Microrisk Lab was designed as an interactive modeling freeware to realize parameter estimation and model simulation in predictive microbiology. This tool was developed based on the R programming language and ‘Shinyapps.io’ server, and designed as a fully responsive interface to the internet-connected devices. A total of 36 peer-reviewed models were integrated for parameter estimation (including primary models of bacterial growth/inactivation under static and non-isothermal conditions, secondary models of specific growth rate, and competition models of two-flora growth) and model simulation (including integrated models of deterministic or stochastic bacterial growth/inactivation under static and non-isothermal conditions) in Microrisk Lab. Each modeling section was designed to provide numerical and graphical results with comprehensive statistical indicators depending on the appropriate dataset and/or parameter setting. In this research, six case studies were reproduced in Microrisk Lab and compared in parallel to DMFit, GInaFiT, IPMP 2013/GraphPad Prism, Bioinactivation FE, and @Risk, respectively. The estimated and simulated results demonstrated that the performance of Microrisk Lab was statistically equivalent to that of other existing modeling system in most cases. Microrisk Lab allowed for uniform user experience to implement microbial predictive modeling by its friendly interfaces, high-integration, and interconnectivity. It might become a useful tool for the microbial parameter determination and behavior simulation. Non-commercial users could freely access this application at https://microrisklab.shinyapps.io/english/.
Keywords: nonlinear regression; interactive interface; non-isothermal condition; stochastic model.
List of symbols

\(Y(t), Y_0, Y_{max}\) the natural logarithm of real-time, initial, and maximum bacterial counts (In CFU/g).

\(y(t), y_0, y_{max}\) the 10-base logarithm of real-time, initial, and maximum bacterial counts (log10 CFU/g).

\(y_{res}\) the 10-base logarithm of the residual bacterial counts (log10 CFU/g).

\(\mu_{max}, \mu_{opt}\) the maximum and optimal specific growth rate.

\(k_{max}\) the maximum specific inactivation rate.

\(D\) the time of decimal reduction in inactivation.

\(D_{ref}\) the referenced decimal reduction time at \(T_{ref}\).

\(t_{lag}\) the time of lag in growth.

\(S_t\) the time of shoulder (or before inactivation) in inactivation.

\(t\) the time point.

\(t_{max}\) the time when entering the stationary phase in growth.

\(S_t\) the time when entering the stationary phase in inactivation.

\(T, pH, aw\) The temperature (°C), pH, and water activity at \(t\).

\(T_{min}, T_{opt}, T_{max}\) the minimum, optimal, and maximum growth temperature (°C).

\(T_{ref}\) the referenced inactivation temperature (°C).

\(pH_{min}, pH_{opt}, pH_{max}\) the minimum, optimal, and maximum growth pH.

\(aw_{min}, aw_{opt}, aw_{max}\) the minimum, optimal, and maximum growth water activity.

\(q_0\) the initial physiological state of the inoculum in the Baranyi model.

\(\delta, p\) the coefficients in the Weibull model.

\(\delta_{ref}\) the referenced \(\delta\) value at \(T_{ref}\).

\(a, b\) the coefficients in the square-root model.

\(A, m\) the coefficients in the dynamic Huang model.

\(z\) the coefficients of the bacterial thermal resistance (°C).
1. Introduction

Foodborne pathogens have caused widespread food safety issues and potential severe risks nowadays (WHO, 2015). It is critical to understand and control the behavior (growth, survival or inactivation) or contaminated level of the focused microorganisms under different environmental conditions to ensure that foods are safe for consumption (Geeraerd, Valdramidis, & Van Impe, 2005; Augustin, 2011; González et al., 2018). For this reason, predictive microbiology has been developed as an efficient solution to estimate the bacterial concentration level in the perspective of mathematical modeling (Ross & McMeekin, 1994; Peleg & Corradini, 2011; Baranyi & Buss da Silva, 2017).

