). Bundles were also identified in cells with increased volume, which
366 allowed visualisation of non-replicating toroidal chromosomes (Wu et al., 2019). We
367 propose that MukBEF axial cores correspond to these bundles; the duality of the bundles
368 observed in WT cells likely relate to the bimodal nature of axial cores in non-replicating
369 MatP⁺ cells. We hypothesize that individual dimer of dimer MukBEF complexes within axial
370 cores form DNA loops using energy from ATP, most likely through progressive loop
371 enlargement (Davidson et al., 2019; Ganji et al., 2018; Goloborodko et al., 2016). Unloading
372 and re-loading of MukBEF complexes will impact nucleoid spatio-temporal dynamics and
373 could be dependent on intra-chromosomal stress (Fisher et al., 2013). The correlative
374 timescale of bundle dynamics is of the order of a minute, similar to the dwell time of
375 individual MukBEF complexes on the chromosome (Badrinarayanan et al., 2012; Fisher et
376 al., 2013; Mäkelä and Sherratt, 2020). MukBEF forms a linear axial core to the chromosome
377 by compacting it lengthwise outside of *ter*, where *matS* bound MatP displaces MukBEF
378 (Mäkelä and Sherratt, 2020). The absence of MatP leads to formation of circular symmetric
379 MukBEF axial cores. Theoretical studies concluded that lengthwise compaction of the
380 chromosome (by MukBEF) would maintain the linear organization and forms rigid
381 chromosome bundles (Marko and Siggia, 1997). We propose that the linearity of the axial
382 core reduces the dimensions of free chromosome movement, thereby preventing
383 longitudinal chromosome rotation and therefore explaining how chromosome loci can be
384 robustly positioned along the long cell axis in a colinear manner outside of *ter* (Fig. 6).

385 Previous attempts to explain chromosome locus positioning by a randomly oriented
386 polymer, or by transcription factor-mediated DNA loops fail to explain nucleoid organization
387 in $\Delta mukB$ or $\Delta matP$ cells (Fritsche et al., 2012; Jun and Mulder, 2006). The presence of

388 MukBEF axial cores explains how loss of a flexible *ter* region in the absence of MatP results
389 in chromosome arms being closer together, as shown here. A flexible *ter* region might be
390 required for efficient chromosome segregation during fast growth as $\Delta matP$ cells exhibit
391 more frequent anucleate cell production than MatP⁺ cells (Mercier et al., 2008). Broadly, we
392 propose that the rigid linear axial core removes the requirement for membrane anchoring
393 to orient and/or position the chromosome. Membrane tethering is generally found in
394 organisms in which MukBEF has been replaced by Smc-ScpAB complexes and which carry a
395 *parABS* segregation system; e.g. through PopZ in *C. crescentus* (Ebersbach et al., 2008),
396 HubP in *V. cholera* (Yamaichi et al., 2012), and RacA/DivIVA in sporulating *B. subtilis* (Ben-
397 Yehuda et al., 2003; Wu and Errington, 2003). Membrane anchoring typically uses ParB
398 bound to *oriC*-proximal *parS* sites as an intermediary. Intriguingly, some bacteria, such as *V.*
399 *cholera* or *P. aeruginosa*, not only encode MukBEF/MksBEF, but also specify a *parABS*
400 system (David et al., 2014; Vallet-Gely and Bocard, 2013). Whether organisms that encode
401 MukBEF orthologs, but not typical Smc-ScpAB complexes, and which lack ParABS systems,
402 generally have life cycles that encompass overlapping replication cycles, similar to *E. coli*,
403 remains to be determined.

404

405 ***Sister chromosome replication and segregation***

406 Chromosome organization specified by the MukBEF axial core directs the translational
407 symmetric (*L-R-L-R*) segregation of sister chromosomes during replication (Fig. 6), which
408 alone is insufficient for this organization (Fig. 6). Lengthwise compaction of newly replicated
409 DNA promotes individualization of sister chromosomes through excluded volume
410 interactions and by maximization of conformational entropy that leads to repulsion
411 between sister chromosomes (Goloborodko et al., 2016; Marko and Siggia, 1997). The
412 presence of the *L-R-L-R* segregation pattern of sister chromosomes in both WT and $\Delta matP$
413 cells indicates that the pre-replication organization of the chromosome, where chromosome
414 arms are directed into separate cell halves only in WT cells, is not required for establishing
415 this pattern. While symmetrically lengthwise compacted chromosomes in $\Delta matP$ cells (Fig.
416 2A)(Mäkelä and Sherratt, 2020) are prone to change *L-R* orientation in non-replicating cells,
417 bi-loped replication intermediates prevent rotation during late replication (Fig. 6).

418 The relationship between *L-R-L-R* chromosome organization and symmetrical
419 segregation of leading/lagging strands has been discussed previously in relation to the
420 observed leading strand spatial segregation pattern (Toro and Shapiro, 2010; White et al.,
421 2008). Consistent with this, we observed accumulation of β_2 -clamps, present primarily on
422 lagging strands, towards cell centers of replicating cells, when compared to both DNA
423 polymerase III and helicase localization. Differential positioning of the replisome and β_2
424 clamps resolves the conundrum that emerged from studies that favoured a model of a
425 single replication 'factory' containing two replisomes at cell center, based on clamp labelling
426 (Mangiameli et al., 2017). The results support the model of independent tracking of the two
427 often spatially separated replisomes in cells undergoing a single round of replication
428 (Japaridze et al., 2020; Reyes-Lamothe et al., 2008) although segregation forces along with
429 the reorganisation of parental and newly replicated DNA leads to frequent movement of
430 sister replisomes towards cell center. A dynamin-like protein YjdA (aka CrfC), a possible

431 candidate for directing β_2 -clamps to the cell centre, was not required for this action.
432 Because clamp localization at the cell center is dependent on the formation of linear axial
433 cores, we hypothesize that MukBEF could plausibly differentiate the strands, e.g. leaving
434 lagging strands less compacted (Fig. 6). However, the different contributions of MukBEF
435 activity to chromosome organization and segregation are difficult to delineate, as in the
436 absence of MukBEF, cohesion time is increased and *L-R* organization prior to replication is
437 impaired (Fig. 1).

