Running Title: Rab7 mediates Wnt signaling *in vivo*
Summary Statement

The late endosomal regulator Rab7 is required for gastrulation movements and axis elongation in *Xenopus* by positively regulating Wnt signaling-mediated mesoderm patterning.

Abstract

Early embryogenesis requires tightly controlled temporal and spatial activity of growth factors. Modulation is achieved at multiple levels, from cellular transcription to tissue-scale propagation, concerning activation, maintenance, or termination of signaling. Intracellularly, the endolysosomal system emerged as important factor for such regulations. Endocytosis and early endosomes mainly orchestrate activation and transduction of signals, while late endosomes are thought to mediate lysosome-based termination. Only few reports attributed activating roles to late endosomes, mainly for Wnt pathway activation. In *Xenopus*, few is known about developmental roles of endosomal regulators, or their function for signaling, especially true for late endosomes. Therefore, we chose to analyze a hypothesized positive role of Rab7 in this context, a small GTPase mainly known for its role as a late endosomal regulator. We analyzed if Rab7 participates in early activation of growth factor signaling, focusing on Wnt signaling. We found *rab7* expressed very localized throughout development, and inhibition resulted in strong gastrulation defects. Concomitantly, Rab7 was strictly required for both, exogenous activation and endogenous Wnt-mediated patterning of the mesoderm.

Introduction

Early embryonic processes like germ layer formation, induction of body axes, neural induction or tissue differentiation require tightly controlled temporal and spatial activation of specific sets of signaling pathways. Regulation of endocytosis or membrane trafficking can control activation, intensity, or duration of intracellular signal transduction upon ligand-mediated activation of transmembrane receptors (Sigismund et al., 2012). However, this has only been analyzed in few developmental processes *in vivo*, as altering such basic cellular processes can have dramatic effects.

Classically, endocytosis of plasma membrane localized receptors is considered a way of downregulation of signaling pathways. Receptors are translocated to early endosomes (EE) by endocytic vesicles, which quickly fuse with EE membranes, representing first intracellular sorting platforms (Platta and Stenmark, 2011). From here, activated receptor complexes can be inactivated (e.g. ligand-separated), and recycled back to the plasma membrane, which enables repeated pathway activation. Alternatively, such activated receptors are retained in EE membranes while these organelles mature into late
endosomes (LE). Here, transmembrane cargo can be translocated into its intraluminal vesicles (ILV) by successive inward budding of the limiting membrane, a process characteristic for maturing LE, and which is performed by the ESCRT (endosomal sorting complexes required for transport) complex (Hanson and Cashikar, 2012). When translocated into ILV, receptors are separated from the cytoplasm, and this is generally thought to be a one-way route to degradation for any cargo, as matured LE fuse with lysosomes for acidic degradation of contents. Thus, in most cases analyzed so far, LE represent an intermediate step between EE and degradation, with no return once LE are matured and transmembrane receptors are translocated into ILV (Dobrowolski and De Robertis, 2011; Horner et al., 2018; Katzmann et al., 2002).

While degradation and recycling as ways of modulating signal strength are well established, the role of endocytosis and endosomes for activation or maintenance of signaling pathways are much less understood. It is known that TGF-β (transforming growth factor beta), BMP (bone morphogenetic protein), Notch, and both, canonical and non-canonical Wnt signaling pathways require endocytosis to activate intracellular signaling upon ligand binding. In addition, BMP and TGF-β need to be transported to EE, where specific adapters are located, which are in turn required to bridge the receptor kinase to its substrate, a Smad family transcription factor (Brunt and Scholpp, 2018; Butler and Wallingford, 2017; Dobrowolski and De Robertis, 2011; Fürthauer and González-Gaitán, 2009; Platta and Stenmark, 2011). A rarer case is the description of a positive role of LE for pathway activation – as opposed to a simple role for degradation. This has been suggested to be the case for EGF (epithelial growth factor) receptor-mediated MAPK (mitogen-activated protein kinase) activation under certain circumstances (Platta and Stenmark, 2011; Teis et al., 2002). Further, for canonical Wnt signaling (from here on simply ‘Wnt signaling’), it has been demonstrated that LE are indispensable for sustained pathway activation, i.e. for maintaining signaling after endocytosis-mediated activation of the Wnt receptor complex (Platta and Stenmark, 2011; Taelman et al., 2010; Vinyoles et al., 2014).

Rab family proteins are a group of small GTPases that regulate most membrane trafficking processes by transiently binding membranes with their C-terminal prenyl anchor. Each Rab is specific to certain types of membranes/organelles and orchestrates the recruitment of a specific set of effectors, thereby giving the membrane a specific ‘identity’ and function. For most routes of cellular membrane trafficking, one or few Rab proteins serve as process-specific molecular switches (Stenmark, 2009). Although, as judged by their important general roles in cellular transport, many Rab proteins are categorized as ‘housekeeping genes’, they might also be involved in specific processes, like regulation of signaling pathways. An example is the endocytic/EE regulator Rab5, which is often
required for internalization of receptor complexes and can therefore regulate intracellular output of signaling.

The LE regulator Rab7a (from here on simply Rab7), and its low expressed, tissue-specific paralog Rab7b are mainly found on LE. Initially, they are recruited to endosomal membranes by EE-located Rab5, which is then replaced by Rab7 when these structures mature into LE. Thus, Rab7 is often used as organelle marker for LE, and more importantly, as a recruiter of many effectors, it is also the main regulator of LE maturation and function (Huotari and Helenius, 2011; Stenmark, 2009). Concerning signaling pathways, it is thus considered as a permissive regulator of endolysosomal degradation, i.e. required for membrane receptor degradation and termination of signaling (Platta and Stenmark, 2011). While this is straightforward logic, controlling the Rab5 to Rab7 conversion, or Rab7 activity itself, could also be a way of positively regulating activity of downstream signal transducers. For instance, this might be the case for canonical Wnt signaling, where fully functional LE have been shown to be required for sustained target gene activation. In addition, the canonical Wnt pathway has been reported to be able to positively influence expression of endosomal regulators, representing an example of a direct influence on the endolysosomal system in a positive feedback loop (Ploper and De Robertis, 2015; Ploper et al., 2015; Taelman et al., 2010).