Microbiological predictive models are ordinarily classified as the primary model, secondary model, and tertiary model (Whiting & Buchanan, 1993). The primary model represents the relation between microbial concentrations and time under a specific condition by introducing the kinetic parameters, such as lag time, maximum specific growth/inactivation rate, and decimal reduction time. While the secondary model describes the influence of environmental conditions on the kinetic parameters, such as growth and inactivation rates. The tertiary model refers to the computer program that integrates validated pertinent information to characterize the situation or explain the trend of the microbial contamination level under a specific condition (Whiting & Buchanan, 1993). Commonly, regression (or fitting) should be firstly applied to obtain the kinetic parameter and the effect of environmental conditions in accordance with the experimental observation (e.g. maximum population density, growth boundaries, and decimal reduction time). After identifying and validating the characteristic of the target microorganism(s), microbial behaviors (e.g. growth,
inactivation, and survival) can be simulated under different conditions.

For realizing the parameter estimation, mathematical computing environments, such as R (www.R-project.org), MATLAB (The MathWorks, Inc., USA), and Python (www.python.org), are widely used in predictive microbiology. For example, ‘nlsMicrobio’ (Baty & Delignette-Muller, 2015) and ‘Bioinactivation’ (Garre, Fernández, Lindqvist, & Egea, 2017) are two packages dedicated to obtaining the microbial kinetic parameters in the R environment. However, the requirement of specific coding skills may increase the learning burden during the modeling process. Thus, many useful interactive modeling systems were developed in the last decades (Huang, 2014/2017b; Tenenhaus-Aziza & Ellouze, 2015; Dolan, Habtegebriel, Valdramidis & Mishra, 2015; Koutsoumanis, Lianou, & Gougouli, 2016). Among the developed freeware, IPMP 2013/ Global Fit (Huang, 2014/2017b), desktop DMFit, GlnaFiT (Geeraerd, Valdramidis, & Van Impe, 2005/2006) and PMM-Lab (Plaza-Rodriguez et al., 2015) provided numerical and graphical interfaces for users to obtain different microbial model parameters without coding. These tools required to be installed and run under the desktop system of Windows or Mac OS. The online free tools, namely, the online DMFit of ComBase (www.combase.cc) and Bioinactivation FE (Garre et al, 2018) could be easily accessed via different internet-connected devices, which provided the ability of cross-platform to users.

On the other hand, some modeling systems put more emphasis on simulating or predicting the bacterial concentration level under different environmental conditions, which have some reference significance to microbial risk assessment and management. As the well-known free tools, Pathogen Modeling Program (USDA, 2016), and ComBase Predictor
supported by their extensive microorganism-food database has been applied to predict the
microbial behavior in culture medium or different food matrices. The applicability of a
tertiary model is very dependent on the quantity and quality of the available knowledge
integrated into the modeling system, such as experimental challenge test data, model types
and associated model parameters. Recently, an updated application MicroHibro (González et
al., 2018) allowed users to freely defined the model type and relevant parameter. This
functionality may practically help users update the knowledge for the simulation when new
evidence is observed. Meanwhile, it is also critical to take account of the uncertainty and
variability of model parameters, especially in the application of the individual cell behavior
modeling and risk assessment (Natau, 2001; Busschaert, Geeraerd, Uyttendaele, & Van Impe,
2011; Cornu et al., 2011; Koutsoumanis & Lianou, 2013; Alonso, Molina, & Theodoropoulos,
2014; Augustin et al., 2014). Thus, it is essential to introduce the stochastic approach in the
prediction and simulation study.

Besides, much more complex situations should be considered to describe the microbial
behavior in the real food chain, namely, the coexistence of multi-microorganisms, and the
concentration change under dynamic conditions (Iannetti et al., 2017; Li, Huang, & Yuan,
2017, Göransson, Nilsson, & Jevinger, 2018; Ndraha et al, 2018; Hwang & Huang, 2018). In
non-isothermal modeling, free tools of ComBase Predictor, IPMP Dynamic Prediction
(USDA, 2017), GroPIN (https://www.aua.gr/psomas/gropin/), FSSP (http://fssp.food.dtu.dk),
and UGPM (Psomas, Nychas, Haroutounian, & Skandamis, 2011) were designed for
microbial simulation. The web-based tool, Bioinactivion FE, was recently developed for
fitting and simulating microbial inactivation under isothermal or non-isothermal conditions
This tool exactly facilitated scientists handle different inactivation analyses without the need to code the mathematical models in a programming environment. However, there was still a lack of tools for kinetic analysis on the microbial dynamic growth (Tenenhaus-Aziza & Ellouze, 2015; Koutsoumanis, Lianou, & Gougouli, 2016). Hence, it may be helpful to design an integrated system containing the functionality for parameter estimation and model simulation under non-isothermal conditions.

