Abstract

Perspectives in conservation are based on a variety of value systems and normative postulates. Such differences in how people value nature and its components lead to different evaluations of the morality of conservation goals and approaches, and often underlie disagreements in the formulation and implementation of environmental management policies. Specifically, whether a specific conservation decision (e.g. killing feral cats to save birds threatened with extinction) is viewed as appropriate or not can vary among people with different value systems. Here, we present a conceptual, mathematical framework that is intended to serve as a heuristic tool to clarify normative postulates in conservation approaches based on the expected consequences of management. Although it is not intended to replace more complex philosophical discursive approaches and moral reasoning, its purpose is to highlight how fundamental differences between value systems can lead to different prioritizations of available management options and offer a common ground for discussion. We compare how management decisions would likely be viewed under three different idealised value systems (ecocentric conservation, new conservation, and sentientist conservation). We illustrate the utility of the framework by applying it to case studies involving invasive alien species, rewilding, and trophy hunting. By making value systems and their consequences in practice explicit, the framework facilitates debates on contested conservation issues. Finally, we believe dissecting the normative postulates on which conservation decisions are based will facilitate understanding and addressing conservation conflicts.

Keywords: environmental management; impact; invasive alien species; moral values; rewilding; speciesism; trophy hunting

INTRODUCTION

The consideration of the moral relationship between humans and nature and the consequent ethical obligations for conservation is relatively recent in Western culture. Environmental ethics only emerged as an academic discipline in the 1970s (Brennan and Lo, 2016) and the concepts of values, duty, and animal welfare, are now increasingly appreciated in applied ecology and conservation (e.g. Díaz et al., 2018; Dubois et al., 2017). These concepts are complex and the formulation and implementation of environmental management policies is often associated with conflicts between different groups of stakeholders and between people with different values and interests, for example for the management of charismatic alien species (Crowley et al., 2017; Jarić et al., 2020; Redpath et al., 2013). An examination of how value systems could be explicitly accounted for in decision making could offer opportunities for better identifying conflicts, potentially helping to resolve them, and overall improve environmental management.

Value systems consider more or less inclusive communities of moral patients (the elements with intrinsic or inherent value towards which humans, considered here as the community of moral agents, are considered to have obligations; in the following, we refer to the community of moral patients as the moral community, for simplification; Table 1), ranging from humans (anthropocentrism), to further incorporate sentient beings (sentientism), living beings (biocentrism), and collectives (such as species and ecosystems; ecocentrism) (Table 1, Figure 1). The definition of moral communities can also be influenced by additional elements (such as spatial elements in the case of nativism), and, at the assessor level, by personal experience. These value systems underlie different sets of explicit or implicit normative postulates that define different conservation approaches (e.g. Soulé, 1985). If the normative postulates of different value systems differ (and excluding considerations that moral reasoning, experience, etc., may change one's value system), conflicts can arise between different groups of stakeholders whose members share common moral values (e.g. Crowley et al., 2017). In particular, conservationists who value biodiversity *per se* [as defined initially by Soulé (1985), called hereafter 'traditional conservation' (Table 1)] can be at odds with those who value biodiversity based on human welfare and economic aspects [including 'new conservation' (Kareiva and Marvier, 2012)], leading to heated debates in the literature (Doak et al., 2015; Kareiva, 2014; Soulé, 2014), or

with those based on animal welfare ['conservation welfare' (Beausoleil et al., 2018), or, to a

certain extent, 'compassionate conservation' (Driscoll and Watson, 2019; Hayward et al., 2019;

Wallach et al., 2018)].

In the following, our aim is to conceptualize and decompose value systems in an explicit and

potentially quantifiable fashion using a common mathematical framework, and to explore their

repercussions for the perception of conservation management actions by stakeholders with

different value systems. We argue that doing so allows for explicit comparison between these

perceptions to identify sources of potential conflicts. First, we recapitulate four archetypal value

systems in environmental affairs and relate them to different conservation philosophies. Since

identifying commonalities in the perspectives of different parties is key in conflict management

(Redpath et al., 2013), we then introduce a formal framework to conceptualise these value

systems, and examine how it can be applied to clarify different perspectives. Finally, we discuss

opportunities for identifying commonalities between different value systems that may enable

identifying widely acceptable solutions to otherwise polarising issues.

Here, we will focus on a Western perspective of value systems that have been internationally

considered for environmental policies and the management of nature (e.g. Mace, 2014). The

archetypes of value systems and of conservation approaches were chosen for their importance in

the past and present literature and their clear differences, to illustrate our framework. We

acknowledge this is a small part of the global diversity of value systems. It would be interesting

to see if our framework could be applied to other contexts, to identify its limitations.

ENVIRONMENTAL ETHICS AND CONSERVATION

From the valuation of humans to that of ecosystems: a complex spectrum of

perspectives.

The Western perspective of moral valuation encompasses a diverse set of value systems with

respect to the components of nature that form the community of moral patients. Traditionally,

one can distinguish at least four archetypal value systems: anthropocentrism, sentientism,

biocentrism, and ecocentrism (Palmer et al., 2014; Rolston III, 2003) (Table 1; Figure 1).

Anthropocentrism values nature by the benefits it brings to people through ecosystem services,

which encompasses economic, biological, and cultural benefits humans can derive from nature

(Díaz et al., 2018). One justification for anthropocentrism is that humans are (arguably) the only

self-reflective moral beings, and people are therefore both the subject and object of ethics

(Rolston III, 2003), therefore constituting the moral community (Table 1). In an anthropocentric

system, individuals from non-human species only have value based on their benefits or

disservices for humans (instrumental or non-instrumental).

Sentientism considers that humans and all sentient animals value their life, and experience

pleasure, pain, and suffering. All sentient individuals should therefore also be part of the moral

community (i.e. have an intrinsic value). In this view, it is the sentience (e.g. measured through

cognitive ability, Singer, 2009), rather than species themselves, that has intrinsic value.

Biocentrism considers that life has intrinsic value. Although different perspectives on why life

has value exist (see e.g. Taylor, 2011), all living organisms are valued equally for being alive,

and not differently based on any other trait.

Some ecocentric, or holistic, value systems consider that ecological collectives, such as species

or ecosystems, have intrinsic value, independently from the individuals that comprise them.

Species can have different values, i.e. speciesism (Table 1), and these values can be influenced

by a multitude of factors, discussed in more details below.