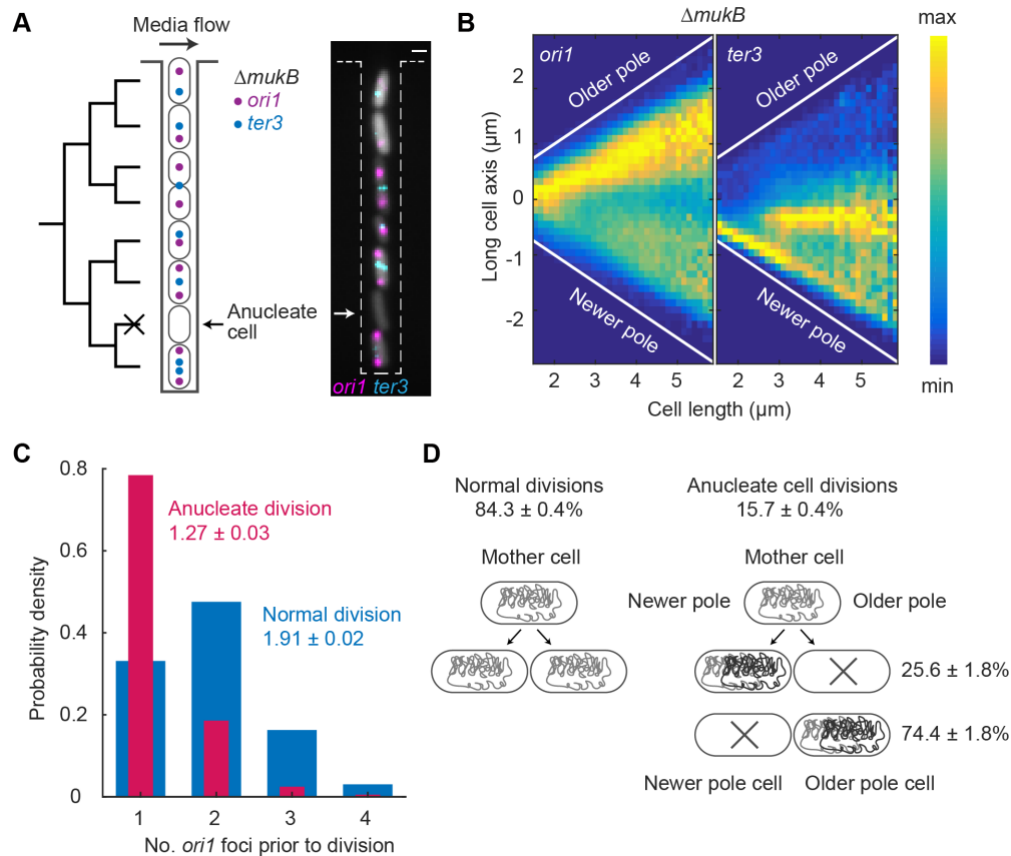

438 Our results also show that the lifetime of individual chromosome-associated clamps
439 (estimated to be ~ 3 min (Moolman et al., 2014)) must be longer than the daughter
440 chromosome cohesion time for chromosomal regions outside of *oriC* and *ter* (estimated ~ 14
441 min and ~ 9 min, respectively) (Nolivos et al., 2016; Wang et al., 2008). Cohesion time is
442 largely determined by the time required for TopoIV to remove replicative catenanes
443 (Nolivos et al., 2016; Wang et al., 2008; Zawadzki et al., 2015). In addition, slower *oriC*
444 segregation may additionally require accumulation of sufficient newly replicated DNA that
445 leads to abrupt separation of newly replicated sister chromosomes (Cass et al., 2016; Fisher
446 et al., 2013). Cohesion time is influenced by the absence of MukBEF, which promotes
447 TopoIV activity (Nolivos et al., 2016; Zawadzki et al., 2015), although tethering of *ter* to the
448 divisome through MatP-ZapB interactions may also influence cohesion time in this region
449 (Monterroso et al., 2019). Precise measurements of cohesion times for the rest of the
450 chromosome have been refractory to precise experimental determination.

451

452 ***Ancestral strand retention at the older pole***

453 We have directly shown preferential retention of the ancestral DNA strand at the older pole
454 in *E. coli*. This non-random segregation is determined by the translational symmetry of the
455 sister chromosomes (*L-R-L-R*), along with efficient maintenance of chromosome orientation
456 over generations. Intriguingly, in the absence of MukBEF, preferential strand retention is
457 lost and chromosomes adopt a longitudinal *oriC-ter* chromosome organization with co-
458 aligned chromosome arms along the long cell axis, similar to *C. crescentus* and sporulating *B.*
459 *subtilis*. However, as *E. coli* lacks the properties of cell differentiation, development and
460 regeneration of a multicellular organism, it is not clear why it has evolved a chromosome
461 organization that preferentially segregates the ancestral DNA strand to the cell with the
462 older pole. *E. coli* older pole containing cells exhibit a constant growth rate for hundreds of
463 generations (Wang et al., 2010). However, the death rate was found to increase with
464 replicative cell age, which was attributed to growth-independent accumulation of protein
465 damage (Wang et al., 2010). Increasing cellular maintenance processes through the general
466 stress response reduced the death rate while its absence increased it (Yang et al., 2019). The
467 older pole accumulates more membrane proteins (e.g. chemoreceptors, efflux pumps) than
468 the new pole and in fluctuating or poor environment, these can significantly contribute to
469 cell growth (Bergmiller et al., 2017; Ping et al., 2008). For example, the main multidrug
470 efflux pump of *E. coli*, AcrAB-TolC, exhibits a partitioning bias for the older cell poles
471 (Bergmiller et al., 2017). Consequently, older pole cells display increased efflux activity
472 relative to new cell pole daughters giving the older pole cell a growth advantage under
473 subinhibitory antibiotic concentrations and possibly protection against other toxic