This research introduced the main features of Microrisk Lab, an online modeling system integrating comprehensive microbial predictive models. Six case studies were implemented to describe a part of functionality and performance of this new application for parameter estimation and model simulation in predictive microbiology. The first version of Microrisk Lab was deployed on the ‘Shinyapps.io’ server, and available at https://microrisklab.shinyapps.io/english/ (in English) and https://microrisklab.shinyapps.io/chinese/ (in Chinese).

2. Materials and methods

2.1. Design logic and programming basics of Microrisk Lab

Microrisk Lab was designed as a R-based web application with a user-friendly interface for performing parameter estimation or model simulation studies in predictive microbiology. The coding language R, an open-source mathematical environment, could run on a wide variety of computer systems, including Windows, UNIX, and Mac OS. Several basic R packages, such as ‘ggplot2’ (Wickham et al., 2019), ‘mc2d’ (Pouillot & Delignette-Muller, 2010), and ‘Metrics’ (Hamner, B., Frasco, M., & LeDell, E., 2018), were referenced in this
tool for mathematical and statistical analysis (see supplementary data). Meanwhile, the
platform of ‘Shiny’ (http://shiny.rstudio.com/), shinydashboard’ (Chang & Borges Ribeiro,
2019), and ‘plotly’ (https://plot.ly) were introduced to improve the operability and
practicability of Microrisk Lab. The simple graphical user interface (GUI) and interactive
output can automatically adapt to different screen sizes (Fig.1). Each section has a uniform
interactive logic from left to right (horizontal view) or up to down (vertical view)
corresponding to problem selection, condition setting, and result analysis. The observed
measurement for parameter estimation or model simulation can be directly typed in the data
dialog or pasted from other table files. After submitting all condition settings, users are free to
make a real-time control on the interactive plot for better visualization then save as the local
image file (Portable Network Frame file).

The structural framework of Microrisk lab is shown in Fig.2, which is basically divided
into the ‘Estimation’ and ‘Simulation’ module. The ‘Estimation’ module was focused on
determining the microbial parameters by the experimental observations under different
conditions. The ‘Simulation’ module aimed to simulate the bacterial concentration changes
under different temperatures by using different built-in predictive models.

In the ‘Estimation’ module, the least-squares method was implemented to search the
optimized model parameter, which was conducted by the nls function in the ‘stats’ package.
Both ‘NL2SOL’ algorithm (for the dynamic regression) and Gauss-Newton algorithm (for
other regressions) were used in Microrisk Lab. If the fitting is successful, results of the fitted
curve, parameter estimation, and model evaluation should be reported in the ‘Results Panel’.
Meanwhile, the raw and generated datasets (observed, fitted, and simulated data) are
downloadable as ‘csv.’ files. Otherwise, a pop-up window would remind the user that regression is failure.

The ‘Simulation’ module in Microrisk Lab does not restrict the type of microorganisms or food. The microbial growth and inactivation should be simulated by defining the model type, microbial kinetic parameter, and temperature condition (or time-temperature profile).

Besides, the stochastic simulation can be performed at static conditions. In this case, probability distribution of the parameter and condition are defined according to the mean value and standard deviation. Here, the duration of growth or inactivation steps is assumed as a Uniform distribution, and other default parameter settings are assumed as the Normal distribution. According to former researches (Baranyi, George, & Kutzaki, 2009; Koutsoumanis & Lianou, 2013; Huang 2016), the LogNormal/ Gamma distribution and LogNormal/ Logistic distribution were additionally considered in the parameter setting of lag time (shoulder) and specific growth rate, respectively. Then the stochastic model can be conducted by using the simple sampling method with optional 100/1,000/10,000 iteration times for Monte-Carlo simulation.