In practice, the separation between these different archetypes is blurry, and values given to

different species may vary under the same general approach. For example, biocentrism can range

from complete egalitarianism between organisms, i.e. universalism (Table 1), to a gradual

valuation resembling sentientism. These four value systems can also interact with other systems

that use other criteria than the intrinsic characteristics of individuals to define the moral

community. For example, nativism is a system that values organisms indigenous to a spatial

location or an ecosystem over those that have been anthropogenically introduced. Nativism can

therefore interact with any of the four systems presented above to alter the value attributed to a

species in a given context. Finally, the attribution of values to individuals from different species

can be deeply embedded in the individual psychologies of the assessor (Palmer et al., 2014;

Waytz et al., 2019). Values and personal interests interact in making and expressing moral

judgements (Essl et al., 2017). Thus, the archetypes of value systems presented above are rarely

expressed in a clear and obvious fashion.

To account for the different elements that can be combined to create the concept of value, in the

following, we distinguish between 'intrinsic', 'inherent', and 'utilitarian', value (our definitions;

Table 1). Intrinsic value is the value possessed by an individual or collective as defined by one of

the systems above, and is therefore independent of context. Intrinsic value is based on objective

criteria (i.e. independent of the assessor), such as cognitive ability (but the choice of these

criteria is subjective). This has been termed "objective intrinsic value" by others (Sandler, 2012).

Inherent value is the value of an individual, species or ecosystem that results from the

combination of its intrinsic value (which can be considered to be null or non-existent) and

context-specific and subjective factors (note that other scholars have used 'inherent' differently,

e.g. Regan, 2004; Taylor, 1987; here it corresponds to what has also been termed "subjective

intrinsic value"; Sandler, 2012). These factors include charisma (Courchamp et al., 2018; Jarić et

al., 2020), anthropomorphism (Tam et al., 2013), organismic complexity (Proença et al., 2008),

neoteny (Stokes, 2007), cultural importance (Garibaldi and Turner, 2004), religion (Bhagwat et

al., 2011), or parochialism (Waytz et al., 2019), or more generally the relationship between

humans and elements of nature (Chan et al., 2016) (Table 1). For example, some alien species

that did not have any inherent value prior to their introduction have been incorporated in local

cultures, therefore providing them a novel and higher inherent value such as horses being linked

to a strong local cultural identity in some parts of the USA (Rikoon, 2006). Inherent value can

often be considered to be fixed at the time scale of a management action, but can nonetheless

vary over short time scales in some situations (see the example of the Oostvaardersplassen nature

reserve below). Utilitarian value is determined only from an anthropocentric perspective. It is

context-dependent and can change rapidly, for example in the case of commercial exploitation.

Moral valuation and the management of nature.

Conservation practices can historically be divided into three main categories, closely related to specific systems of moral valuation (Mace, 2014). At one extreme, a 'nature for itself' (Table 1) view mostly excludes humans from the assessment of the efficacy of conservation management actions. This ecocentric perspective is the foundation of traditional conservation as defined by Soulé (1985), and relies on the four following normative postulates: "diversity of organisms is good," "ecological complexity is good," "evolution is good," and "biotic diversity has intrinsic value" (Soulé, 1985). It historically underlies widely-used conservation tools, like the IUCN Red List of Threatened Species (IUCN, 2019), in which threat categories are defined in terms of probability of extinction (Mace and Lande, 1991) (i.e. a species-level criterion aimed at preserving biodiversity). Ecocentrism is often not limited to the valuation of species, but can encompass wider collectives, i.e. assemblages of species and functions, or ecosystems. This other perspective is captured, for example, by the IUCN Red List of Ecosystems (IUCN-CEM, 2016), and it is strongly reflected in international conservation-legislation such as the Convention on Biological Diversity (UNEP CBD, 2010). In the following we refer to traditional conservation as an ecocentric value system where species are intrinsically valuable (nature for itself; Figure 1) and humans are mostly excluded from management. We acknowledge that this is an archetypal view of traditional conservation, and is used here simply for illustrative purposes.

By contrast the anthropocentric 'nature for people' perspective (Mace, 2014) values species and ecosystems only to the extent that they contribute to the wellbeing of humans. These values encompass ecosystem services that help sustain human life (Bolund and Hunhammar, 1999) or economic assets (Fisher et al., 2008), and can rely on the assessment of species and ecosystem services in terms of their economic value (Costanza et al., 1997), which can be considered as the most general form of utilitarian value, and has also been termed economism (Norton, 2000). The 'nature for people' perspective can nonetheless incorporate additional measures linked to human wellbeing, such as poverty alleviation or political participation. This more holistic measure of impacts on humans is exemplified by 'new conservation', also termed 'social conservation' (Doak et al., 2015; Kareiva, 2014; Miller et al., 2011) (Table 1). It has been argued that such an anthropocentric perspective will, by extension, help and even be necessary to maximize the

conservation of nature (Kareiva and Marvier, 2012). This view was first laid out as the

convergence hypothesis (Norton, 1986). It is nonetheless important to note that the exact set of

normative postulates proposed by the proponents of new conservation is not clearly defined

(Miller et al., 2011), leading to differences of interpretation and heated debates in recent years

(Doak et al., 2015; Kareiva, 2014; Kareiva and Marvier, 2012; Soulé, 2014).

Environmental pragmatism (Katz and Light, 2013; Norton, 1984), proposed the notion of weak

anthropocentrism, in which the value of elements of the environment is not only utilitarian, but

defined by the relationship between humans and nature (Chan et al., 2016), and therefore is

influenced by context and people's experience (see also the notion of inherent value described

above). More recently, the necessity to account for the interdependence between the health of

nature and human wellbeing (i.e. 'people and nature' Mace, 2014) has been advocated in the

United Nations Sustainable Development Goals (Weitz et al., 2018). Similarly, "nature-based

solutions" is an approach endorsed by the IUCN, which aims at protecting, sustainably

managing, and restoring, natural or modified ecosystems, to simultaneously provide human

wellbeing and biodiversity benefits (Cohen-Shacham et al., 2016). The 'One Health' approach,

endorsed by the Food and Agriculture Organization, the World Health Organization, and the

World Organisation for Animal Health also acknowledges the interdependence between the state

of ecosystems and human health and zoonoses (Gibbs, 2014). The difference between people and

nature and new conservation approaches therefore lies in the fact that it merges anthropocentric

and ecocentric systems, rather than considering that the latter will be addressed by focusing on

the former (see Section "Nature despite/for/and people" below for details).