In fact, studies dealing with the in vivo function of Rab7 are rare, especially in a developmental context, and most information about its influence on pathway activity derives from work in cell culture, i.e. from out-of-tissue contexts (Guerra and Bucci, 2016). This might be due to the important role of Rab7 in every cell, causing classical knockout (KO) approaches to result in embryonic lethality. This is exemplified by work in the mouse, where rab7 KO resulted in early death before embryonic day 8. KO embryos had strong defects in endosomal transport, especially in the anterior visceral endoderm (AVE), which resulted in antero-posterior (AP) patterning and AVE migration defects, and thus in failure to complete gastrulation (Kawamura et al., 2012; Stower and Srinivas, 2014). If these phenotypes were related to mis-regulation of Wnt signaling or other developmentally important pathways was not addressed in this study. So, while cytoskeletal or endosomal regulators like Rab proteins turned out to be important modulators of pathway activity at multiple levels, not many studies analyzed this in a developmental context.

In this work, we chose to analyze the in vivo function of rab7 and its potential participation in Wnt pathway activation during early development of Xenopus laevis. In contrast to its housekeeping role, we found rab7-mRNA specifically enriched in distinct types of tissues during early development, reflecting dynamic changes of enhanced requirement. Using morpholino-mediated knockdown and CRISPR/Cas9-mediated genome editing, we found that loss of rab7 resulted in gastrulation defects without impacting
embryonic organizer induction on the dorsal side. Further, *rab7* was required for ligand-mediated activation of exogenously induced, as well as for endogenous canonical Wnt signaling in the mesoderm.

**Results**

**Loss of *rab7* results in gastrulation defects**

We speculated *rab7* could show distinct spatial enrichment of mRNA expression during early *Xenopus* development. If the case, such enhanced abundance would give indications about tissue- and process-specific requirements of *rab7*. Indeed, expression analysis by *in situ* hybridization (ISH) revealed very dynamic spatial and temporal signals. Strong maternal expression was found in the animal half of cleavage stages, a signal still detected at the onset of zygotic transcription after midblastula transition (MBT; Fig. 1A,B; Fig. S1A). At early gastrula stages, transcripts were mainly found in the deep mesodermal ring, omitting the dorsal lip, i.e. the anterior/head part of Spemann-Mangold organizer (Fig. 1C,D; Fig. S1B). During late gastrulation, stronger signals were detected in the neural plate ectoderm and in the axial, notochordal mesoderm, latter of which continued to be positive for *rab7* during neurulation (Fig. 1E; Fig. S1C). By then, ectodermal expression became more restricted to the lateral neural plate, and later in the deep cells of the neural tube and brain tissues (Fig. 1F-H; Fig. S1D-E). In following tailbud stages, *rab7* signals were detected in the cement gland and dermal areas, slightly in the notochord, and strong in the pronephric kidney, eyes, ventro-lateral neural tube, pharyngeal arches, trigeminal nerve complex, dorsal fin mesenchyme, and in the trunk neural crest cells (Fig. 1I,J; Fig. S1F,G; and data not shown). This analysis supported our hypothesis that *rab7* could be required for early embryonic development by participating in regulation of signaling activity in multiple tissues.

Next, we wanted to test such an early *in vivo* requirement of *rab7* using a loss-of-function approach. We designed a morpholino oligomer (MO) targeting the 5'UTR of the L- and S-form of *Xenopus laevis rab7* to block translation initiation of both homeologs (*rab7*-TB-MO). Morphant embryos passed through cleavage and blastula stages without detectable phenotypes (not shown). However, subsequent gastrulation movements were strongly inhibited, causing failure to close the dorsal blastopore and resembling strong convergent extension (CE) defects in about 50% of the embryos at early neurula stage (Fig. 1K,L). This phenotype became more prevalent at tailbud stages, with further extension of the AP axis in control specimens, while morphant embryos remained wide open dorsally with a strong dorsal curvature (Fig. 1N,O). Importantly, co-injection of a constitutively-active (ca) *rab7* mRNA was able to rescue the strong gastrulation and CE phenotype in a highly significant manner, demonstrating specificity of the observed MO effect (Fig. 1M,Q). At tailbud stages, nearly all rescued embryos were able to close the dorsal blastopore and to elongate their AP.
axis, albeit with a slight delay in AP elongation (Fig. 1P,Q). To further underline specificity of
this effect we next designed single guide RNAs (sgRNA) to target the genomic loci of both
\textit{rab7} homeologs for CRISPR/Cas9-mediated mutagenesis, either in parallel, or individually.
KO efficiency of injected embryos was determined by sequencing and subsequent analysis
of indel distribution (Synthego ICE; for details see Method section). These analyses resulted
in a predicted gene editing rate between 60\% and 88\% for L- or S-forms of the different
sgRNAs (Fig. S1H-J). Genome editing of \textit{rab7} L/S at the one-cell stage caused strong
gastrulation defects, again resulting in tailbud stages with open dorsal part in over 50\%
of specimen, resembling the phenotype shown for morphants (Fig. 1R,S,V). Interestingly, while
selective targeting of homeolog L with sgRNA (L) caused also a similar phenotype in about
25\% of injected specimen (Fig. S1K-M), no gastrulation defects were observed by only
targeting homeolog S with sgRNA (S) (not shown). Finally, we also designed a splice-
blocking (SB) MO targeting the splice acceptor site at intron 2 of the \textit{rab7} pre-mRNA to
prevent splicing, and thus should cause translational read-through and early termination (Fig.
S1N). Successful inhibition of splicing could be demonstrated by RT-PCR for both
homeologs, resulting in intron retention for each form (Fig. S1O). Additionally, injection of the
\textit{rab7}-SB-MO resulted in significant reduction of \textit{rab7}-transcript amounts in morphant neurula
or tailbud stage embryos, indicating nonsense-mediated decay of unspliced \textit{rab7}, and thus
successful knockdown of zygotic transcripts (Fig. S1P-S). Phenotypically, \textit{rab7}-SB-MO
injected embryos showed also gastrulation defects, but to a lower extend and degree (Fig.
1T,U,W). Those specimens who managed to close the blastopore were raised until tailbud
stages. Such milder affected morphants displayed deficits in AP elongation, indicating a
milder CE phenotype (Fig. S1V,W). Finally, by raising the few surviving \textit{rab7}-TB-MO, or
sgRNA (S+L) injected embryos, this late phenotype could be phenocopied in early tadpole
stages, again showing specificity of the effect (Fig. S1T,U,X,Y). In summary, our loss-of-
function approach demonstrated a requirement of \textit{rab7} for early embryonic development.