474 compounds. Notably, AcrAB-TolC pump activity is also required for acquiring a resistance
475 gene from mobile genetic elements in the presence of antibiotics, as it reduces antibiotic
476 concentrations inside the cell (Nolivos et al., 2019). A common epigenetic mechanism to
477 regulate phase variation in bacteria involves formation of DNA methylation patterns by
478 proteins binding near a hemimethylated GATC site, and blocking methylation, e.g. *pap* or
479 *foo*, *clp*, and *pef* systems, which all encode pili (Casadesús and Low, 2013). Preferential
480 retention of the old strand at the old pole could potentially cause the old pole cell to more
481 likely to maintain the previous methylated state. We also hypothesize that ancestral strand
482 retention at older pole cells could be beneficial to structured growth of *E. coli* in colonies
483 where younger bacteria could progress to a new terrain while the older ones stay closer to
484 the colony center. Finally, older strand retention could simply be an evolutionary by-product
485 of maintaining the *left-oriC-right* chromosome organization over division cycles.
486 Nevertheless, since ancestral strand retention occurs in only ~70% of older-pole cells, this
487 gives opportunities for selection in fluctuating or harmful environments independent of
488 whether older or newer pole cells thrive better.

530 **Fig. 3. DnaN visualizes the lagging strands during replication.** (A) Schematic of
 531 accumulation of β_2 -clamps (DnaN) on the lagging strand and its template during replication
 532 (Moolman et al., 2014). The DNA polymerase ϵ -subunit (DnaQ) marks the location of the
 533 replisome. (B) Representative images of WT cells with fluorescently labeled DnaN and DnaQ.
 534 Scale bars: 1 μ m. (C) DnaQ and DnaN localization in WT cells as a function of cell length
 535 (37720 cells). White lines denote cell borders. Shaded areas denote intermediate cell
 536 lengths for localization data in (E). (D) Distance from a DnaQ focus to the closest DnaN
 537 focus. DnaQ and DnaN colocalize in $58.8 \pm 5\%$ (\pm SD) of focus pairs (38855 pairs) as defined
 538 by a threshold (red lines) below which two proteins colocalize (dictated by a diffraction limit
 539 of 300 nm). Inset shows the same data as a cumulative distribution. Same data as in (C). (E)
 540 DnaQ or DnaN localization with intermediate cell lengths (3.3-3.7 μ m) in WT (DnaN 7104,
 541 DnaQ 8006 spots), $\Delta matP$ (DnaN 11925, DnaQ 8025 spots) and $\Delta mukB$ (DnaN 5060, DnaQ
 542 4205 spots) cells (see C, F, G). Full width at half maximum (FWHM) (\pm SD) of the distribution
 543 in WT: DnaN 0.67 ± 0.06 μ m, DnaQ 1.67 ± 0.08 μ m; and in $\Delta matP$: DnaN 1.85 ± 0.04 μ m,
 544 DnaQ 1.14 ± 0.14 μ m. Grey areas denote cell poles. (F) DnaQ and DnaN localization in
 545 $\Delta matP$ cells (51956 cells) and in (G) $\Delta mukB$ cells (22902 cells) as a function of cell length.
 546 White lines denote cell borders. Data from 3 repeats in all analyses.

547

548 **Fig. 4. Visualization of ancestral DNA strand retention in *E. coli*.** (A) Ancestral DNA strand
 549 propagation shown following an EdU pulse and the subsequent growth. After the 2nd
 550 round of replication only one of the chromosomes inherits the EdU label. Note that only a part of
 551 the chromosome is labelled with EdU. The 15 min EdU pulse and growth period are also
 552 shown relative to a schematic of cell cycle stages (B, C and D periods, generation time ~150
 553 min). (B) Representative EdU^{Alexa488}, Tsr^{TMR} and DAPI images of a cell at stage (ii) (see (A))
 554 after the EdU pulse. Note that each chromosome has two EdU foci because pulse-labeled
 555 chromosome arms are separated. Scale bars: 1 μ m (C) Representative EdU^{Alexa488}, Tsr^{TMR} and
 556 DAPI images after the complete pulse-chase protocol (stage (iv-a), see (A)). The older pole is
 557 indicated with an arrow. Scale bars: 1 μ m. (D) Accuracy of the older pole classification using
 558 Tsr prior to cell division. Shaded areas denote SD. Data from 2505 cells and 3 repeats.