Finally, although the animal right movement, based on sentientism, originated in the 19th century

(Salt, 1894), it has not, to our knowledge, been formally considered in conservation approaches

until recently. Two main approaches can be found in the literature. Conservation welfare

(Beausoleil et al., 2018) is a consequentialist perspective that considers conservation under the

prism of animal welfare maximisation. Compassionate conservation (Ramp and Bekoff, 2015;

Wallach et al., 2018), also incorporates animal sentience, but from a virtue ethics perspective.

Although conservation welfare aims at aligning with more traditional conservation approaches

presented above (Beausoleil et al., 2018), compassionate conservation appears to be set on

different values and proposes, for example, to incorporate emotion to provide insight in
conservation (Batavia et al., 2021).

FRAMING MORAL VALUES FOR OBJECTIVE-DRIVEN
CONSERVATION

Formulation of a mathematical framework.

Many of the conflicts in conservation are grounded in the failure to identify and formalize
differences in world views, which contain elements of the four archetypes presented above,
influenced by cultural norms, economic incentives etc. (Essl et al., 2017). Here, we propose a
mathematical formulation as a method to clarify moral discourses in conservation, based on a
consequentialist perspective. We therefore consider an objective-driven type of conservation. Our
purpose is not to argue about the relevance of consequentialism vs. deontology, or on the place of
virtue ethics in conservation. Rather, we consider that, from a management perspective,
conservation necessarily includes objective-driven considerations. A better understanding of how
and why objectives can differ between stakeholders is therefore useful to anticipate and manage
potential conflicts. In particular, we argue that defining concepts as mathematical terms can
make differences in value systems and their normative postulates more transparent to all
participants of the discourse. Doing so can help to identify and facilitate the discussion of shared
values and incompatibilities between different environmental policies and management options
(Miller et al., 2011), and contribute to manage conflicts (Redpath et al., 2013). In a similar vein,
Parker et al. (1999) proposed a mathematical framework for assessing the environmental impacts
of alien species. This work was highly influential in the conceptualisation of biological invasions
(being cited over 2,000 times until April 2021 according to Google Scholar), rather than by its
direct quantitative application. We also acknowledge that this approach has specific limitations,
which are discussed below.

Our mathematical formalisation conceptualises the consequences of environmental management
actions. We argue that it can account for different value systems, including the anthropocentric,
sentientist, biocentric and species-based ecocentric systems (see Appendix S1 for an extension to

ecocentrism beyond species and considering wider collectives, i.e. ecosystems), while also

accounting for cultural and personal contexts. These consequences C can be conceptualised as a

combination of the impact of an action on the different species or individuals involved and the

value given to said species and individuals under different value systems as follows:

$$C = \sum_{species\ s} \bar{I}_s \times V_s \times N_s{}^a$$ Eq.1

where $\bar{I}_s$ is a function (e.g. mean, maximum, etc.) of the impact (direct and indirect) resulting

from the management action on all individuals of species s, V_s is the inherent value attributed to

an individual of species s (as described above), N_s is the abundance of species s, and a

determines the importance given to a species based on its abundance or rarity (and enables to

account for the importance of a species rather than an individual, see below). The unit of C

depends on how other parameters are defined, which themselves depend on the value system

considered. In summary, the higher the impact on species with high values, the higher the

consequences.

Inherent value V_s can have a monetary unit, or be unit-less, for example, depending on how it is

defined. Our definition of inherent value here is extremely broad, as the purpose of this work is

not to define what such value should be. Rather, it is flexible to encompass multiple perspectives

and the subjectivity of the assessor, and can be based on intrinsic, utilitarian or relational values

(Chan et al., 2016).

The parameter a can take both positive and negative values. A value of 1 means that

consequences are computed over individuals. If all values V_s were the same, $a = 1$ implies that all

individuals in the moral community (Table 1) weigh the same when computing C, irrespective of

the species they belong to. This is typical of individual-centred value systems, i.e. sentientism,

and biocentrism, whose characteristics (sentience and life) are defined at the individual level

(note that since anthropocentrism only includes individuals from one species as moral patients,

the term $N_s{}^a$ is irrelevant in this case). As a result, impacts on larger populations would weigh

more on the consequences. As a decreases towards 0, the correlation between the value of a

species and its abundance decreases. For $a = 0$, the consequence of a management action

becomes abundance-independent. For $a < 0$, rare species would be valued higher than common

species (or the same impact would be considered to be higher for rare species), for example due

to the higher risk of extinction. $a > 1$ would give a disproportionate weight to abundant species,

which are often important for providing ecosystem services (Gaston, 2010).

The impact I_s is computed at the individual level. It can be limited to the probability of death of

individuals or changes in per capita recruitment rate, thus allowing to compute a proxy for

extinction risk if $a \leq 0$, but can also include animal welfare, biophysical states, etc. Different

measures of impact can be considered under a same system of value, in which case Eq.1 should

be applied to each one separately (see section "Application of the mathematical framework"

below for details). I_s can only encompass the direct impact of a management action (in a narrow

view that only the direct impact of humans, i.e. the moral agents, should be considered, and that

the direct impacts from non-moral agents should not be considered), but also its indirect impact

resulting from biotic interactions (considering that, in the context of management and therefore

human actions, these indirect impacts are ultimately the result of the actions of the moral agents).

One would therefore need to define a baseline corresponding to either i) the lowest possible

measurable level of impact (e.g. being alive if death is the only measure of impact, or no sign of

disease and starvation for biophysical states; this would obviously be more complicated for

welfare), so that I would only be positive; ii) the current state of the system, in which case

impacts could be positive or negative for different species; or iii) the past state of a system, for

example prior to the introduction of alien species (see Rohwer and Marris, 2021 for a discussion

on the notion of ecosystem integrity). The duration over which to measure such impact should

also be determined. The exact quantification of impact will be influenced by different value

systems and personal subjectivity. Some impacts may be considered incommensurable (Essl et

al., 2017), therefore falling out of the scope of the framework. The average impact $\bar{I}_s$ over all

considered individuals from a species could be used as a measure at the species-level, as

different individuals may experience different impacts, if the management action targets only

part of a given population. Using the average impact is not without shortcomings though, since it

does not account for potential discrepancies in impacts suffered by different individuals in a

population. In other words, to which point do "the needs of the many outweigh the needs of the

few" (Littmann, 2016)? Other measures such as the maximum impact experienced by

individuals, or more complex functions accounting for the variability of impacts and values

across individuals of a same species may also be used, to account for potential disproportionate

impacts on a subset of the considered individuals. Under anthropocentric perspectives, impacts

are influenced by the utilitarian values of species.

Application of the mathematical framework.