\textbf{Rab7 is required for convergent extension and notochord morphogenesis}

To better understand this gastrulation phenotype, we specifically knocked down \textit{rab7} in
the dorsal mesoderm. When mid-sagittal sections were analyzed at early gastrula stages,
\textit{rab7} morphants formed a lip, but involution movements and archenteron formation were
significantly impaired (Fig. 2A-D). Interestingly, bisections revealed a concomitant lack of
Brachet’s cleft, implying incorrect tissue remodeling during early gastrulation (Fig. 2C-F;
(Fagotto, 2020). These phenotypes became also apparent when such embryos were
analyzed for notochordal \textit{noggin} (\textit{nog}) expression at mid-gastrula, supporting strongly
impaired axial mesoderm elongation and reduced \textit{nog} expression itself, the latter one
indicating a failure in maintaining notochordal fates in morphant tissue (Fig. 2G-J). Analysis
of cell-matrix/cell-cell adhesion revealed a reduction of β1-Integrin and Ctnnb1 (β-catenin) in the axial mesoderm of morphants (Fig. 2K-M and Fig. S2A-C). Similar reductions were observed in animal caps, where loss of rab7 reduced Ctnnb1 in targeted areas, suggesting a general effect (Fig. S2D).

As these phenotypes also indicated a failure in CE and thus, to form a proper elongated notochord subsequently, we next examined notochord fate and appearance directly. When we checked expression of the marker notochord homeobox (not) in morphant embryos at early neurulation, a lack of CE was obvious, explaining the embryos’ inability to close the dorsal part of the blastopore (Fig. 2N-P). When using the rab7-SB-MO for dorsal knockdown, a milder but significant effect was observed as well, (Fig. S2E-G). Interestingly, while not expression was not reduced in the axial mesoderm and extended into the lateral somitic area, analysis of sonic hedgehog (shh) in the same set of experiments revealed a different effect. Morphant embryos showed a similar lack of CE but expression intensity of shh was reduced in most cases, again suggesting partial lack of notochordal fate (Fig. 2Q-S).

Morphant embryos were grown to tailbud stages to analyze notochordal tissue differentiation. In these stages, not expression was also not reduced, but appeared enhanced in milder affected specimens, especially in the mid-trunk area, where in wildtype embryos expression had already faded by that stage (Fig. S2H-J). Overall, notochordal appearance in sagittal sections confirmed attenuated CE. Stronger affected specimens developed open dorsal tissues and mostly retained not expression, but often split as two separated areas relocated medially (Fig. S2K). Staining such embryos with an MZ-15 antibody, which detects outer keratan sulphates of the notochordal sheet, revealed absent or strongly reduced signals, supporting a lack of notochord differentiation (Fig. S2L-O). These phenotypic analyses showed that rab7 is participating in axial tissue morphogenesis and CE-dependent notochord formation during gastrulation.

**Rab7 is required for dorsal mesoderm specification but not for the organizer**

To understand the role of rab7 in this context, we next analyzed if organizer induction was impaired by targeting this dorsal lineage. Neither knockdown with rab7-TB-MO or rab7-SB-MO, nor CRISPR-induced KO impacted on correct organizer induction, as judged by unaltered expression patterns of the organizer genes goosecoid (gsc) and chordin (chd; Fig. 3A-C and Fig. S3A-H). Next, we wanted to test if early pre-gastrula dorso-ventral (DV) axis formation was altered in rab7 morphants. We knocked down rab7 and checked dorsal chd or ventral ventx1 expression to analyze for altered Bone Morphogenetic Protein (BMP) gradient. Both genes were found in similarly extending domains as in control embryos (Fig. 3D-F and Fig. S3I-K). This suggested that rab7 is dispensable for both, organizer induction and DV patterning.
As a main regulator of LE, rab7 would be expected to be indispensable for maternally activated canonical Wnt signaling, and thus for endogenous organizer induction. However, the reduced expression pattern of shh suggested that rab7 might be required for other early dorsal mesoderm genes as well. Therefore, we checked expression patterns of nodal3 and forkhead box J1 (foxJ1), two Wnt-dependent marker genes expressed in the superficial mesoderm (SM), i.e. the outer layer of the trunk organizer tissue (Glinka et al., 1996; Smith et al., 1995; Stubbs et al., 2008; Walentek et al., 2013). Interestingly, while the very early expressed nodal3 was reduced in a fraction of embryos, foxJ1 was strongly reduced after loss of rab7 (Fig. 3G-L). The paraxial presomitic expressed marker myogenic factor 5 (myf5), also well-known to be dependent on Wnt (Kjolby and Harland, 2017; Shi et al., 2002), was strongly downregulated (Fig. 3M-O), indicating a potential fate shift as indicated by the lateral extension of not into these areas (cf. Fig. 2O). Finally, we wanted to test, if mesodermal identity was altered more generally, as this has been reported to depend on Wnt pathway activation as well (Vonica and Gumbiner, 2002). Analysis of T-box transcription factor T (tbxT, also known as brachyury) revealed a significant reduction of expression after rab7 knockdown in this area (Fig. 3P-R), explaining the morphogenetic phenotype in the axial mesoderm (cf. Fig. 2). The down-regulation of these marker genes suggested a role of rab7 for Wnt-dependent development of the dorsal mesoderm, probably downstream or in parallel of endogenous organizer induction.