559

560

562

563

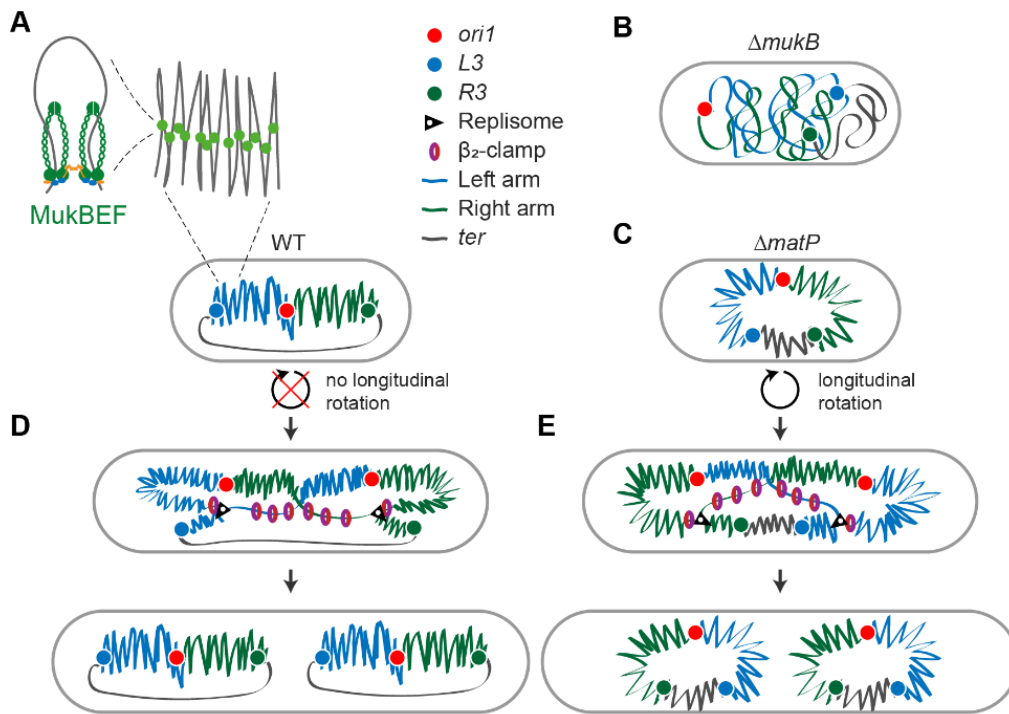

564

565 **Fig. 5. Preferential retention of the ancestral strand at older cell poles requires functional**
566 **MukBEF and MatP.** Percentage of ancestral strands retained at the older pole in WT (988
567 cells), $\Delta mukB$ (427 cells), $\Delta matP$ (1050 cells), non-divisible interacting $matP\Delta C20$ mutant
568 (1617 cells), $\Delta zapB$ (969 cells), Δdam (717 cells) and $\Delta seqA$ (473 cells). Dashed line shows
569 random retention. p-value from two-proportion two-tailed z-test was used to test if
570 binomial distributions significantly differ from WT; indicated by n.s. (> 0.01, non-significant)
571 and * (< 0.01, significant) (p-values <10⁻⁵, <10⁻⁵, 0.51, 0.83, 0.26, and 0.03, respectively).
572 Shaded areas denote SD. Data from 3 repeats.

573

574

575

576 **Fig. 6. Chromosome organization and segregation by MukBEF and MatP.** (A) MukBEF dimer
 577 of dimer complexes form DNA loops dependent on ATP hydrolysis. Ubiquitous loop
 578 formation outside of *ter* compacts the chromosome lengthwise forming a linear axial core to
 579 the chromosome. Axial cores form stiff linear nucleoid bundles that localize chromosomal
 580 loci linearly along the long cell axis and maintain chromosome orientation by preventing
 581 longitudinal cell axis rotation. (B) Absence of functional MukBEF increases the effective
 582 contour length of chromosomes, leading to mis-localization of chromosome loci and loss of
 583 *left-oriC-right* organization of the chromosome. (C) MukBEF forms a complete circular axial
 584 core to the chromosome in the absence of MatP. Consequently, chromosome arms cannot
 585 be efficiently directed to opposite cell halves, *left-oriC-right* organization in non-replicating
 586 cells is impaired and chromosomes rotate in the longitudinal cell axis. During replication and
 587 prior to division, WT (D) and $\Delta matP$ cells (E) exhibit translational symmetric (*L-R-L-R*)
 588 segregation of sister chromosomes. This is accompanied by the symmetric segregation of
 589 lagging strands and their templates during replication, as visualized by accumulation of β_2 -
 590 clamps. Relative FROS marker, replisome and β_2 -clamps localizations are derived from the
 591 data generated here.

592

593

594 **Materials and Methods**

595 **Bacterial strains and growth conditions**

596 Bacterial strains and primers are listed in Table S1 and S2, respectively. All strains were
597 derivatives of *E. coli* K12 AB1157 (Bachmann, 1996). *kan*, *cat*, *gen*, and *hyg* refer to insertions
598 conferring resistance to kanamycin (Km^r), chloramphenicol (Cm^r), gentamycin (Gm^r) and
599 hygromycin B (Hyg^r), respectively. The insertions are flanked by Flp site-specific
600 recombination sites (*frt*) that allow removing the resistance gene using Flp recombinase from
601 plasmid pCP20 (Datsenko and Wanner, 2000). *tsr-HaloTag-kan* and *tsr-mYpet-kan* were
602 inserted into the native *tsr* chromosomal locus using λ -red recombination (Datsenko and
603 Wanner, 2000). The generated gene loci were transferred by phage P1 transduction to
604 AB1157 yielding strains JM122 (*tsr-HaloTag-kan*) and JM133 (*tsr-mYpet-kan*). Deletion strains
605 of JM122 were constructed by P1 transduction, first removing the *kan* resistance gene using
606 Flp recombinase. *L3-R3* deletion strains were constructed from RRL66 using P1 transduction.
607 The microfluidics strain (JM09) was constructed from RRL189 by introducing Δ *flhd-kan* and
608 Δ *mukB-kan* by consecutive rounds of P1 transduction and Flp recombination. GFPmut2 cell
609 marker was inserted at an *attTn7* site by a plasmid transformation as described in (McKenzie
610 and Craig, 2006). The DnaQ and DnaN labeled strain (JM141) was constructed from RRL388
611 using P1 transduction from RRL36. Deletion strains of JM141 were constructed by P1
612 transduction, first removing the *kan* resistance gene using Flp recombinase. JM142 and
613 JM143 were constructed by P1 transduction from JW4070. All genetic modifications were
614 verified by PCR and/or sequencing and behavior in quantitative imaging. *mukB* deletions were
615 verified by temperature-sensitivity in rich media, as described in (Nolivos et al., 2016).

616 Cells were grown in M9 minimal medium supplemented with 0.2% (v/v) glycerol, 2 μ g
617 ml⁻¹ thiamine, and required amino acids (threonine, leucine, proline, histidine and arginine;
618 0.1 mg ml⁻¹) at 30 °C. For microscopy, cells were grown overnight, diluted 1000-fold and
619 grown to an A₆₀₀ of ~0.1. Cells were then pelleted, spotted onto an M9 glycerol 1% (w/v)
620 agarose pad on a slide and covered by a coverslip. In mother machine microfluidics
621 experiments, cells were first grown in M9 minimal medium with 0.2% (v/v) glycerol at 30 °C
622 (as above), and then placed inside the microfluidics device, when the media was changed to
623 M9 minimal medium supplemented with 0.2% (v/v) glucose, 2 μ g ml⁻¹ thiamine, MEM amino
624 acids (Gibco, #11130-036), 0.1 mg ml⁻¹ proline, and 0.85 mg ml⁻¹ Pluronic F127 (Sigma-Aldrich,
625 P2443), and the temperature was set to 37 °C.