For each measure of impact and each system of values, Equation 1 produces relative rather than

absolute values. The values of consequences C of a management action under different value

systems and measure of impact cannot be directly compared with each other, because the unit

and range of values of C can vary between value systems. Instead, Equation 1 can be used to

rank a set of management actions for each value system or measure of impact based on their

assessed consequences, to identify management actions representing consensus, compromises or

conflicts amongst value systems.

If different types of impacts are considered simultaneously under a value system, Equation 1

might rank management actions differently for these different impacts under the same system of

moral values, potentially leading to moral dilemmas. Similarly, some actions might not follow

moral norms compared to others despite having more desirable consequences. For example,

killing individuals may be considered less moral, but more efficient to preserve biodiversity or

ecosystem services than using landscape management. Solving these moral dilemmas is

complex, and beyond the scope of this publication, but approaches such as multi-criteria decision

analyses (MCDA, Huang et al., 2011) may offer avenue to do so (Goetghebeur and Wagner,

2017). Similarly, environmental conflicts will likely emerge when comparing the rankings

generated by Equation 1 under different value systems considering different distributions of

values, and different measures of impact. MCDA (Wittmer et al., 2006) and operational research

(Kunsch et al., 2009), have also been proposed to resolve such conflicts. We nonetheless argue

that, regardless of the capacity to resolve environmental conflicts (or moral dilemmas), being

able to understand where these conflicts emerge from in Equation 1 can only be beneficial for

decision making.

In the following, we show how, despite the difficulty to quantify the variables described above, this framework can be used as a heuristic tool to capture the implications of considering different value systems for determining the appropriateness of a conservation action, and to better understand conservation disputes.

NATURE DESPITE/FOR/AND PEOPLE

Over the past decade there has been some debate between proponents of traditional conservation, and those of new conservation (Table 1), as each group assumes different relationships between nature and people. Here, we show how the formal conceptualisation of Equation 1 could help clarifying the position of the new conservation approach in response to its criticisms (Kareiva, 2014).

Nature despite people and traditional conservation

Traditional conservation is based on an ecocentric value system and seeks to maximize diversity of organisms, ecological complexity, and to enable evolution (Soulé, 1985). For simplification, we will consider an extreme perspective of traditional conservation, championed by 'fortress conservation' (Büscher, 2016; Siurua, 2006), i.e. excluding humans from the moral community. To capture these aspects, consequences C in Equation 1 can be more specifically expressed as follows:

$$C = \sum_{\text{species s (excluding humans)}} \bar{I}_s \times V_s \times N_s^{\text{a}<0}$$ Eq. 2

Assigning a stronger weight to rare species ($a < 0$) accounts for the fact that rare species are more likely to go extinct, decreasing the diversity of organisms. Evolution and ecological complexity are not explicitly accounted for in Equation 2. To do so, one may adapt Equation 2 and consider lineages or functional groups instead of species as the unit over which impacts are aggregated.

Nature for people and new conservation

New conservation considers that many stakeholders ("resource users", Kareiva, 2014) tend to have an anthropocentric value system, and that conservation approaches that do not incorporate such a perspective will likely not succeed at maximizing diversity of organisms (Kareiva, 2014; Kareiva and Marvier, 2012). Under anthropocentrism, species are only conserved due to their utilitarian value, i.e. their effect on I for humans, rather than based on an inherent value V. Different groups of stakeholders are likely to be impacted differently (e.g. different monetary benefits / losses), and we propose the following extension of Equation 1 to account for this variability:

$$C = \sum_{\text{stakeholders } t} \bar{I}_t \times V_t \times N_t \qquad \text{Eq.3}$$

where $\bar{I}_t$ is the average impact of management on the group of stakeholders t, including indirect impacts through the effect of management of non-human species, V_t is the value of the group of stakeholders t, and N_t is its abundance. Note that including inherent values V_t in Equation 3 does not imply that we consider that different humans should be valued differently, but that is a view that some people have, and this needs to appear here to capture the full spectrum of perceived consequences of a management action.

New conservation holds an ambiguous perspective, stating that it should make "sure people benefit from conservation", while at the same time does not "want to replace biological-diversity based conservation with a humanitarian movement" (Kareiva, 2014). Using our framework, we interpret this as considering that one can design management actions that minimize consequences C under both Equations 2 and 3 (i.e. a mathematical expression of the convergence hypothesis; Norton, 1986). The link between biodiversity and ecosystem services is strongly supported, even if many unknowns remain (Cardinale et al., 2012; Chivian and Bernstein, 2008), implying that high biodiversity can indeed support the provision of ecosystem services to humans. Such an approach will necessarily distinguish between "useful" species and others, and impacts will be perceived differently by different groups of stakeholders. Considering multiple types of impacts (economic benefits/losses, access to nature, health, etc.) while accounting for cultural

differences, would increase the pool of useful species (comparing the resulting equation outputs

using, for example, MCDA). The outcome of the two approaches would then potentially be more

aligned with each other. This broad utilitarian perspective is captured in the most recent

developments of new conservation approaches, which consider a wide range of nature

contributions to people, rather than just ecosystem services (Díaz et al., 2018).

People and nature

People and nature views seek to simultaneously benefit human wellbeing and biodiversity. Under

this perspective, Equations 2 and 3 should therefore be combined in a single approach, for

example using MCDA (Huang et al., 2011), to capture a more diverse set of value systems than

Equations 2 and 3 alone, even if the two approaches generate divergent results.

We expressed traditional and new conservation with Equations 2 and 3, which correspond to

extreme interpretations of these two approaches (excluding humans or considering specific

utilities of species). Doing so illustrates how our mathematical framework can capture in an

explicit fashion the pitfalls of failing to explicitly define normative postulates for conservation

approaches. As a result, Equations 2 and 3 will likely generate conflicting results in the ranking

of different management actions, especially if few types of impacts are considered. The debates

over new conservation have taken place in a discursive fashion, which has not provided a clear

answer to the values defended by this approach (Doak et al., 2015; Kareiva, 2014; Soulé, 2014).

It has therefore been argued that the normative postulates of new conservation need to be more

explicitly defined (Miller et al., 2011). Our framework could help doing so, by being more

explicit about how new conservation would be defined relative to the traditional conservation

and the people and nature perspective through the addition of specific terms to Equation 3 and a

thorough comparison of the resulting equations. In particular, it would be interesting to explore,

if inherent values are attributed to different species under a new conservation approach, how

these values are determined compared to a traditional conservation approach (e.g. relational vs.

intrinsic value; Chan et al., 2016) and how their distributions differ.