2.2. Mathematical models and statistical indicators in Microrisk Lab

In version 1.0, Microrisk Lab contained 36 peer-reviewed models to implement parameter estimation or model simulation in predictive microbiology. Specifically, 20 explicit equations were chosen by considering different shapes of the growth/ inactivation curve for microbial dynamics under static conditions (Tab.1); 10 secondary models were selected in view of the impact of temperature/ pH/ water activity on the specific growth rate (Tab.2); 2
piecewise functions were applied to describe two flora competition growth (Tab.3); and 4 groups of ordinary differential equations were presented by combining the primary model and secondary model for microbial growth/ inactivation under non-isothermal conditions (Tab.3). The definition of each parameter was illustrated in the list of symbols.

Note that the 2\textsuperscript{nd} order Runge-Kutta method or Heun's method (Eq.1, Press, Teukolsky, Vetterling, & Flannery, 2007) was applied as the rapid numerical method to solve the ordinary differential equations in the dynamic kinetic analysis. During the computational procedures, the non-isothermal growth/ inactivation was firstly solved by the 2\textsuperscript{nd} order Runge-Kutta method to calculate the predicted value, corresponding to each of the sampling time for bacterial counting. Then, the predicted values were applied to match the observed values by a nonlinear least-squares function to determine the optimized parameter estimation. Similar algorithm of the 4\textsuperscript{th} order Runge-Kutta method was also realized by R and other programming languages in previous studies (Press, Teukolsky, Vetterling, & Flannery, 2007; Cattani et al., 2016; Li et al., 2017; Huang, 2017a; Hwang & Huang, 2018). The time step (0.1, 0.01, or 0.001) could be selected by the user in the regression of non-isothermal growth and inactivation.

\[
\begin{align*}
Y_{n+1} &= Y_n + \frac{h}{4}(k_1 + 3k_2) \\
k_1 &= f(t_n, Y_n) \\
k_2 &= f(t_n + \frac{2h}{3}, Y_n + \frac{2h}{3}k_1)
\end{align*}
\]

Eq. 1

In the module of parameter estimation, a recognition algorithm (if/ else statement) was preset to transfer the input (counting) data into the appropriate unite before fitting to a specific model, which allowed users to freely choose the preferred input unit of the counting data ("Log10 CFU/g or CFU/ml", "Ln CFU/g or CFU/ml", or "CFU/g or CFU/ml") in Microrisk.
Lab. Meanwhile, results of the model parameter, the estimated value, standard error, and lower and upper 95% confidence intervals (Eq.2), were provided by the R package of “stats” and “nlstool”. After obtaining the estimated and evaluated values, users could select the decimal digits (0, 1, 2, 3, or 4) of the generated results, which should be determined according to the unit precision of the parameter.

$$\begin{align*}
L95\%CI &= \hat{\beta} - t_{95\%} df \cdot MSE \cdot \hat{B} \\
U95\%CI &= \hat{\beta} + t_{95\%} df \cdot MSE \cdot \hat{B} \\
t_{95\%} df &= t_{95\%, \infty} \approx 1.96
\end{align*}$$

Eq. 2

where $\hat{\beta}$ is the estimated parameter; $\text{MSE}$ is the mean sum of square error; $\hat{B}$ is the inverse of the matrix of second derivatives of the log-likelihood function as a function of $\beta$ evaluated at the parameter estimates $\beta = \hat{\beta}$; $df$ is degrees of freedom, which is assumed infinite; $t_{95\%} df$ is the value from the t distribution for 95% confidence for the specified number of df.