626

627 **EdU pulse labeling**

628 Cells grown until A₆₀₀ of ~0.1 were labelled with 10 μ M EdU (5-Ethynyl-2'-deoxyuridine,
629 Thermofisher, C10337) for 15 min after which cells were washed, introduced to fresh media
630 containing 60 μ g/ml thymidine and allowed to grow for 3 h. Following this, cells were fixed
631 with 4% PFA (v/v) for 30 min and permeabilized with 0.5% Triton X-100 (v/v) for 30 min. EdU
632 click-chemistry reaction was conducted following the instructions (Thermofisher, #C10337)
633 using Alexa 488 azide in a final volume of 50 μ l for 30 min at room temperature, followed by
634 washing. Cells were then labelled with TMR HaloTag ligand as in (Banaz et al., 2019). Briefly,
635 cells were incubated with 2 μ M TMR ligand for 30 min and washed several times. Finally,

636 nucleoids were labelled with 1 $\mu\text{g}/\text{ml}$ DAPI for 15 min and washed, after which the cells were
637 ready for imaging.

638

639 **Epifluorescence microscopy**

640 Fluorescence images were acquired on an inverted fluorescence microscope (Ti-E, Nikon)
641 equipped with a perfect focus system, a 100 \times NA 1.4 oil immersion objective, a motorized
642 stage, an sCMOS camera (Orca Flash 4, Hamamatsu), and a temperature chamber (Okolabs).
643 Exposure times were 300 ms for TMR, Alexa 488 and mCherry, mYpet; 150 ms for mCerulean,
644 and 100 ms for DAPI using an LED excitation source (Lumencor SpectraX). Phase contrast
645 images were collected for cell segmentation. Microscopy data was collected automatically
646 from the sample area. Time-lapse images were collected every 10 min for 3 h with a shorter
647 exposure time of 150 ms, except fluorescence images from the microfluidics device were
648 collected every 5 min.

649

650 **Microfluidic devices**

651 The microfluidic single-cell imaging device (“mother machine”) was prepared as in (Uphoff,
652 2018). The device was designed using Autodesk AutoCAD software. The dimensions of the
653 cell channels were 1.2 μm x 1.2 μm x 20 μm and the media flow channels were 100 μm x 25
654 μm . The structures were fabricated on a silicon wafer (Kavli Nanolab, Delft University)
655 (Moolman et al., 2013) and a negative polydimethylsiloxane (PDMS) mold was created from
656 the silicon wafer using a 5:1 mixture of monomer and curing agent (Dow Corning Sylgard
657 184 Kit). After removing air bubbles using vacuum, the chip was cured at 65 $^{\circ}\text{C}$ for 1.5 hours.
658 The mould was treated with Trichloro(1H,1H,2H,2H perfluorooctyl)silane (Sigma) in vacuum
659 overnight. The PDMS device was generated from the negative mold using a 10:1 mixture of
660 monomer and curing agent and cured at 65 $^{\circ}\text{C}$ for 1.5 hours. Media flow holes were punched
661 through the device with 0.75 mm diameter. Cover slips were cleaned by sonication in
662 acetone for 20 min, washing with dH₂O, sonication in isopropanol for 20 min, and dried
663 with nitrogen. The PDMS device was washed with isopropanol and dried with nitrogen. The
664 device and a cover slip were bonded using air plasma (Plasma Etch PE-50) and placed in an
665 oven at 95 $^{\circ}\text{C}$ for 30 min. Cells were pipetted into the device and the device was centrifuged
666 at 4000 rpm for 10 min to place cells into the channels. The media supplemented by
667 Pluronic F127 was fed into the device through silicon tubing (Tygon ND 100-80 microbore,
668 VWR) using a motorized infusion pump (New Era Pump Systems). Initially, a high flow rate of
669 1.5 ml/hr was applied to flush the excess cells and then lowered to 0.5 ml/hr. After this, cells
670 were allowed to grow for \sim 2 h before starting the time-lapse imaging.

671

672 **Image analysis**

673 Cell based information, including cell outlines, lineages, pole ages, per pixel fluorescence
674 intensities, and fluorescent marker localization, was extracted using SuperSegger (Stylianidou
675 et al., 2016) in MATLAB (MathWorks). SuperSegger uses an image-curvature method to
676 identify foci to avoid the identification of false positive foci due to background intensity from
677 cytoplasmic fluorescence and uses a gaussian fit to find the subpixel resolution location of
678 foci. Focus quality is determined by a combination of intensity and fitting parameters and bad
679 quality foci were filtered out. A threshold value was confirmed by visual inspection and the

680 same threshold was used for all compared data sets. The channels were aligned prior to
681 analysis.

682

683 *Mother machine analysis*

684 From the lineage data, cells were classified as 'normal' growing cells, anucleate cells, mothers
685 of anucleate cells and sisters of anucleate cells. Cells that disappeared early or didn't have a
686 tracked lineage were excluded from the analysis. Anucleate cells were considered as cells that
687 didn't divide, didn't elongate and lacked an *ori1* marker present, while its sister cell elongated
688 and divided normally, and had *ori1* marker(s). If neither of the sister cells divided normally,
689 cells were excluded from analysis. The older pole of the anucleate cell was traced back ≥ 2
690 generations to determine whether the anucleate cell formed on the older or newer pole of
691 the mother. The cell size at birth (Fig. S1B) was determined at the first frame of each cell and
692 the number of *ori1* foci prior to division (Fig. 1C) at the last frame of a cell.