THE CASE OF ANIMAL WELFARE

The question of if and how animal welfare should be integrated into conservation practice is increasingly debated (e.g. Hampton and Hyndman, 2018). Recently, conservation welfare (Table 1) has proposed to consider both the "fitness" (physical states) and "feelings" (mental experiences) of non-human individuals in conservation practice (Beausoleil et al., 2018). Based on virtue ethics rather than consequentialism, compassionate conservation (Table 1) also emphasises animal welfare and is based on the "growing recognition of the intrinsic value of conscious and sentient animals" (Wallach et al., 2018). It opposes the killing of sentient invasive alien species; the killing of sentient native predators threatening endangered species; or the killing of sentient individuals from a given population to fund broader conservation goals.

Despite the near-universal support of conservation practitioners and scientists for compassion towards wildlife and ensuring animal welfare (e.g. Hayward et al., 2019; Oommen et al., 2019; Russell et al., 2016), compassionate conservation has sparked vigorous responses (Driscoll and Watson, 2019; Griffin et al., 2020; Hampton et al., 2018; Hayward et al., 2019; Oommen et al., 2019). Amongst the main criticisms of compassionate conservation is that the absence of action can result in unintended detrimental effects and increased suffering for individuals of other or the same species (including humans), as a result of altered biotic interactions across multiple trophic levels, i.e. "not doing anything" is an active choice that has consequences (Table 2). However, since compassionate conservation is not based on consequentialism, it uses different criteria to assess the appropriateness of conservations actions (but see Wallach et al., 2020 for responses to some criticisms). Our purpose here is not to discuss the relevance or irrelevance of virtue ethics for conservation (see Griffin et al., 2020 for such criticism). Instead, we propose discussing animal welfare from the perspective of consequentialism (Hampton et al., 2018), i.e. more aligned with the approach of conservation welfare (Beausoleil et al., 2018), and to show how it may be aligned with or oppose the traditional and new conservation approaches.

A mathematical conceptualisation of animal welfare

A consequentialist, sentientist perspective aims at maximizing happiness, or conversely minimising suffering, for all sentient beings, an approach also termed 'utilitarianism' (Singer,

1980; Varner, 2008). Suffering is therefore considered as a measure of impact (or, in

mathematical terms, impact is a function of suffering, which can be expressed as $I(S_s)$ in

Equation 1).

It has become widely accepted that animals experience emotions (de Waal, 2011). Emotions have

been shown to be linked to cognitive processes (Boissy and Lee, 2014), which differ greatly

among species (MacLean et al., 2012), and behavioural approaches have been used to evaluate

and grade emotional responses (e.g. Désiré et al., 2002; but see Shriver, 2006 and Bermond et al.,

2008 for different conclusions about the capacity of animals to experience suffering). We

therefore postulate that the quantification of suffering is conceptually feasible in the context of

the heuristic tool presented here. In a utilitarian approach, the inherent value of a species would

therefore be a function of its capacity to experience emotions and suffering E_s, which can be

expressed as $V(E_s)$ instead of V_s in Equation 1.

Under these considerations for defining impact and value of species, the consequences of a

conservation action can be computed as:

$$C = \sum_{\text{species } s} \overline{I(S_s)} \times V(E_s) \times N_s{}^{a=1}$$ Eq.4

Although $V(E_s)$ should be measured in an objective fashion, many factors may influence the

relationship between the inherent value and the emotional capacity of a species. For example,

high empathy (Table 1) from the observer will tend to make the distribution uniform, whereas

anthropomorphism and parochialism (Table 1) may lead to higher rating of the emotional

capacities of species phylogenetically close to humans or with which humans are more often in

contact, such as pets. Finally, we assumed that $a = 1$, to give equal importance to any individual

regardless of the abundance of its species, as suffering and wellbeing are usually considered at

the individual level (Beausoleil et al., 2018).

Assessing suffering in the presence and absence of conservation management actions

The short-term suffering resulting from pain and directly caused by lethal management actions,

such as the use of poison to control invasive alien species (Twigg and Parker, 2010) or the use of

firearms and traps to cull native species threatening other native species (e.g. Proulx et al., 2016)

or humans (e.g. Gibbs and Warren, 2015), is the most straightforward type of suffering that can

be assessed, and is usually sought to be minimised in all conservation approaches. Suffering can

have many other causes, and suffering of an individual may be assessed through a wide variety

of proxies, including access to food and water, death, number of dead kin for social animals,

physiological measurements of stress hormones, etc. Suffering can take various forms, and

commensurability can be an issue (Table 2), making the distinction between the morality of

lethal actions and non-lethal suffering complex. Non-lethal suffering can result from

unfavourable environmental conditions (e.g. leading to food deprivation) and occur over long

periods, while lethal actions could be carried out in a quick, non-painful fashion (e.g. Shao et al.,

2018), and even lead to improved animal welfare (Wilson and Edwards, 2019), but may be

deemed immoral.

The concept of animal welfare and how to measure it is extremely complex (Beausoleil et al.,

2018), and defining it precisely is beyond the scope of this study. We nonetheless advocate a

conceptual approach that takes into account indirect consequences of management actions within

a certain timeframe and consider uncertainty (Table 2). Direct and indirect biotic interactions

may be explicitly modelled to quantify the impact on animals and their suffering. Simulation

models can also make projections on how populations may change in time, accounting for future

suffering.

Are traditional conservation and animal welfare compatible?

It has been argued that sentientism and ecocentrism are not fully incompatible (Varner, 2011).

The relationship between biodiversity and animal suffering can be formalised more clearly using

the traditional conservation and the sentientist Equations 2 and 4, to explore if the same

management action can minimize the consequences evaluated using the two equations (see also

Appendix S2 for the application of the framework to theoretical cases). The main difference with

the traditional vs new conservation debate here is that Equations 2 and 4 share a number of

species, whereas the new conservation Equation 3 only contains humans, which are excluded

from Equation 2. Even though the variables of Equation 4 differ from those of Equation 2 (V and

I are computed differently, and the value of a is different), it is possible that these equations will

vary in similar way for different management actions due to their similar structure, although this

would depend on the variety of impacts on humans that are considered in Equation 3. Finally, as

for the people and nature approach, the consequences of sentientist and ecocentric approaches

can be evaluated in combination, as suggested by conservation welfare (Beausoleil et al., 2018),

using tools such as MCDA (Huang et al., 2011; Wittmer et al., 2006).