Furthermore, several statistical indicators were reported to evaluate and compare the goodness-of-fit between observed and predicted values, such as the residual sum of squares (RSS, Eq.3, Draper & Smith, 1998), mean sum of squared error (MSE, Eq.4, Geeraerd et al., 2005), root mean sum of squared error (RMSE, Eq.5, Ratkowsky, 2003), regular Akaike information criterion (AIC, Eq.6, Akaike, 1974), corrected AIC (AICc, Eq.7, Burnham & Anderson, 2003) and Bayesian information criterions (BIC, Eq.8, Schwarz, 1978). As pointed out by Ratkowsky (2003), the coefficient of determination ($R^2$, Eq.9, Rawlings, Pantula, & Dickey, 2001) and the adjusted coefficient of determination (Adjusted $R^2$, Eq.10, Rawlings, Pantula, & Dickey, 2001) might be inappropriate to evaluate the non-linear models. Thus, Microrisk Lab provided these two indicators only for linear models.

$$\text{RSS} = \sum_{i=1}^{n} (y_i - \hat{y}_i)^2$$

Eq.3
MSE = \frac{\text{RSS}}{n} \quad \text{Eq.4}

\text{RMSE} = \sqrt{\text{MSE}} \quad \text{Eq.5}

\text{AIC} = -2 \log(\hat{\theta}) + 2k \quad \text{Eq.6}

\text{AIC}_c = \text{AIC} + \frac{2k(k+1)}{n-k-1} \quad \text{Eq.7}

\text{BIC} = -2 \log(\hat{\theta}) + k \ln(n) \quad \text{Eq.8}

R^2 = \frac{\sum_{i=1}^{n}(\hat{y}_i - \frac{1}{n}\sum_{i=1}^{n}y_i)^2}{\sum_{i=1}^{n}(y_i - \frac{1}{n}\sum_{i=1}^{n}y_i)^2} \quad \text{Eq.9}

\text{Adjusted } R^2 = 1 - (1 - R^2)\frac{n-1}{n-k-1} \quad \text{Eq.10}

where \( y_i \) is the i th value of the observation; \( \hat{y}_i \) is the i th value of the prediction; \( k \) is the number of parameters; and \( n \) is the number of sample data; \( \log(\hat{\theta}) \) is the numerical value of the log-likelihood for the fitted model (the probability of the data given a model in the model), which is donated by the \text{logLik()} function built in the R package ‘stats’.

Besides, for stochastic simulation, the Pearson correlation coefficient (Eq.11) is also calculated to measure the linear correlation between different model variables (\( P \)) and the final bacterial concentration (\( y_{final} \)). The dependence or association relationship can be measured by the generated tornado plot.

\[ \rho_{X,Y} = \frac{\text{cov}(X,y_{final})}{\sigma_X \sigma_{y_{final}}} \] \quad \text{Eq.11}

where \( \text{cov}(X,y_{final}) \) is the covariance of the final bacterial concentration and different model variables; \( \sigma_X \) is the standard deviation of different model variables; \( \sigma_{y_{final}} \) is the standard deviation of the final bacterial concentration.

### 2.3. Practical examples for Microrisk Lab

To illustrate the performance of Microrisk Lab, we collected 6 datasets from the peer-
reviewed papers and lab observation for parameter estimation and simulation. Specifically, the study on the static/ non-isothermal growth regression, static/ non-isothermal inactivation regression, secondary model regression, and static stochastic growth simulation. The datasets for the kinetic analyses (Case I – V) were attached in the supplementary data. It should be noted that only a part of models was compared with the relevant modeling system in this study. More results on the comparison between built-in models were provided in the user manual (see supplementary data).

2.3.1. Case I – Kinetic analysis of *Listeria monocytogenes/ Listeria innocua* growth under a static condition

A growth measurement of *L. monocytogenes/ L. innocua* in tryptose phosphate broth (TPB) was obtained from the ComBase browser (ComBase ID: LM127_11) according to the research of Buchanan & Phillips (1990). In order to compare with the online DMFit and Excel DMFit, the ‘Complete Baranyi model’ in Microrisk Lab was chosen to determine the kinetic parameter of *L. monocytogenes*.