**Rab7 is required for canonical Wnt pathway activation in vivo**

In order to support our conclusion that the loss of rab7 blocked an endogenous dorsal Wnt signal, and to bypass the possibility that maternally deposited rab7 mRNA or protein would ‘cover’ its requirement for Wnt-induced organizer induction in our experiments, we next used radial injections of wnt8a mRNA, which is well-known to dorsalize the embryo (Hikasa and Sokol, 2013; Smith and Harland, 1991). Injections caused radial expression of dorsal-specific organizer genes and erased that of ventral-specific ventx1 (Fig. 4A,B,D and Fig. S4E-H). Importantly, co-injection of rab7-TB-MO restored the DV-axis highly significantly without impacting on endogenous organizer-specific expression of chd or nog (Fig. 4C,D; Fig. S4A-D). Early gastrula embryos tested for ventx1 showed restoration of their DV axis but ventx1 expression was partially reduced (Fig. S4G,H). These results suggest that rab7 is required for ligand-dependent activation of canonical Wnt signaling in vivo.

If rab7 participated in Wnt pathway activation in vivo, then knockdown should also prevent induction of secondary axes, the classical readout for canonical Wnt pathway in Xenopus (Sokol et al., 1991). Indeed, co-injection of rab7-TB-MO was sufficient to prevent wnt3a-induced double axis induction in a highly significant manner, whereas the efficiency of ctnnb1 (β-catenin) to induce double axes was not altered after rab7 knockdown (Fig. 4E-H).
and Fig. S4I-L). To further rule out that this effect was due to an impairment of processes downstream of organizer induction, we also analyzed secondary organizers for expression of gsc, which clearly demonstrated a blockage of the exogenous organizer (Fig. S4M-O). This was also supported by the β-catenin activated reporter (BAR; Biechele et al., 2009), which was used to perform a luciferase-based Wnt assay in animal caps. Here, wnt8a-induced reporter activation was also blocked by rab7 inhibition (Fig. 4I). These results supported our conclusion that rab7 is required to mediate early Wnt signaling in Xenopus. Further, this excluded the possibility that its knockdown could impact on processes downstream of cttnb1-dependent target gene activation. Altogether, from this set of experiments we conclude that the small GTPase Rab7 is required for Wnt pathway activation in early frog embryos, upstream of Ctnnb1 stabilization.

**Rab7 is required for specification of the ventro-lateral mesoderm**

On the one hand, our experiments have demonstrated that rab7 participates in the canonical Wnt pathway *in vivo* when ligand-activated exogenously in the mesoderm or ectoderm. On the other hand, endogenous organizer induction was not blocked after loss of rab7, yet, dorsal Wnt-dependent mesoderm specification was significantly impaired. Therefore, we next asked if rab7 also participated in ventro-lateral mesoderm specification, which is known to be dependent on zygotic wnt8a (Hoppler and Moon, 1998). During gastrulation, the organizer secretes Wnt antagonists dorsally in the axial mesoderm, while wnt8a is expressed in the ventro-lateral mesoderm. Using targeted injections, we blocked rab7 only in the ventral mesoderm. Morphant embryos developed milder phenotypes with low lethality rates and could thus be raised until tadpole stages. Such embryos showed ventro-posterior malformations, which became more pronounced as early tadpoles, when tail formation was strongly inhibited in most cases (Fig. 5A-C and S5A,B).

Therefore, we analyzed Wnt-dependent ventro-lateral genes during late gastrulation, to test if rab7 was required for wnt8a-dependent specification of ventral fates. Expression of myogenic differentiation 1 (*myod1*) and T-box 6 (*tbx6*) were strongly inhibited or lost in morphants, demonstrating a requirement of rab7 for ventral mesoderm identity (Fig. 5D-F; Fig. S5C-E). We also injected the BAR reporter in this area to directly quantify the effect of rab7 inhibition on endogenous Wnt activity. Loss of rab7 reduced Wnt reporter signals by about 90%, strongly indicating that the loss of marker genes was caused by Wnt pathway inhibition (Fig. 5G). To get further support for this conclusion, we performed epistasis experiments using suboptimal doses of the rab7-TB-MO together with a well-established cttnb1(β-catenin)-MO (Heasman et al., 2000). While injection of effective doses of cttnb1-MO resulted in loss of myod1 expression comparable to rab7 morphants, low-dose injections of either cttnb1-MO or rab7-TB-MO both had only minor effects on ventral myod1 (Fig. 5H
and Fig. S5F-I). When both MOs were combined using low doses, myod1 expression was lost in all double-morphants examined, supporting the conclusion of an epistatic interaction of Rab7 and Ctnnb1 (Fig. 5H and Fig. S5I).

Together, this set of experiments supports the conclusion that rab7 is necessary for endogenous Wnt8a-mediated specification of ventral and somitic fates during gastrulation, downstream of Wnt receptor activation.

Rab7 acts epistatically with the endosomal regulator Vps4

In most contexts, Rab7 acts via its well-studied role as a regulator of late endosomal function. However, in some cases it has been shown to perform a cellular role independent of LE, and potentially not in the endo-lysosomal pathway (Guerra and Bucci, 2016). Therefore, we aimed to address this point here as well, namely by testing if other late endosomal regulators known to be required for Wnt pathway function would co-regulate ventral, Wnt-dependent fates in concert with Rab7. We chose two components of the ESCRT machinery (Horner et al., 2018), which have previously been characterized in Wnt signal transduction in Xenopus, i.e. hepatocyte growth factor-regulated tyrosine kinase substrate (hrs) and vacuolar protein sorting 4 homolog (vps4; Taelman et al., 2010).