One issue that may be irreconcilable between ecocentric approaches such as traditional

conservation and approaches based on sentientism is the fate of rare and endangered species with

limited or no sentience. Under utilitarian sentientism, the conservation of non-sentient species

ranks lower than the conservation of sentient species, and consequently they are not included in

Equation 4. For example, endangered plant species that are not a resource for the maintenance of

sentient populations would receive no attention, as there would be few arguments for their

conservation. Traditional conservation would focus on their conservation, as they would have a

disproportionate impact in Equation 2, due to low abundance leading to a high value for $N^{a<0}$.

Finally, it is important to note that the current body of knowledge shows that the link between

biodiversity and animal welfare mentioned above especially applies to the increase of native

biodiversity. Local increase of biodiversity due to the introduction of alien species may only be

temporary due to extinction debt (Kuussaari et al., 2009) and often results in a reduction of

ecosystem functioning (Cardinale et al., 2012). Therefore, it is important to distinguish between

nativism (Table 1) and the detrimental effects of *invasive* alien species on biodiversity and

ecosystem functioning and services (Bellard et al., 2016). Nativism would result in increasing the

inherent value V_s of native species (Figure 1), whereas in the second case, insights from science

on the impact of invasive alien species would modify the distribution $I(S)$ rather than the

distribution V_s. This can also apply to native species whose impacts on other species, such as

predation, are increased through environmental changes (Carey et al., 2012).

UNRESOLVED QUESTIONS AND LIMITATIONS

This framework shares similarities with mathematical approaches used in conservation triage

(Bottrill et al., 2008), but has two crucial differences. First, conservation triage is an ecocentric

perspective with variables that are comparatively easy to quantify. Bottrill et al. (2008) provided

an example using phylogenetic diversity as a measure of value V, and a binomial value b to

quantify biodiversity benefit that can be interpreted as the presence or absence of a species (i.e. I

$= 1 / b$). Because it is ecocentric, local species abundance is not considered, which corresponds

to setting $a = 0$. In this example, consequences (C) in the general Equation 1 are therefore

defined simply by V / b.

In contrast, our framework allows much more flexibility to encompass a range of value systems,

as shown above. Given that the data needed for quantifying parameters of Equations 1 to 4

related to value, impact, emotional capacity and suffering are scarce and often very difficult to

measure, this framework in its current form would nonetheless be difficult to use as a

quantitative decision tool to evaluate alternative management actions, contrary to triage

equations. Rather, our equations decompose the question underlying many controversies around

management decisions in conservation: what or who is valued, how, and by how much?

There are nonetheless a number of approaches that may be used to develop quantification

schemes for the different parameters of the framework. Grading systems may be developed to

assess impact and suffering based on various indicators, including appearance, physiology, and

behaviour (Beausoleil et al., 2018; Broom, 1988). For assessing the value of different species,

questionnaires may be used to assess how different species are valued by people, and influenced

by their social and cultural background, similar to what has been done to assess species charisma

(e.g. Albert et al., 2018; Colléony et al., 2017). It will nonetheless be important to acknowledge

the corresponding uncertainties in the assessment of impact and value, differences in perception

among societal groups for different taxa and potential shifts in perception over time (Table 2).

The second difference from conservation triage is that the latter considers additional criteria that

were not addressed here, including feasibility, cost, and efficiency (including related

uncertainties). The combination of these different perspectives calls for appropriate methods to

include them all in decision making, which can be done using MCDA (Huang et al., 2011). Here, good communication and transparency of the decision process is key to achieve the highest possible acceptance across stakeholders, and to avoid biases in public perception (see case studies below for examples).

The issue of spatial and temporal scale also warrants consideration (Table 2). In the case of a species that may be detrimental to others in a given location but in decline globally, the spatial scale and the population considered for evaluating the terms of Equations 1 to 4 is crucial to determine appropriate management actions. Similarly, management actions may also result in a temporary decrease in welfare conditions for animals, which may increase later on (Ohl and Van der Staay, 2012), or the impacts may be manifested with a temporal lag. In that case, determining the appropriate time period over which to evaluate the terms of Equations 1 to 4 will not be straightforward. Impacts will be of different importance depending on whether they occur in the short- or long-term, especially since long-term impacts are harder to predict and involve higher uncertainty. Discount rates (Table 2) may therefore be applied, in a similar way they are applied to the future effects of climate change and carbon emissions (Essl et al., 2018), or to assess the impact of alien species (Essl et al., 2017).

Equations 1 to 4 assume that all individuals from a given species have the same value or emotional capacities (or use the average of the value across individuals). However, intraspecific differences in value may be important for conservation. For example, reproductively active individuals contributing to population growth/recovery may be given a higher value in an ecocentric perspective. Trophy hunters might prefer to hunt adult male deer with large antlers. Intraspecific value may also vary spatially, for example between individuals in nature reserves or in highly disturbed ecosystems. Equation 1 may therefore theoretically be adapted to use custom groups of individuals with specific values within species, similar to Equation 3.

Finally, it is crucial to account for biotic interactions in our framework to comprehensively assess the indirect impacts of management actions on different species (Table 2). Some species with low values V_s in a certain value system may be crucial for assessing the impact I_s on other species. These biotic interactions will therefore determine the time frame over which the

framework should be applied, as impacts on one species at a given time may have important
repercussions in the future. These biotic interactions can be complex, and several tools, such as
simulation models and ecological network analyses can be used to address them. Concepts such
as keystone species (Mills et al., 1993) can also offer a convenient way to overcome such
complexity by modifying V_s rather than $\bar{I}_s$. Let us assume that a management action will have a
direct impact on a keystone species, which will result in indirect impacts on multiple other
species with inherent values. Increasing the value of the keystone species can result in the same
assessment of C as to explicitly model the biotic interactions and compute the resulting indirect
impacts $\bar{I}_s$.

653

CASE STUDIES ILLUSTRATING ETHICAL CONFLICTS IN CONSERVATION DECISIONS

656
In the following, we present three case studies where conservation actions have either failed, had
adverse effects, or were controversial, and we explore how our framework can help to identify
normative postulates underlying these situations. Although these case studies have been
discussed at length in the articles and reports we cite, we argue that our framework helps
capturing the different components of the surrounding controversies in a more straightforward
and objective fashion than using a discursive and sometimes emotionally loaded language.

663
Invasive alien species management: the case of the alien grey squirrel in Italy

665
The grey squirrel (*Sciurus carolinensis*) is native to North America and was introduced in
various locations in Europe during the late nineteenth and the twentieth century (Bertolino,
2008). It threatens native European red squirrel (*Sciurus vulgaris*) populations through
competitive exclusion, and is also a vector of transmission of squirrel poxvirus in Great Britain
(Schuchert et al., 2014). Furthermore, it has wider impacts on woodlands and plantations,
reducing value of tree crops, and potentially affects bird populations through nest predation
(Bertolino, 2008).