693

694 *Fluorescent marker localization*

695 For *ori1*, *ter3*, *L3* and *R3* markers, intensity profiles with different cell lengths were
696 normalized, as the expectation is that a cell will have at least a single focus at all times. As
697 cell orientation is random relative to the pole age, cells were oriented to place *L3* more
698 towards the negative pole than *R3* and, in the *ori1* data, *ter3* was oriented more towards
699 the negative pole. To determine flipping frequency of *L3-R3-L3-R3* markers from time-lapse
700 imaging, first mother cells that contained at *L3-R3-L3-R3* or *R3-L3-R3-L3* were identified.
701 Next, their daughter cells with *L3-R3-L3-R3* or *R3-L3-R3-L3* were identified. The angle (Fig.
702 S2) between vectors pointing from the more polar *L3* to the more polar *R3* was calculated
703 between mother and daughter cells. If the angle exceeded 90° , the chromosome orientation
704 was considered flipped. To measure width of a unimodal distribution and to avoid
705 inaccuracy from binning the data, the data was fitted by a kernel distribution in MATLAB
706 and full width at half maximum (FWHM) was calculated from the fitted distribution.

707

708 *EdU pulse labelling*

709 A functional HaloTag fusion of the endogenous *tsr* gene was used in the EdU labeling, as click-
710 chemistry reaction conditions are detrimental to conventional fluorescent proteins. To
711 measure EdU association with the older pole, the following criteria were used to select cells
712 from an asynchronous cell population (see Fig. S4). First, Otsu's thresholding (Otsu, 1979) was
713 used to segment nucleoid area(s) from the cellular background and only cells that have two
714 separate, large-enough nucleoid areas were analysed. Second, a cell must exhibit a clear
715 difference in polar Tsr intensity. The center line of a cell was extracted to find coordinates of
716 cell poles by fitting a cell mask to a second-order curve. The intersection of the cell mask
717 border and the curve was used to define cell poles. Median Tsr intensity of the cell area was
718 subtracted from all Tsr pixel intensities and a sum of 9 brightest pixels from each pole were
719 used to quantify the pole intensity. To minimize effects of noise and discrete pixel size in
720 segmentation, only cells with >1.5 -fold difference in polar Tsr intensity were analysed. The
721 pole that had a higher intensity of Tsr was designated as the older pole. Third, only one of the
722 nucleoids must be labelled by EdU. EdU with short incorporation times appear as distinct foci
723 (see Fig. 4 and Fig. S4). The foci below a fixed threshold for the score were discarded. The foci

724 were mapped to the nucleoids by projecting coordinates of both on the center line of the cell.
725 With these criteria, the processed microscopy data from SuperSegger was automatically
726 analysed to extract the result of EdU association with older cell pole. To avoid segmentation
727 errors of the cell area, correct cell segmentation was visually inspected and inaccurately
728 segmented cells were removed.

729

730 *Tsr time-lapse*

731 The accuracy of Tsr-based identification of the old cell pole in our growth conditions was
732 estimated by tracking cells with a functional mYpet fusion to the endogenous *tsr* gene over
733 generations under a microscope. Only cells that both were born and divided during the
734 time-lapse were analysed. Tsr intensity at each pole was calculated with same criteria as in
735 the EdU experiment. The accuracy of Tsr as the older pole marker was determined for each
736 frame separately by comparing results between Tsr intensity analysis and lineage tracking.
737 The accuracy (Fig. 4D) was shown for the last frame prior to division to mimic the EdU
738 experiment where only cells with segregated chromosomes were analysed.

739

740 **Acknowledgements**

741 We thank other members of the Sherratt and Uphoff group, and Katarzyna Ginda-Mäkelä
742 for insightful discussions. The research was supported by a Wellcome Investigator Award to
743 DJS (200782/Z/16/Z). SU was in receipt of a Henry Dale-Wellcome Fellowship.

744

745 **Author contributions**

746 JM and DJS conceived the project and directed it. JM undertook and analyzed experiments.
747 SU developed the microfluidics, advised on its use and was generally involved in project
748 discussions. JM, SU and DJS wrote the paper.

749

750 **Conflict of interest**

751 The authors declare no competing interests.

752

753 **Data and code availability**

754 All data required to understand and assess the conclusions of the research are available in
755 the main text and supplementary materials. All materials and codes are available upon
756 reasonable request.

