ABSTRACT

Shotgun proteomics techniques infer the presence and quantity of proteins using peptide proxies, which are produced by cleavage of all isolated protein by a protease. Most protein quantitation strategies assume that multiple peptides derived from a protein will behave quantitatively similar across treatment groups, but this assumption may be false for biological or technical reasons. Here, I describe a strategy called peptide correlation analysis (PeCorA) that detects quantitative disagreements between peptides mapped to the same protein. Simple linear models are used to assess whether the slope of a peptide's change across treatment groups differs from the slope of all other peptides assigned to the same protein. Reanalysis of proteomic data from primary mouse microglia with PeCorA revealed that about 15% of proteins contain one discordant peptide. Inspection of the discordant peptides shows utility of PeCorA for direct and indirect detection of regulated PTMs, and also for discovery of poorly quantified peptides that should be excluded. PeCorA can be applied to an arbitrary list of quantified peptides, and is freely available as a script written in R.

Introduction

Shotgun proteomics relies on the inference of protein identity and quantity from peptide pieces. Proteins are regulated before mRNA translation through alternative splicing of mRNA transcripts, and after translation by post-translational modifications (PTMs); thus, different subsections of the whole protein sequence might be influenced differently by biological perturbations. Such fine-grained protein regulation may be responsible for the diversity of function from our genome, and enables precise control of metabolism and gene expression. However, proteomic analysis is almost entirely based on combining multiple peptide quantities unique to a protein into one quantity[1,2].

Although the magnitude of peptide abundance will differ due to different detection sensitivity[3,4], most protein quantitation strategies assume that multiple peptides derived from a protein will behave quantitatively similar across treatment groups. For example, if a treatment causes a protein to increase, we assume that all peptides mapped to that protein will increase (**Figure 1A**). Because each protein encoded by a gene exists as a population of unique states, called proteoforms[5], there are many biological reasons that multiple peptides from a protein may disagree quantitatively. For example, a change in the proportions of one gene's proteoforms (i.e. post-translational modification[6] or alternative splicing[7,8]) across biological conditions might result in differences in quantities for peptides that harbor those protein subregions. For example, if a protein quantity is unchanged, but one PTM site is increased with our treatment, that would cause the apparent disappearance of the peptide sequence that harbors that PTM (**Figure 1B**). Further, analytical problems during both sample preparation and data analysis can produce low quality peptide quantitation for a subset of peptides mapped to a protein, which would be desirable to remove[9]. Therefore, strategies are needed to assess concordance of quantitation for multiple peptides mapping to the same protein.

This work presents a simple strategy called peptide correlation analysis (PeCorA) to detect peptides with discordant quantitation across treatment groups. PeCorA uses a linear model to statistically assess the interaction between peptide and treatment groups. Peptides with quantitative patterns that differ from all other peptides in that protein are reported as potentially interesting. Examples of those peptides include direct detection of a regulated methionine oxidation in PKA R1α, indirect detection of a lost phosphorylation in VAV1 protein, and incorrect peak picking of a peptide from CALR. PeCorA can be easily applied to any dataset and is freely available implemented in R.

EXPERIMENTAL

Data. Raw proteomic data from a published study of mouse primary microglia[10] was downloaded from the Pride repository[11] (identifier PXD014466, https://www.ebi.ac.uk/pride/archive/projects/PXD014466). The data set was composed of five biological replicates each from three sample groups: control, 50 mM ethanol treatment, or 5 ng lipopolysaccharide (LPS) treatment (15 total files). Each sample was analyzed with a 120-minute liquid chromatography gradient and online electrospray ionization into a hybrid quadrupole-orbitrap mass spectrometer (Q-Exactive Plus). Please see the original publication for more data collection and sample preparation details.

Peptide Identification by database search of MS/MS spectra. All raw files from the microglia dataset were converted to mzML format using msconvertGUI (part of ProteoWizard)[12] and searched against mouse proteins including isoforms downloaded from uniprot (04/08/20) with MS-Fragger version 2.4[13]. Reversed protein sequences and common contaminants were added to the database by the Philosopher

Peptide quantification. Filtered peptide
identifications were imported into Skyline for
quantification[16] by MS1 filtering[17,18]. Only
protein identifications supported by two
peptides were included, and peptides that
were not unique to only one protein
accession were excluded. Precursor signal
within 10 ppm of the theoretical peptide
mass for charge states 2-5 was extracted
within 5 minutes of peptide identifications,
and peaks were automatically picked by the
software.