2.3.2. Case II – Kinetic analysis of *Salmonella enterica* inactivation under a static condition

A thermal inactivation curve of *S. enterica* in Brain Heart Infusion (BHI) under 60°C reported by Wang, Devlieghere, Geeraerd, & Uyttendaele (2017) was used to evaluate the inactivation model in Microrisk Lab. According to the suggestion by the author, ‘Log-linear + Shoulder’ model in GInaFiT (version 1.7) was selected for fitting. Therefore, performance of ‘No tail Geeraerd model’ in Microrisk Lab was compared in parallel with GInaFiT as well.

2.3.3. Case III– Effect of temperature on the specific growth rate of *Salmonella Typhimurium*

We cited a study on the maximum specific growth rate of *S. Typhimurium* (ATCC
14028) in chicken breast (Oscar, 2002) to estimate the growth boundary and optimal parameter by fitting the cardinal parameters model. The value of the specific growth rate under different static temperature conditions was converted to the same units (natural logarithm) in Microrisk Lab before regression. Both IPMP 2013 and Prism (version 7.0, GraphPad Software, USA) were applied for comparison.

2.3.4. Case IV – Kinetic analysis of L. monocytogenes growth under non-isothermal conditions

For growth modeling under non-isothermal conditions, the observed concentration and time-temperature profile were introduced from a study on L. monocytogenes growth in cooked beef samples under non-isothermal conditions. During the experiments, four L. monocytogenes strains (serotype 1/2a, 1/2b, 1/2c and 4b, meat isolated) were inoculated in a heat-treated ready-to-eat braised beef product (ca. 1% NaCl, pH=6.2, aw=0.983) and incubated in an air-packaged sterile stomacher bag under the fluctuating temperature ranging from 5 to 40°C. To date, there were no other integrated systems specialized for non-isothermal growth regression analysis. Thus, the measurements would be fitted by the ‘Baranyi-Cardinal parameter model’ and ‘Huang-Cardinal parameter model’ in Microrisk Lab.

2.3.5. Case V – Kinetic analysis of Bacillus sporothermodurans IC4 spores inactivation under non-isothermal conditions

In this case, a dataset was adopted from the supplementary data of the verification research on the non-isothermal inactivation modeling by Bioinactivation core (Garre, Fernández, Lindqvist, & Egea, 2017). This example data described the inactivation of B. sporothermodurans IC4 spores under non-isothermal heating conditions. Bioinactivation FE
(Garre et al, 2018), a web tool based on Bioinactivation core, was introduced to compare for
the estimated results with Microrisk Lab. The dynamic Bigelow model was selected with the
non-linear regression algorithm for inactivation fitting under non-isothermal conditions.

2.3.6. Case VI – Simulation of S. Typhimurium stochastic growth under a static condition

The stochastic simulation was based on the study of Koutsoumanis & Lianou (2013)
which obtained the growth parameters of S. Typhimurium individual cells with an automated
time-lapse microscopy method. A 10,000 times Monte-Carlo simulation was realized in
commercial software, @Risk for Excel (version 6.0, Palisade Corporation, USA), to describe
the stochastic growth of S. Typhimurium individual cells. According to the distribution of the
conditions and parameters, the stochastic growth of a single cell with the Buchanan model
was reproduced in Microrisk Lab for comparison.

3. Results and discussion

3.1. Comparison of the primary and secondary modeling

Case studies of the growth/ static inactivation under static conditions and the effect of
temperature on the specific growth rate were evaluated in Microrisk Lab and compared with
other integrated modeling systems. The fitted curves of Case I, Case II, and Case III
downloaded from Microrisk Lab are shown in Fig.3, which illustrates the consistency in the
result rendering of different sections. Note that the interactivity of Microrisk Lab allows users
to change the coordinate axis settings and the displayed results freely.