Based on the impacts of the grey squirrel, an eradication campaign was implemented in 1997 in

Italy, with encouraging preliminary results (Genovesi and Bertolino, 2001). However, this

eradication campaign was halted by public pressure from animal rights movements. The strategy

of the animal rights activists consisted in (i) humanising the grey squirrel and using emotive

messages (referring to grey squirrels as "Cip and Ciop", the Italian names of the Walt Disney

"Chip and Dale" characters) and (ii) minimising or denying the effect of grey squirrel on native

taxa, especially the red squirrel (Genovesi and Bertolino, 2001). In addition, the activists did not

mention (iii) the difference in abundance between a small founding population of grey squirrels

that could be eradicated by managers, and a large population of native red squirrels that would be

extirpated or severely impacted by grey squirrels if control was not implemented.

Genovesi & Bertolino (2001) explain that the main reason for the failure of the species

management is a different perspective on primary values: the eradication approach was underlain

by species valuation, following traditional conservation, whereas the animal right activists and

the public were more sensitive to animal welfare. However, the application of our framework

reveals some inconsistencies in the animal right activists' arguments that could have been used to

advocate for the eradication approach. Translating this situation in our framework indicates that

(i) the humanisation of the grey squirrel consists of increasing the perception of its emotional

capacity $E_{gs} > E_{rs}$ (and therefore $V(E_{gs}) > V(E_{rs})$), (ii) minimising the impact of the grey squirrel

is equal to restricting the time scale to a short one and to likely minimising the amount of

suffering S caused by grey squirrels on other species, i.e. $S_{gs} = S_{rs}$ (and therefore $I(S_{gs}) = I(S_{rs})$)

without management and $S_{gs} > S_{rs}$ (and therefore $I(S_{gs}) > I(S_{rs})$) under management, and (iii) not

mentioning differences in species abundance corresponds to setting $a = 0$. Following these three

points, the consequences under management $C_m = I(S_{gs}) \times V(E_{gs}) + I(S_{rs}) \times V(E_{rs})$ are

higher than without management, due to the increase in $V(E_{gs})$ and $I(S_{gs})$. The application of our

framework therefore allows to clarify a discourse whose perception could otherwise be altered

because of techniques such as appeal to emotion.

The framework can thus be used to provide recommendations for what the advocates for the

eradication campaign would have needed to have done: i) increase the value E_{rs} of red squirrels

in a similar way as what was done for grey squirrels, so that their relative values compared to

grey squirrels would remain the same as before the communication campaign by the animal right

activists; ii) better explain the differences in animal suffering caused by the long-term presence

of the grey squirrel compared to the short-term, carefully designed euthanasia protocol, which

would avoid a subjective perception of the distribution of S; and iii) highlight the differences in

the number of individuals affected. The consequences would then be computed as $C = V(E_{gs}) \times$

$I(S_{gs}) \times N_{gs} + V(E_{rs}) \times I(S_{rs}) \times N_{rs}$. In that case, assuming for simplification the same

suffering through euthanasia for grey squirrels as red squirrels suffer from the grey squirrels, and

the same value to individuals of each species (i.e. avoiding nativism), the mere differences $N_{rs} >$

N_{gs} in abundance would lead to a higher value of C without management. This would further

increase by extending the impacts of grey squirrels to other species, as mentioned above.

A more fundamental issue, however, is that in some value systems it would not be acceptable to

actively kill individuals, even if that meant letting grey squirrels eliminate red squirrels over long

periods of time (e.g. Wallach et al., 2018). The reluctance to support indirectly positive

conservation programs is a common issue (Courchamp et al., 2017). Whether an acceptable

threshold on consequences over which killing individuals could be determined through

discussion would depend, in part, on the willingness of the affected parties to compromise.

De-domestication: the case of Oostvaardersplassen nature reserve

De-domestication, the intentional reintroduction of domesticated species to the wild is a recent

practice in conservation that raises new ethical questions related to the unique status of these

species (Gamborg et al., 2010). Oostvaardersplassen is a Dutch nature reserve where two

domesticated species of large herbivores (Heck cattle, *Bos primigenius*, and konik horses, *Equus*

ferus caballus) have been 'rewilded' in addition to the reintroduction of the red deer (*Cervus*

elaphus) to act as landscape engineers by grazing (ICMO2, 2010). The populations increased

rapidly, as natural predators are missing and population regulation was not conducted, as a result

of a 'non-intervention-strategy'. The project was widely criticized when a considerable number

of individuals died from starvation during a harsh winter, resulting in the introduction of

population reduction by culling weak animals in order to prevent starvation (other approaches,

such as the reintroduction of large predators were discarded due to lack of experience and too

many uncertainties in efficiency, ICMO2, 2010).

From a traditional conservation perspective, disregarding animal welfare and focusing on species

diversity and ecological restoration, the project was a success. The introduction of the three

herbivore species led to sustainable populations (despite high winter mortality events), and

ensured stability of bird populations without the need for further interventions (ICMO2, 2010),

i.e. the conditions of many species were improved (the impact was lowered), leading to lower

consequences C overall (Equation 2). However, the welfare of individuals from the three

charismatic large herbivorous species became a point of conflict. Interestingly, it appears that the

conflict was driven by a shift in attitude, from considering the herbivore species as a natural way

to manage the grasslands to being part of the ecosystem changed the value V_s, or by the

importance given to their emotional capacity E_s (Ohl and Van der Staay, 2012), therefore leading

to increasing the consequences $C = V(E_s) \times I(S_s) \times N_s{}^1$ under sentientism, with S_s and N_s

constant. Temporal changes in the distributions of the V and E variables should therefore be

taken into account when implementing conservation management actions, and even monitored

through time in a way similar to adaptive management approaches. Another possible explanation

for this shift in attitude is that the notion of responsibility (Table 2) affected the moral aspect of

culling that should then be considered in parallel to its consequences. If culling animals can be

considered acceptable in some cases, it may not be the case if these individuals were

purposefully introduced.

As a result, the reserve management has examined a number of sustainable measures to improve

the welfare of individuals from the three species (therefore decreasing S_s to compensate the

increase in V_s). Among those were recommendations to increase access to natural shelter in

neighbouring areas of woodland or forestry, to create shelter ridges to increase survival in winter

as an ethical and sustainable solution, and to use early culling to regulate populations and avoid

suffering from starvation in winter (ICMO2, 2010). This example shows how a combination of

two complementary management actions (the rewilding of the OVP and the provision of shelter)

led to minimised consequences under both the traditional conservation and the sentientist

Equations 2 and 4, whereas only rewilding would increase consequences under Equation 4.