Peptide Correlation Analysis (PeCorA).
Total peak area for each peptide precursor
was exported from Skyline (report template
PeCorA.skyr available with data repository)
with the protein annotation, condition group,
biological replicate number, and charge
state. This report was read into R for
processing. First, the values were filtered to
include only precursors with measured MS1
areas in all samples. Next, the peak areas
were log transformed, and the global
distribution of all peak areas was scaled to

**Figure 1: Protein quantification based on
multiple measures of peptide parts.** In
shotgun proteomics, peptides are produced
from proteins by proteases, and then the
quantities of those peptides are used as a
proxy for the protein. (A) Illustration of the
case where a protein is increased by a
biological treatment. The quantitative values
from multiple peptides from one protein
change in the same direction across
biological treatment groups. (B) Illustration
of the case where a protein modification is
increased due to a biological treatment, but
the protein quantity is unchanged. The
quantitative values for multiple peptides
from that one protein disagree.

have the same center. After global scaling, each peptide scaling was performed to center each peptide relative to the mean of the control group's peak area. This twice-scaled data was then used for peptide correlation analysis. At a high level, the slope of each peptide's quantity across experimental conditions was compared with the slope of all other peptides measured from that protein. This was achieved by iteratively setting each peptide to its own factor group against the factor group of all other peptides, and then fitting a linear model that includes a term for the interaction between the peptide groups. The p-value of significance for an interaction was recorded for each peptide group in each iteration of the loop before moving to set the next peptide as the out group. All p-values for the peptide interaction terms within one protein were then correction with the Benjamini-Hochberg procedure[19].

Data and code availability. Peptide correlation analysis code is written in R and available on github from https://github.com/jessegmeyerlab/PeCorA. The github repository also contains the Skyline report template (skyr), skyline report from microglia data used here, and PeCorA outputs from analysis of the microglia data used here. The raw mass spectrometry data from the microglia dataset is available from the Pride repository of the original publication (PXD014466), and also on massive.ucsd.edu (dataset MSV000085712). The skyline file used to generate peptide areas from microglia data is available on Panorama at: https://panoramaweb.org/HRvw2O.url.

RESULTS

The first step in PeCorA is data preparation. The global distribution of data is scaled to have the same center (**Figure 2A**), and then each peptide is scaled to the center of the control condition (**Figure 2B**). The former is standard practice in large-scale omics experiments, and the latter is

required for PeCorA because we must align all peptides to the same scale if we want to accurately test if each peptide is different than all other peptides. Peptide scaling removes the spread of peptide quantities that results from differences in ionization efficiencies, and results in a much tighter distribution of peptide quantities for each protein. After the data is scaled, the PeCorA algorithm iteratively compares each peptide to all other peptides in the same protein (pseudocode in **Figure 2C**). At a high level, the slope of each peptide quantity is compared with the slope of all other peptide quantities across biological conditions using a linear model that includes an interaction term between the treatment and peptide groups. This enables calculation of a p-value testing whether each peptide agrees quantitatively with the group of all other peptides in that protein. All p-values for all peptides are recorded, and then multiple hypothesis testing is applied to adjust the distribution. Comparing the interaction p-value with and without peptide scaling demonstrates the improved statistical power (**Figure 2D**). Peptide quantities from the same protein (Psmd14) are used in **Figure 2B** and **Figure 2D** to illustrate these concepts. Thus, PeCorA is an algorithm that determines statistically whether a peptide's quantity across experimental treatments disagrees with other peptides assigned to the same protein.