Using doses that have previously been shown to block double axis formation, we then knocked down hrs in the ventral mesoderm, or overexpressed a dominant-negative version of vps4 (dnvps4; Bishop and Woodman, 2000), to analyze Wnt-dependent mesoderm patterning. In both cases, loss of these late endosomal regulators also caused reduction or loss of myod1 in the ventral part, demonstrating their necessity for correct patterning (Fig. 6A,B,E and Fig. S6A-C). As this implicated a functional cooperation with Rab7 on LE, we next performed an epistatic analysis to demonstrate interaction. Either low-dose injection of dnvps4 mRNA, or that of rab7-TB-MO caused only minor reduction of myod1 expression, however, parallel injection of both agents caused strong inhibition of myod1 in a significant manner (Fig. 6B-E). From these results we conclude that Rab7 participates in Wnt-dependent patterning of the ventral mesoderm as an endosomal regulator together with other effectors of normal LE function.

Discussion

In this study, we analyzed the in vivo role of the small GTPase Rab7 in the frog Xenopus with focus on its role in early patterning and regulation of morphogenetic processes during gastrulation. We were able to demonstrate a requirement for Wnt-dependent processes in the early embryo, both, endogenously in the mesoderm, or if exogenously induced. Further, our analyses implicated that Rab7 might participate in further Wnt-dependent, or putatively independent processes.
**rab7 has distinct activity pattern throughout embryonic development**

In developmental studies, genes with housekeeping function are mostly used as molecular tools – developmental expression is rarely included (Kim et al., 2012; Lee and Harland, 2010 for Rab coding examples). Our analysis of rab7 revealed strikingly dynamic and spatially restricted expression patterns throughout early development, suggesting a tissue- and context-specific requirement. Therefore, we would predict that many housekeeping genes are enriched in specific tissues, and expression of different endosomal regulators (e.g. hrs or vps4) could reveal distinct endosomal synexpression groups, following a concept proposed before (Niehrs and Pollet, 1999). Such analyses could reveal novel roles for endosomal regulation of developmental processes or signaling pathways, in line with common transcriptional regulation, as demonstrated for genes coding endosomal components (Ploper et al., 2015; Sardiello et al., 2009). In the case of rab7, strong signals in the neural plate border (Fig. 1F-H), pronephric kidney, and cranial and trunk neural crest (Fig. 1I,J) suggest such possible roles in other Wnt-regulated tissues (Borday et al., 2018; Burstyn-Cohen et al., 2004; Honoré et al., 2003; Pla and Monsoro-Burq, 2018; Villanueva et al., 2002; Zhang et al., 2011).

**Rab7 is required for dorsal mesoderm specification and tissue remodeling during gastrulation**

In our approach presented here, we performed loss of function of rab7 using antisense oligos and CRISPR/Cas9-mediated genome editing. Reflecting the late expression in diverse tissues, mildly affected, or low-dose injected tadpoles displayed shortened AP axes, head and eye defects, and edema formation, the latter putatively due to loss of rab7 in the pronephric system (cf. Fig. 1 and S1; Wessely and Tran, 2011). Yet, while developing no phenotypes during cleavage and blastula stages, the most prominent developmental defects of rab7-deficient embryos became apparent during gastrulation, as a result of both, morphogenetically as a lack of CE and notochord specification on the dorsal side, and ventrally due to a lack of mesoderm specification and subsequent posterior truncations. The lack of very early phenotypes despite the presence of a large supply of maternal rab7 mRNA in cleavage and blastula stages suggest that this pool might be required mainly after midblastula transition (MBT), i.e. at least partially during gastrulation. This is supported by the fact that the rab7-TB-MO was slightly more efficient in causing gastrulation defects than the rab7-SB-MO. Yet, some maternal Rab7 protein might mask an early role during cleavages as well.

Interestingly, work in mice strongly supports an evolutionary conserved role of rab7 in this context (Kawamura et al., 2012). Here, rab7 KO also prevented gastrulation by
interfering with AVE development, resulting in early embryonic death. More importantly, in a recently published follow-up report, the authors demonstrated that this gastrulation phenotype was caused by lack of proper mesoderm formation, recognizable by a failure in correct tissue remodeling and subsequent germ layer formation (Kawamura et al., 2020). These cellular phenotypes are highly reminiscent of our observations in the dorsal mesoderm after loss of rab7, where cellular arrangements were disorganized as well, and correct formation of Brachet’s cleft was impaired, i.e. germ layers also failed to separate correctly (cf. Fig. 2 C-M and Fig. S2). Another indication for a conserved role of rab7 in these processes is the reduction of cell adhesion markers we observed (cf. Fig. 2K-M and Fig. S2A-D). In the mouse, such altered cell adhesion was also observed after loss of rab7, paralleling the failed tissue remodeling (Kawamura et al., 2020).

From work in cell culture it is known that Rab7 is required for correct activation and localization of β1-Integrin at the cell membrane in a permissive way, i.e. as a component required for transport towards the membrane (Arjonen et al., 2012; Margiotta et al., 2017). Thus, such a function of Rab7-mediated transport would explain the reduction of β1-Integrin we observed after rab7 inhibition (Fig. 2L,M). Yet, we cannot clearly distinguish whether the reduction of β1-Integrin (and Ctnnb1) in the dorsal mesoderm is a direct result of loss of Rab7-mediated transport of these molecules, or an indirect consequence of the lack of mesodermal specification. The significant down-regulation of tbxt in most embryos might argue for the second possibility (Fig. 3P-R), which could explain all observed problems of tissue remodeling, CE and notochord morphogenesis – as Tbxt is a well-known upstream regulator of mesoderm specification and non-canonical Wnt pathways required for CE (Bruce and Winklbauer, 2020; Schulte-Merker and Smith, 1995; Tada and Smith, 2000).