Tab.4 lists the results of the estimation and evaluation in Microrisk Lab and DMFit by
fitting the complete Baranyi model for Case I. Although most of the estimated results were
similar, there was around four-hour distinction between Online DMFit and Microrisk Lab/Excel DMFit on the estimated lag time. It should be noted that, in the DMFit systems, two curvature parameters of model need to be determined and fixed before regression. According to the help documentation for Online DMFit (https://browser.combase.cc/DMFit_Help.aspx) and manual for Excel DMFit (version 3.5), the default values for two curvature parameters, nCurv and mCurv, were 1 and 10, respectively. In contrast, all estimable parameters were determined by globally searching for the optimized estimates in Microrisk Lab, which could also cause the discrepancy of results. The evaluation indicators and standard errors of parameters are getting close to that in Microrisk Lab when increasing the value of nCurv from default 1 to 2 in Excel DMFit. However, it is noticeable that the reason for differences of the estimated value between the online DMFit and Excel DMFit is inexplicable. Meanwhile, the model evaluation indicators were different in DMFit tools and Microrisk Lab, we further calculated adjusted $R^2$ by Eq.8 according to the regression in Microrisk Lab for comparison (Tab.4). The results illustrate that the estimated adjusted $R^2$ has no obvious differences between Microrisk Lab and DMFit tools with different curvature settings.

As listed in Tab.5, for the static inactivation modeling, results of estimated parameters and evaluation indicators show no difference between Microrisk Lab and GInaFiT 1.7 when using the same model. Similarly, the effect of temperature on the $\mu_{max}$ of S. Typhimurium in chicken breast has been equivalently described in Microrisk Lab, IPMP 2013, and GraphPad Prism by the cardinal parameters model (Tab.6). Remember that the equation of AIC built-in IPMP 2013 was referred to the study by van Boekel, & Zwietering (2007), which was different from that of built-in Microrisk Lab. Above results indicated that Microrisk Lab could
offer an equivalent accuracy to other integrated systems on primary and secondary modeling studies.

### 3.2. Comparison of the dynamic modeling

In Case IV, both time-temperature profile and bacterial counting data were needed for the dynamic analysis. Initial guesses of the model parameter were required to assist in regression converge easily. According to former studies (ICMSF, 1996; Magalhães et al., 2014), L. *monocytogenes* probably has a growth temperature range from 0 to 45°C, the optimal specific growth rate is around 1 ln CFU/h (or 1/h) under 37°C in meat products. Initial guesses (Default values) of $q_0$, $A$, and $m$ are preset as 1 in Microrisk Lab when there has no reliable basic knowledge on these parameters. With the above initial settings, both regressions could converge successfully. The fitted curve and the estimated result are exhibited in Fig. 4 and Tab. 7, respectively. The results illustrated that the microbial growth parameters could be obtained from Microrisk Lab with the measurements under non-isothermal conditions in one analysis. Meanwhile, the Baranyi - Cardinal parameter model and Huang - Cardinal parameter model could well describe the non-isothermal growth of L. *monocytogenes* in cooked beef.

Similarly, with the microbial enumeration data and time-temperature profile in Case V, the non-isothermal inactivation fitting could be performed in Microrisk Lab (Fig. 5). Initial guesses of the estimable parameters were quoted from the primary study and listed in Tab. 8, where the referenced temperature was fixed to 120°C (Garre, Fernández, Lindqvist, & Egea, 2017). As illustrated in Tab. 8, the obtained estimations of Microrisk Lab are close to that of Bioinactivation FE. It should be noted, however, that numerical methods for the ordinary differential equations were different in these two tools. The **LSODA** solver in R package
‘deSolve’ (Soetaert, Petzoldt & Setzer, 2010) was introduced in Bioinactivation series to conduct the predictor-corrector method or backward differentiation formulae method for the dynamic model. In contrast, the Runge-Kutta method was provided by Microrisk Lab. These numerical methods have their own advantages and disadvantages respectively, but the choice might cause different truncation errors in a regression (Butcher, 2016). Thus, it is recommended to take care when using the evaluation indicators of AIC, AICc, and BIC provided from different modeling platforms for model comparison.