932 **Supplementary Figures**

933

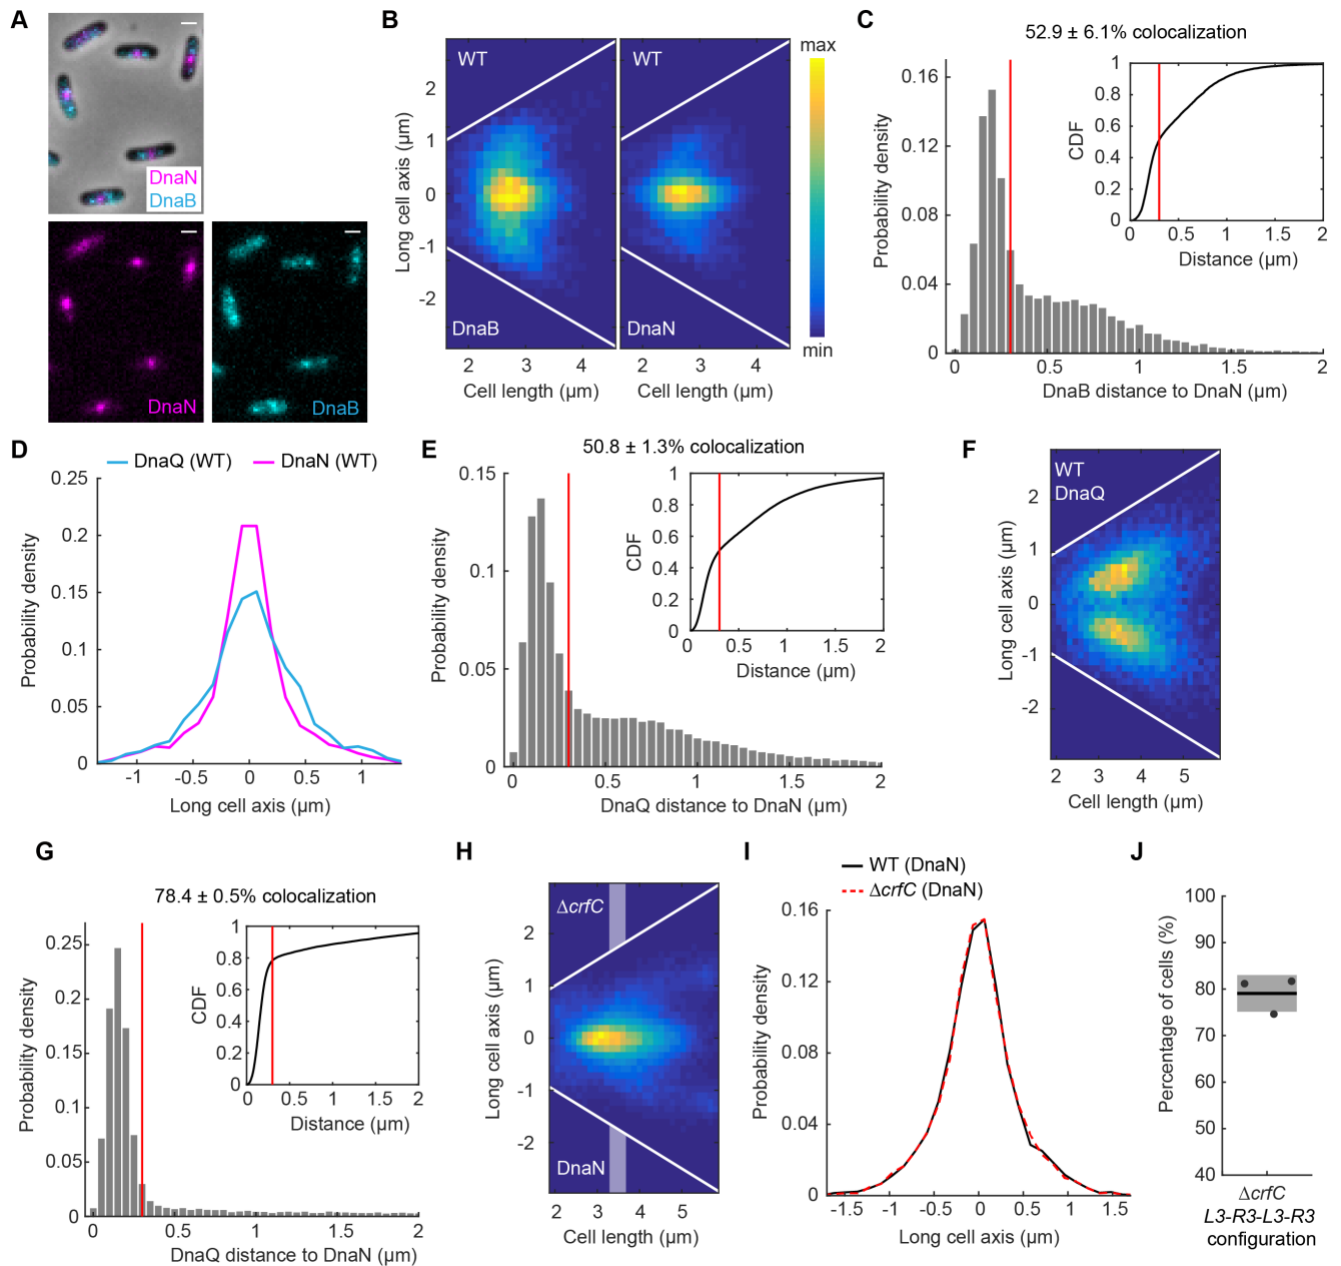

934

935 **Fig. S1. (A)** Generation time in normally dividing cells (12103 cells) and in sisters of
936 anucleate cells (1605 cells). Two-sample t-test of mean generation time p-value 0.2176.
937 Data from 3 repeats. **(B)** Difference in cell length at birth between anucleate and growing
938 sister cells at anucleate cell division. Black dashed line indicates symmetric division and solid
939 line shows a linear fit to the data. Black circles show binned mean. 2266 cell pairs from 3
940 repeats.