Rab7 mediates dorsal development independent of the organizer

Strikingly, we did not observe a change in organizer induction as judged by expression of gsc or chd at early gastrulation. Further, the embryos show no signs of ventralization or dorsalization, neither phenotypically, nor when analyzed for mid-gastrula expression of the DV-specific genes ventx1 or chd (Figs. 3D-F and S3F-K). These results argue against an involvement of rab7, first, in early Wnt-mediated Nieuwkoop center/organizer induction (Fagotto et al., 1997; Heasman et al., 1994), second, in TGF-β/Nodal pathway-induced activation of organizer genes, and third, in BMP-mediated ventral development (E.M. De Robertis, 2009). These conclusions are again supported by the recent report showing also no alteration of Nodal or BMP signaling in rab7 KO mice (Kawamura et al., 2020). For the TGF-β members BMP and Nodal it is known that endocytosis and subsequent translocation of activated receptor complexes to EE is required for intracellular signal transduction, i.e. correct function of Rab5-mediated processes should be a prerequisite of this (Platta and
However, in *Xenopus*, Rab5-mediated endocytosis has been reported neither to be required for long-range signaling, nor for cells generally to respond to activin ligands (i.e. another TGF-β member) during mesendoderm induction (Hagemann et al., 2009). So far, an involvement of Rab7 or LE in general has not been linked to the activation of TGF-β signaling, a finding we also conclude from our *Xenopus* analyses. However, we cannot exclude a role in specific tissues during later development.

In contrast to the wildtype expression of organizer genes, we found that *rab7* was clearly necessary for *myf5*, *foxj1* and *tbxt*, and partially for correct *nodal3* expression (Figs. 3G-R). These genes are known to depend on active Wnt signaling (although with some uncertainty for *tbxt*), however, it is not fully understood to which extent the maternally or zygotically activated Wnt signals contribute to their activation (Shi et al., 2002; Smith et al., 1995; Stubbs et al., 2008; Monica and Gumbiner, 2002; Walentek et al., 2013). *nodal3* expression, which was impacted least after *rab7* inhibition, is initiated very early on and is thought to be a direct Wnt target (Glinka et al., 1996; Smith et al., 1995). Therefore, these results might indicate a role for Rab7 only for processes relying (at least partially) on zygotic Wnt activation. In the recently analyzed *rab7* KO mouse, gastrulation phenotypes and lack of *tbxt* expression have been demonstrated to be related to mis-regulation of Wnt signaling by upregulating the activity of the Wnt antagonist Dickkopf (Dkk; Kawamura et al., 2020). While this, probably mammal-specific, AVE-to-epiblast crosstalk of Wnt activity modulation cannot easily be transferred to *Xenopus* gastrula embryos, the common Wnt-dependent induction or maintenance of *tbxt* seems to support a conserved general role of *rab7*. Yet, a further confirmation of this Wnt connection comes from another analysis in mouse, where notochord-specific inhibition of Wnt signaling resulted in reduced expression of *noto*, *shh* and *tbxt*, resulting in posterior truncations as well (Ukita et al., 2009).

**Rab7 is necessary for Wnt activation in *Xenopus* in a context-dependent manner**

The unexpected lack of ventralization phenotype contradicted the reported role of LE for Wnt pathway activation, as we expected Rab7 to be also required for maternal Wnt-dependent organizer induction (Taelman et al., 2010; Vinyoles et al., 2014). This was even more puzzling, as we could demonstrate an absolute requirement for exogenously induced activation of Wnt-dependent processes, i.e. double axis assay, Wnt reporter activation, and the restoration of the DV axis after Wnt8a-mediated dorsalization – and some of these processes act also early during cleavage stages (cf. Figs. 4 and S4). The last result exemplified this discrepancy clearly, as exogenously induced Wnt-dependent dorsal fates were blocked after loss of *rab7*, while the endogenous, organizer-induced expression of *chd* and *nog* stayed unaltered (cf. Fig. 4A-D and S4A-D). A compensatory action by the
paralogous rab7b can be excluded, as it is not present in the zygote (Peshkin et al., 2019; Session et al., 2016; our unpublished data). One possible, straightforward explanation would be that endogenous early Wnt activation does not require ligand-mediated receptor activation and endocytosis, which we used for our experiments with exogenous Wnt pathway induction. This could thus include a mechanism that bypasses the endolysosomal system. However, it has been reported that organizer induction does require autocrine and paracrine Wnt ligand perception (Cha et al., 2008; Kofron et al., 2007; Tao et al., 2005). Another possibility would be that maternal Wnt does not use LE at all. In cell culture and in Xenopus embryos, LE have been reported to be necessary to establish a robust Wnt output, i.e. to maintain continuous inhibition of glycogen synthase kinase 3 (GSK3), and thus Wnt pathway activation. However, endogenous organizer induction has not been analyzed in these experiments (Niehrs and Acebron, 2010; Taelman et al., 2010). In fact, we cannot exclude that early dorsal Wnt activation might only rely on ‘fast-acting’, LE-independent mechanisms (like Axin inhibition), which have been suggested to be required for GSK3-inhibition and Wnt activation (cf. Clevers and Nusse, 2012; Li et al., 2012). Alternatively, the Xenopus zygote might already contain fully or partially matured LE, as proposed before, but whose functionality we are not able to interfere with using embryonic injections (Dobrowolski and De Robertis, 2011). Finally, there might be simply enough maternally deposited Rab7 protein present, just sufficient to participate in organizer induction. Yet, due to the close temporal proximity of endogenous organizer induction and that mediated by our wnt8a mRNA injections, we would question this possibility. Future analyses might reveal the nature of this phenomenon.

In contrast to the rather complex involvement of Rab7 for dorsal Wnt-mediated fates, we could show a requirement for endogenous ventro-lateral mesoderm patterning, as all marker genes (myf5, tbx6, myod1) were strongly downregulated after loss of rab7 (Figs. 3M-O, 5D-F, S5C-E). These genes have all been shown to depend on a ventral source of Wnt, mediated by Wnt8a (Hoppler and Moon, 1998; Hoppler et al., 1996; Kjolby and Harland, 2017; Shi et al., 2002), which was supported by the epistatic effect of rab7 knockdown with ctnnb1 knockdown (Figs. 5H and S5F-I). Furthermore, we could also demonstrate that rab7 knockdown strongly blocked endogenous Wnt target gene activation, as monitored using a ventral mesodermal BAR reporter signal (Fig. 5G). Finally, ventx1 expression was also reduced after ventral injections (Figs. 3D-F and S4E-G), which is in agreement with a recent report showing such a reduction of ventx1 after ventral loss of (zygotic) wnt8a (Nakamura et al., 2016). From these experiments we conclude that rab7 participates in ventral mesoderm specification by acting as a necessary factor for Wnt activation. This effect on mesoderm specification was phenocopied by loss of LE-associated ESCRT factors vps4 and hrs, which are known to be required for Wnt pathway
activation (Taelman et al., 2010). As we could demonstrate an additive relationship with loss of rab7 (Fig. 6), we conclude that Rab7 fulfills this role as an endosomal regulator required for correct LE-mediated Wnt transduction (Dobrowolski and De Robertis, 2011; Hikasa and Sokol, 2013).