3.3. Comparison of the stochastic growth simulation

The stochastic type model is possible to be applied to the static simulation in Microrisk Lab by defining the distribution of different model variables. As previously mentioned, the behavior of microorganisms may be quite different when the population size decreases to the single-cell level. It is thus necessary to consider the uncertainty and variability of the cells during the simulation. In the referenced study of Case VI, Koutsoumanis & Lianou (2013) described the growth of the S. Typhimurium at the different single-cell level by establishing a stochastic model. Depending on the condition for the software of @Risk for Excel, the parameter setting of Microrisk Lab was listed in Tab.9, and the simulated results are presented in Fig.6(A). The probability distribution of the specific growth rate and the final bacterial concentration is provided with the mean value and standard deviation in Fig 6(C). According to the definition of the coefficient of variation (%CV = 100×standard deviation/mean) in the original study, the estimated %CV for S. Typhimurium final concentration is also around 25.5% in Microrisk Lab. The above result demonstrates that Microrisk Lab can perform a Monte-Carlo simulation for bacterial stochastic modeling. Moreover, Fig 6(D) shows the
tornado graph of the sensitivity analysis on bacterial counts obtained by different associated
parameters. Thus, restricted by the above settings, the uncertainty of the duration of growth
time has a relatively higher impact (than other variables) on the bacterial count during the
stochastic growth of S. Typhimurium single cell.

From the above cases, Microrisk Lab can be easily applied in microbial predictive
modeling, however, functionalities should be improved to handle more practical modeling
tasks. The model applicability could be expanded, for example, paying more attention to the
impact of the interaction between different intrinsic or extrinsic factors on the microorganism.
Algorithms involved in regression and simulation are also deserved to be developed for more
options. Bioinactivation FE provides a good example for containing different fitting
algorithms, while the functionality of fixed parameter could help users decide the estimable
parameter (Garre et al, 2018). Meanwhile, Latin Hypercube sampling is a widely used method
for the Monte-Carlo simulation in qualitative microbiological risk assessments (Ding et al.,
2013; Membré & Boué, 2017; Dogan, Clarke, Mattos & Wang, 2019), which should be
considered in our future update to improve the sampling efficiency.

4. Conclusions

In this study, a web-based freeware, Microrisk Lab, was introduced and used to validate
its performance limited regression and simulation analysis in predictive microbiology. The
interactive interface and simple manipulation logic help users readily obtain the modeling
results. Practical examples elucidated that, in most cases, there was no statistical difference
between the results obtained from Microrisk Lab and other existing modeling systems (except
the online DMFit) in both regression and simulation studies. The new tool could provide more statistical results for the estimated parameter or evaluated indicator. Besides, it was also easy to perform the growth kinetic analysis under non-isothermal conditions without any coding skill in Microrisk Lab. This freeware might serve as a useful modeling tool and relevant educational resource for predictive modeling in microbiology.

Figures (Color should be used)

Fig. 1 Overview of the layout of Microrisk Lab and its visual interface on different internet-connected devices.

Fig. 2 The structural framework and workflow of Microrisk Lab.

Fig. 3 The fitted curve of (A) Case I with the ‘Complete Baranyi model’, (B) Case II with the ‘No tail Geeraerd model’, and (C) Case III with the ‘Cardinal parameter model’ downloaded from Microrisk Lab. (The blue dot represents the observed bacterial count, and the origin line represents the fitted curve.)

Fig. 4 The fitted curve of Case IV with (A) the Baranyi-Cardinal parameter model and (B) the Huang-Cardinal parameter model downloaded from Microrisk Lab. (The blue dot represents the observed bacterial count, and the origin line represents the fitted curve.)

Fig. 5 The fitted curve of Case V with the Dynamic Bigelow model downloaded from Microrisk Lab. (The blue dot represents the observed bacterial count, and the origin line represents the fitted curve.)

Fig. 6 Monte-Carlo simulation of 1 cell growth with 10,000 iterations in (A) Microrisk Lab, and (B) @RISK for Excel (adapted from Fig.7 of Koutsoumanis, & Lianou, 2013). (C) Simulated distribution of the maximum specific growth rate and final bacterial count. (D) Tornado graph of the sensitivity analysis between model variables and bacterial counts.
Fig. 1
Fig. 2

*Only in the regression under non-isothermal conditions.
Fig. 3

(A) Graph showing bacterial count vs. time in hours.

(B) Graph showing bacterial count vs. time in minutes.

(C) Graph showing maximum bacterial growth vs. temperature.