941

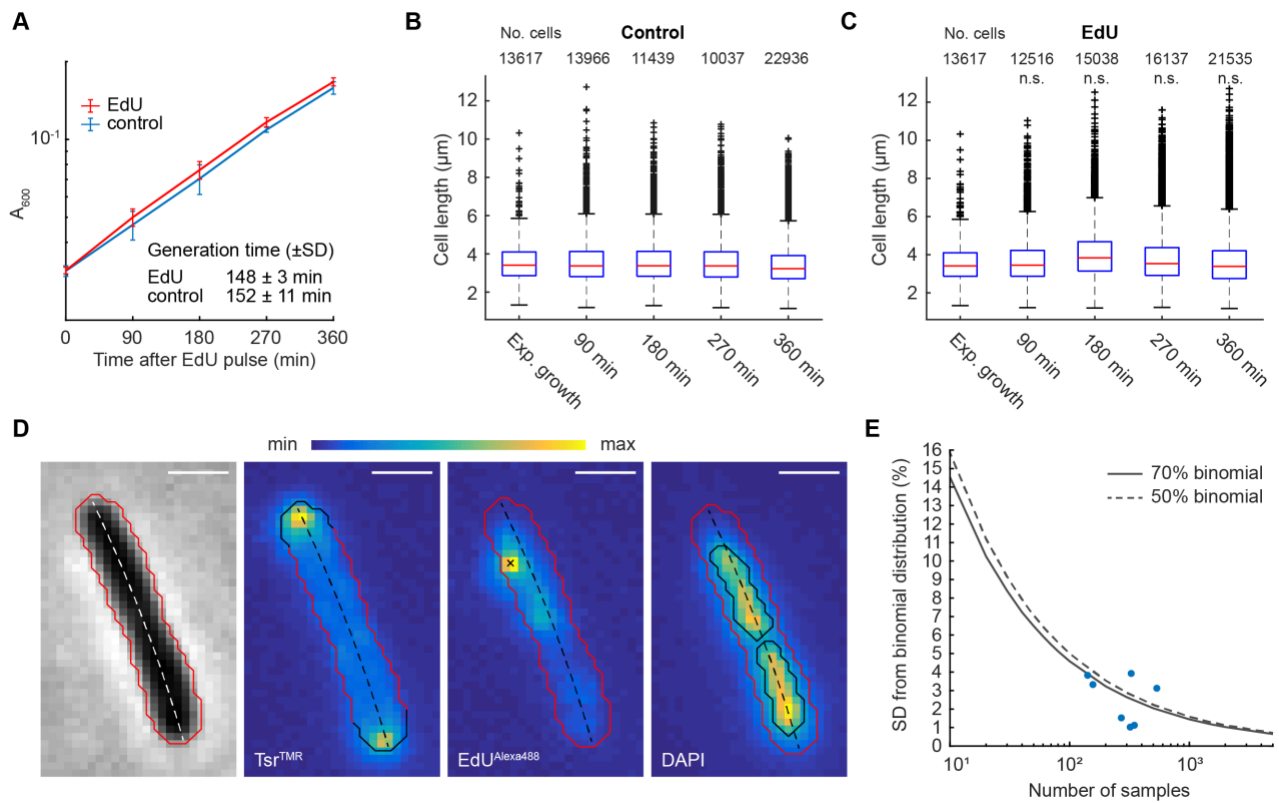

942 **Fig. S2.** (A) *ter3* localization along long cell axis in WT (26926 cells), $\Delta mukB$ (48770 cells) and
 943 $\Delta matP$ (45532 cells). From same data as in Fig. 2D; *ter3* is oriented more towards the
 944 negative pole than *ori1*. Data from 3 repeats. (B) Representative time-lapse images of WT
 945 (top) and $\Delta matP$ (bottom) cells with *L3* and *R3* markers. (top) *L3-R3-L3-R3* orientation is
 946 maintained over a generation while (bottom) *L3-R3-L3-R3* orientation is flipped. From *L3-R3-*
 947 *L3-R3* cells, angle between vectors pointing from the more polar *L3* to the more polar *R3* is
 948 calculated between mother cell (red arrow) and daughter cells (orange arrow) and, if the
 949 angle exceeds 90° , the chromosome orientation is considered flipped (blue arrow). Scale
 950 bars: $1 \mu\text{m}$. Angle between mother and daughter cell *L3-R3-L3-R3* vectors in (C) WT (859
 951 pairs) and (D) $\Delta matP$ (1054 pairs) cells. Data from 3 repeats. (E) Angle between *L3-R3*
 952 vector in first frame of daughter cell and *L3-R3-L3-R3* vector in mother cell in flipped cells
 953 of (D). Same data is in (D).

954

955 **Fig. S3. (A)** Representative images of WT cells with labelled DnaN and DnaB. Scale bars: 1
 956 μm . **(B)** DnaB and DnaN localization in WT cells as a function of cell length (16134 cells).
 957 White lines denote cell borders. **(C)** Distance from a DnaB locus to the closest DnaN locus.
 958 DnaB and DnaN colocalize in $52.9 \pm 6.1\%$ ($\pm\text{SD}$) of pairs (11714 pairs) as defined by a
 959 threshold (red lines) below which two proteins colocalize (dictated by a diffraction limit of
 960 300 nm). Inset shows the same data as a cumulative distribution. Same data as in (B). **(D)**
 961 DnaQ (4567 spots) or DnaN (5393 spots) localization with early replication cells in WT (cell
 962 lengths $2.5\text{-}2.9\ \mu\text{m}$) (same data as in Fig. 3C). **(E)** Distance from a DnaQ locus to the closest
 963 DnaN locus in ΔmatP cells. DnaQ and DnaN colocalize in $50.8 \pm 1.3\%$ ($\pm\text{SD}$) of pairs (46330
 964 pairs). Inset shows the same data as a cumulative distribution. Same data as in (Fig. 3F). **(F)**
 965 DnaQ localization as a function of cell length in WT cells in which DnaQ foci are spatially
 966 separate from DnaN (16158 cells). Same data as in Fig. 2C and D. **(G)** Distance from a DnaQ
 967 locus to the closest DnaN locus in ΔmukB cells. DnaQ and DnaN colocalize in $78.4 \pm 0.5\%$

968 (\pm SD) of pairs (32603 pairs). Inset shows the same data as a cumulative distribution. Same
969 data as in (Fig. 3G). **(H)** DnaN localization in $\Delta crfC$ cells as a function of cell length (49955
970 cells). Shaded areas denote intermediate cell lengths for localization data in (I). White lines
971 denote cell borders. **(I)** DnaN localization with intermediate cell lengths (3.3-3.7 μ m) in WT
972 (8006 spots) and $\Delta crfC$ (10691). Data from (H) and Fig. 3E. **(J)** Percentage of $\Delta crfC$ cells (8393
973 cells) with *L3-R3-L3-R3* (or *R3-L3-R3-L3*) configuration (versus *L3-R3-R3-L3* or *R3-L3-L3-R3*) in
974 double *L3* and *R3* focus cells. All data from 3 repeats.
975

976

977 **Fig. S4.** (A) Cell growth following a 15 min EdU pulse compared to no EdU. Cell length at
 978 different time intervals (B) without or (C) with EdU pulse. n.s. indicates two-sample t-test of
 979 mean cell length compared to control p-value > 0.01. Data from 3 repeats. (D) Image
 980 analysis of EdU experiment. A representative cell after EdU protocol showing Tsr^{TMR},
 981 EdU^{Alexa488} and DAPI labelling. Red line is the cell border and dashed line shows the center
 982 line of the cell. Black line in Tsr^{TMR} channel shows the pole areas from where the Tsr
 983 intensity is calculated. Black cross in EdU^{Alexa488} channel indicates a detected EdU focus.
 984 Black lines in DAPI channel indicate segmented nucleoid areas. For more information see
 985 Methods. Scale bars: 1 μm (E) Accuracy of the retention measurement as function of sample
 986 size. Different sample sizes were drawn from a binomial distribution with 50% (dashed line)
 987 or 70% (solid line) success rate and SD was calculated between them (10^5 repeats for each
 988 value). The data from Fig. 5 are shown with dots.