The connection of Rab7 to other signaling pathways – beyond Wnt activation

While our findings about a role of Rab7 in Xenopus Wnt pathway activation seem clear for exogenously induced and for endogenous ventral mesoderm specification, some results with dorsal marker gene might indicate further, perhaps Wnt-independent roles of Rab7 during gastrulation. While dorsal loss of rab7 resulted in gastrulation and CE defects, selective downregulation of shh seems puzzling (Fig. 2Q-S). Regulation of shh in the ventral neural tube is well-analyzed (Dessaud et al., 2008), however, surprisingly little was reported about induction and maintenance of its notochordal expression. Activin was shown to be able to induce shh in animal caps, but not endogenously in the mesoderm (Yokota et al., 1995), and we have no evidence for a participation of Rab7 in TGF-β pathways for now. Yet, in the well-studied limb bud, Wnt7a has been shown to be required for induction and/or maintenance of shh, offering a potential link to our observations (Parr and McMahon, 1995; Yang et al.). Another interesting aspect also comes from the limb bud, where fibroblast growth factor (FGF) signaling was reported both, to induce and to maintain shh expression (Scherz et al., 2004; Vogel et al., 1996; Yang et al.). FGF signaling is known to cooperate with Wnt in different contexts, and both are required additively to induce myf5 in the somitic mesoderm (e.g. Shi et al., 2002). Thus, if rab7 also participated in FGF pathway activation in some way, this would explain the strong effect on myf5 after loss of function – and the differential impact on nodal3 versus foxj1 and tbxt (Fig. 3G-R). All depend on Wnt signaling, but only tbxt and foxj1 have been shown to be regulated by the FGF pathway dorsally, downstream of Nodal3-induced activation of Fgf receptor 1 (Glinka et al., 1996; Schneider et al., 2019; Smith et al., 1995; Vick et al., 2018; Yokota et al., 2003)!

Materials and methods

Xenopus laevis care and maintenance

Frogs were purchased from Nasco (901 Janesville Avenue P.O. Box 901 Fort Atkinson). Handling, care and experimental manipulations of animals was approved by the Regional Government Stuttgart, Germany (V349/18ZO ‘Xenopus Embryonen in der Forschung’), according to German regulations and laws (§6, article 1, sentence 2, nr. 4 of the animal protection act). Animals were kept at the appropriate conditions (pH=7.7, 20°C) at a 12 h light cycle in the animal facility of the Institute of Zoology of the University of Hohenheim. Female frogs (4-15 years old) were injected subcutaneously with 300-700 units of human chorionic gonadotropin (hCG; Sigma), depending on weight and age, to induce ovulation. Sperm of male frogs was gained by dissection.
of the testes that was stored at 4°C in 1x MBSH (Modified Barth`s saline with HEPES) solution. Embryos were staged according to Nieuwkoop and Faber (1994). Only clutches of embryos from healthy females were used for the experiments reported here – provided the early embryonic stages showed normal survival rates as well. Individual embryos from one batch were randomly picked and used either as control or tested specimens. If control groups displayed unusual developmental defects later in development, such clutches were excluded as well, based on empirical judgement.

**Morpholino design and microinjections**

The rab7-5'UTR-/TB-MO was designed using the sequence of the S-form from the genomic sequence as deposited in gene bank (one mismatched base pair for the L-Form). TB-MO-sequence is 5'-GTCTCGCTTTCTACCCCTGCCAGC-3'. The rab7-SB-MO was designed using the sequence of the L-Form from the genomic sequence as deposited in gene bank (three mismatched base pairs for the S-Form). Splice acceptor site at intron 2 of the rab7 pre-mRNA is targeted by SB-MO (5'-GCCAACCCTAGAATGGAAGATACAA-3'). Further MOs used in this study were ctnnb1- and hrs-MO as published (Heasman et al., 2000; Taelman et al., 2010) or a random co-MO as a MO fill up for epistatic analyses. Generally, embryos were injected at the 4-cell stage into both dorsal or ventral blastomeres, respectively, unless indicated differently, using a Harvard Apparatus setup. Drop size was calibrated to 4 nl per injection. Total amounts of injected MOs were: 0.4 pmol ctnnb1-MO (suboptimal dose), 0.8 pmol ctnnb1-MO (optimal dose), 1.6-2.0 pmol hrs-MO, 0.7 pmol rab7-TB-MO (suboptimal), 1.0-1.4 pmol rab7-TB-MO (optimal), 1.4-4.0 pmol rab7-SB-MO.

**mRNA synthesis and microinjections**

Plasmids were linearized with NotI and transcribed in vitro (Sp6 polymerase) using Ambion message machine kit. Drop size was calibrated to 4 nl per injection. Total amounts of injected mRNA per embryo are as followed: 80 pg ca-rab7 mRNA, 400 pg dnvp4 mRNA, 400 pg GFP mRNA, 160 pg wnt8a mRNA

**sgRNA design and microinjections**

Two single guide RNAs were designed for the *Xenopus laevis* rab7a gene, rab7-CRNP (S+L), target sequence: 5'-GGTGATGGTGGATGACAGAT TGG-3' (on exon 3), and rab7-CRNP (L), target sequence: 5'-GGGACACAGCTGGGCAGGAA AGG-3' (on exon 4), using the publicly available ‘CRISPscan’ software. sgRNAs were transcribed with the MEGAshortscript T7 Kit from synthetic DNA oligomers and purified with the MEGAClear Transcription Clean-Up Kit (both ThermoFisher).