The frequency of quantitative peptide disagreements in a dataset is useful first analysis to understand the potential utility of PeCorA. In total, after excluding peptides that map to multiple proteins, qualitative analysis of this dataset from microglia discovered a total of 27,685 peptides that map to a total of 2,918 proteins (requiring at least 2 peptides per protein). Data was further filtered to keep only peptides with peak areas over 100, and only peptides with quantities in all replicates, which left 26,444 peptides from 2,858 proteins. Of those, 416 proteins were found to harbor at least one peptide that disagreed with the other peptides in that

Figure 2: Peptide correlation analysis (PeCorA) to detect differentially modified peptides. (A) First, global data distributions are scaled to be centered around zero. (B) Next, each peptide is scaled to the mean of the control group to produce a unitless relative peptide quantity across groups. This helps correct the problem of differential peptide ionization and detection efficiency to produce more uniform data distributions. (C) Third, the quantitative values of one peptide from a protein is compared with the quantities of all other peptides in that protein using a linear model with a term for the interaction between peptides and biological treatment groups. This is repeated in a loop to compare each peptide to all other peptides. The p-value of the interaction is used to determine whether the quantity of each peptide is statistically different from all other peptides in that protein. (D) Example of one peptide that is statistically different from the quantities of all the other peptides. The p-value of the interaction between peptide and treatment group decreases when peptide scaling aligns the data.

protein, which corresponds to about 15% of quantified proteins. From the perspective of quantified peptides, the frequency of disagreement is much lower; 489 of the 26,444 peptides, or 1.9%, were found to disagree quantitatively with the other peptides mapped to the same protein. Overall, these results suggest that quantitative disagreements are rare at the peptide level, but relatively common from

the protein perspective. Further investigation of these results reveal how PeCorA can discover multiple types of interesting peptide disagreements in a quantitative proteomics dataset: (1) direct evidence of regulated PTMs, (2) indirect evidence of regulated PTMs, and (3) incorrect peak picking.

As an example of direct evidence for a regulated PTM discovered by PeCorA, the peptide with the most significant adjusted p-value was from PKA R1α and contained methionine 331 oxidation (**Table S1, Figure 3A**). This peptide was detected with and without the oxidation, but only the oxidized peptide was increased due to LPS stimulation. PKA R1α is thought to be regulated by oxidative stress [20–22], and the finding that LPS can induce this site-specific oxidation may prove to be yet another mechanism by which cellular metabolism is tuned. This site M331 is on the surface of second nucleotide binding domain (CNB-B) near the cAMP binding site[23], and could regulate cAMP binding or protein-protein interactions (**Figure 3B**). This example of direct observation of this regulated PTM site uncovered by PeCorA would be missed using standard protein quantity summaries based on grouped peptide quantities.

As an example of indirect evidence for an altered PTM, a peptide from the proto-oncogene Vav1 was found to increase due to LPS treatment (**Figure 3C**). Vav1 is known to signal downstream of tyrosine kinases, and this peptide revealed by PeCorA contained two known phosphorylation sites, pY110 and pS113. Prior literature provides strong evidence that this change in the unmodified peptide quantity may reflect a change in the abundance of the phosphorylated peptide form. Vav1 pY110 was decreased with IL-33 stimulation by 33%[24], and IL-33 has been suggested as the signal mediating microglial response to LPS[25]. A decrease in the phosphorylation of this peptide would appear as an increase in the unmodified peptide quantified here. Further work is needed to verify if the peptide containing this phosphotyrosine is indeed altered in microglia in response to LPS stimulation, but the current evidence allows generation of hypothesis that unobserved PTMs are changing.

A third example shows the utility of PeCorA for quality control of peptide quantification. Due to the large number of peptides in any proteomics experiment, automated peak picking is required for quantification, which undoubtably leads to errors. In fact, active research is ongoing to develop methods that detect and exclude poorly quantified signals[9,26]. One peptide assigned to the protein Calreticulin (CALR) appeared to decrease due to LPS treatment (**Fig 3D**), but manual inspection of this peptide's areas in Skyline revealed that the wrong peak was chosen for most replicates (**Fig 3E**). In summary, PeCorA was found to reveal poorly quantified peptides, and may find use as a filter to improve protein-level quantification in shotgun proteomics experiments.

CONCLUSION

PeCorA is a new strategy to detect biologicially interesting protein sub-regions based on discordant peptide quantification across treatment groups. PeCorA is also useful for flagging peptides with poor quantitative reproducibility that should be excluded from analysis. PeCorA of proteomic data from mouse microglia treated with ethanol or LPS revealed that a significant proportion of proteins (15%) contain at least one peptide with discordant regulation. Such peptides may result from altered post-translational modification states, changes in protein sequence due to alternative splicing, or technical problems with peptide quantitation. PeCorA is an easy to use tool that should find widespread application to proteomic datasets.