Oligos for synthesis were: rab7-CRNP (S+L) Forward: 5'-GCAGCTAATACGACTCACTATAGGTGATGGTGGATGACAGATTTTCTAGAGCTAGAAATAGGAG-3, rab7-CRNP (L) Forward 5'-GCAGCTAATACGACTCACTATAGGGACACAGCTGGGCAGGAAAGTTTTAGAGCTAGAAATAGCAAG-3', and general Reverse_5'-AAAAGCACCAGACTCGTGTCGCCACTTTTCTAAGGTGATAACCGACTAGCCTTATTCTTTATTTCTTAACTCCTTCTTCTTCTAAAAAC -3'

Embryos were injected with 1 ng Cas9 protein (PNA Bio) and 300 pg sgRNA at 1-cell stage and cultivated at room temperature until desired stage. DNA was isolated from 10 mutant or 5 control embryos. For verification of successful genome editing, isolated DNA was proceeded by RT-PCR and sequenced. Analysis of sequenced DNA was analyzed via Synthego ICE. PCR-Primers for sequencing were the following: rab7-CRNP(S+L), L-form (FP 5'-AGCCGTATTTCTTTGTGTGCCA-3'; RP 5'-ATCCAGGTGACTGATGATGT-3'), rab7-CRNP(S+L), S-form (FP 5'-TGAGTGCATTGTGTGGTG-3'; RP 5'-
For verification of SB-MO, a standard RT-PCR was performed. SB-MO was injected in all 4 blastomeres of 4-cell embryos, cultivated until st. 13, and fixed for RNA isolation. Following PCR primers were used: Forward 5'-CCTCCAGGAATATGCAGGAA-3'; Reverse 5'-CTGCATTGTGACCAATCTGTC-3'

Luciferase based Wnt assay

For Luciferase based Wnt assay (Promega Dual-Luciferase® Reporter Assay System), embryos were injected into two animal or ventral blastomeres at 4-cell stage (80 pg BAR reporter DNA plus 40 pg Renilla DNA). For exogenously induced reporter activity, embryos were injected of 240 pg wnt8a mRNA +/- 1.4 pmol rab7-TB-MO and cultivated until stage 10.5, then animal caps were dissected and further processed. For endogenous analysis, embryos were co-injected with rab7-TB-MO, cultivated until st. 12, the ventral halves were dissected. Dissection of tissues was performed in 0.1x MBSH. Extracted tissues (10 animal caps or ventral halves) were transferred into lysis buffer (Promega) and incubated for 15 min. Lysates were centrifuged repeatedly for 15 min, then supernatant transferred in triplets onto a 96-well plate for Luciferase analysis by the GloMax Explorer system. Relative luciferase units (RLU in [%]) were calculated by the ratio of Luciferase and Renilla values.

In situ Hybridization

For in situ mRNA detection, ISH was performed after fixation in MEMFA for 2-3 h at room temperature and processed following a customized standard protocol (Sive et al., 2000; customization after R. Rupp, personal communication). RNA in situ probes were transcribed using SP6 or T7 polymerases.

Axis induction Assay

Double axis assay was performed by single injection of 0.8 pg wnt3a mRNA +/- 0.7 pmol rab7-TB-MO into one ventral mesodermal blastomere at 4-cell stage as described (Beyer et al., 2012). Embryos were raised until gastrulation or neurula stage. Double axes were scored empirically by second ventral gsc expression (early gastrula) and for visible induction of secondary axes (late neurulas).

Embryo sections

For vibratome sections, embryos were embedded in a glutaraldehyde-crosslinked gelatin-albumin mix and razor blade-sectioned. Hoechst stained vibratome sections were incubated on microscope slide before imaging (1:10000 Hoechst). Bisections of embryos was performed using a razor blade.

Immunofluorescence Analysis

Co-injected fluorescein dextran (70,000 MW, ThermoFisher, D1822) was used as lineage tracer for dorsal lips in IF analyses. For IF analyses, embryos were fixed in 4% paraformaldehyde for 1 h at RT, followed by 2 washes in 1x PBS- for 15 min each. For staining of animal caps or bisected specimens, embryos were manually dissected horizontally or sagittally after fixation, transferred to 24 well plates, and washed twice for 15 min in PBST (PBS/0.1% Triton X-100). After blocking for 2h at RT in CAS-Block (1:10 in PBST; ThermoFisher, #008120) blocking reagent was replaced by antibody solution (diluted in CAS-Block) for incubation ON at 4°C. Antibodies used were: β1-integrin (DSHB 8C8-s; 1:70), Ctnnb1 (clone H102; Santa Cruz Biotechnology sc-7199; 1:200), MZ-15 (DSHB; 1:200). Then antibody solution was removed and explants washed twice for 15
min in PBS. Secondary antibodies (ThermoFisher, all 1:1000 in CAS-Block) were incubated for 2 h at RT. Cell borders were visualized using AlexaFluor™ Plus 405 Phalloidin (ThermoFisher A30104) overnight at 4°C (1:100 in PBS). For photo documentation, bisected embryos or caps were transferred onto microscope slides or positioned in low melt agarose on a Petri dish (0.5% low melt agarose in 1x PBS).

**Photo Documentation**
LSM images of IF data were taken with a Zeiss LSM 700 Axioplan2 Imaging microscope and then adjusted using the Zeiss Zen 2012 Blue edition. All other pictures were taken with a Zeiss SteREO Discovery.V12 microscope or an Axioplan2 inverted microscope using AxioVision 4.6. Afterwards Adobe Photoshop CS6 was used for cropping and careful brightness adjustments. All figures were arranged using Adobe Illustrator CS6.

**Statistical analysis**
Statistical calculations of marker gene expression patterns were performed using Pearson’s chi-square test (Bonferroni corrected, if required). *=p<0.05, **=p<0.01, ***=p<0.001 were used for all statistical analyses, as well as the declaration N = the number of experiments (i.e. number of biological replicates of batches of embryos from different fertilizations), and n = the number of embryos analyzed (i.e. number of biological replicates of embryos).