Culling may still face opposition based on moral arguments though.

Trophy hunting

Trophy hunting, the use of charismatic species for hunting activities, has been argued to be good

for conservation when revenues are reinvested properly into nature protection and redistributed

across local communities, but faces criticisms for moral reasons (Di Minin et al., 2016; Lindsey

et al., 2007a). The action of killing some individuals to save others might be incompatible with a

deontological perspective, but, assuming a consequentialist perspective, the framework can be

applied to formalise the assessment of different management options (we are not considering

canned hunting here, the practice of farming animals for the specific purpose of being hunted).

In traditional conservation, trophy hunting is desirable if it directly contributes to the

maintenance of species diversity. The potential of trophy hunting to contribute to the

maintenance of biodiversity is via creating economic revenues, i.e. an anthropocentric

perspective, and it therefore falls under the umbrella of new conservation. In theory, trophy

hunting should lead to lower consequences than doing nothing for both the traditional and new

conservation (Equations 2 and 3), and therefore for the 'people and nature' approach, as they are

in this case not independent from each other (Lindsey et al., 2007b). Many social and biological

factors currently affect the efficacy of trophy hunting as a conservation tool. Corruption and

privatisation of the benefits have sometimes prevented the revenues to be reinvested into

conservation, but also to be redistributed across local communities, whereas doing so has been

shown to increase their participation in conservation actions with proven benefits for local

biodiversity (Di Minin et al., 2016). In other words, a decrease in the anthropocentric Equation 2

leads to a decrease in the ecocentric Equation 3. In addition, trophy hunting can lead to

unexpected evolutionary consequences (Coltman et al., 2003), overharvesting of young males

(Lindsey et al., 2007a), and disproportionate pressure on threatened species (Palazy et al., 2013,

2012, 2011) and therefore to population declines and potential detrimental effects on

biodiversity. Despite these issues, it has been argued that banning trophy hunting may create

replacement activities that would be more detrimental to biodiversity (Di Minin et al., 2016).

From an animal welfare perspective, trophy hunting appears to be in direct contradiction with a

decrease in animal suffering, and has been criticised by proponents of compassionate

conservation (Wallach et al., 2018). However, as for the culling of invasive alien species, we

suspect the story is more complex. First, there may be direct benefits for animal welfare, if

money from trophy hunting is reinvested in protection measures against poaching (which is

likely more detrimental to the hunted individuals). Second, to our knowledge, only few studies

have compared the welfare of individual animals to quantify the elements of the sentientist

Equation 4 (for example assessed through access to resources) in areas where trophy hunting is

practiced and where it is not. Given the links between biodiversity and animal welfare described

above, it seems plausible that good practice in trophy hunting may benefit the welfare of

individuals from other and from the same species.

CONCLUSIONS

A variety of value systems exist in conservation, which are based on different underlying

normative postulates and can differ between stakeholders, resulting in differing preferences for

conservation practices among people. Here, we have proposed a framework with a formal set of

equations to conceptualize and decompose these different perspectives from a consequentialist

point of view. In this framework, the different value systems supported by different conservation

approaches follow the same structure, but can differ in the variables that are used, and in the

values they are taking. While such a formalisation by necessity does not capture the full range of

complex and nuanced real-world situations in environmental decision-making, it provides a

method to make their underlying value systems and the resulting conflicts explicit and

transparent, which is essential for the planning and implementation of pro-active management.

The search for consensus in conservation can be counter-productive and favour status-quo

against pro-active management (Peterson et al., 2005), however our framework may help

identify hidden commonalities between seemingly antagonistic stances. We hope that this

framework can foster debates on contested conservation issues, and will ultimately contribute to

a broader appreciation of different viewpoints. In an increasingly complex world shaped by

human activities, this is becoming ever more important.

Tables

Table1. Glossary of terms as they are used for the purposes of this paper.

Term	Definition
Anthropocentrism (strong)	Value system that considers humans to be the sole, or primary, holder of moral standing, and therefore the concern of direct moral obligations. Non-human species are considered only to the extent that they affect the statisfation of felt preference of human individuals (Norton, 1984; Palmer et al., 2014; Rolston III, 2003).
Anthropocentrism (weak)	Value theory in which all values are "explained by reference to satisfaction of some felt preference of a human individual or by reference to its bearing upon the ideals which exist as elements in a world view essential to determinations of considered preferences" (Norton, 1984). That is, the value of an individual or species is not only exploitative, but incorporates human experience and the non-utilitarian relationship between humans and nature.
Anthropomorphism	"The attribution of human personality or characteristics to something non-human, like an animal, object, etc." (Oxford English Dictionary).
Biocentrism	Value system considering all living beings as the concern of direct moral obligations (Palmer et al., 2014; Rolston III, 2003).
Collectivism	Value system in which a group or collective has a higher value than the individuals that compose it (Wallach et al., 2018).
Compassionate conservation	Conservation approach inspired by virtue ethics based on four tenets: i) do no harm; ii) individuals matter; iii) inclusivity (the value of an individual is independent from the context of the population, e.g. nativity, rarity, etc.); and iv) peaceful coexistence (Ramp and Bekoff, 2015; Wallach et al., 2018).
Community of moral agents	The group of beings considered to have moral responsibility in their actions (Talbert, 2019). We consider it here to be restricted to humans.

Community of moral patients	The group of beings considered to have intrinsic moral value, and towards which moral agents have moral obligations (Warren, 2000). The size of the group (referred to as the moral community in this work, for simplification) depends on the value system. For example, the moral community is restricted to humans in case of Anthropocentrism.
Conservation welfare	Conservation approach aiming at minimizing animal suffering (Beausoleil et al., 2018).
Consequentialism	"An ethical doctrine which holds that the morality of an action is to be judged solely by its consequences" (Oxford English Dictionary).
Convergence hypothesis	"If the interests of the human species interpenetrate those of the living Earth, then it follows that anthropocentric and nonanthropocentric policies will converge in the indefinite future" (Norton, 1986).
Deontology	A normative ethical theory considering that "choices are morally required, forbidden, or permitted" (Alexander and Moore, 2016).
Ecocentrism	Value system considering that species, their assemblages and their functions, as well as more broadly ecosystems, rather than individuals, are the concern of direct moral obligations (Palmer et al., 2014; Rolston III, 2003).
Empathy	"The quality or power of projecting one's personality into or mentally identifying oneself with an object of contemplation, and so fully understanding or appreciating it." (Oxford English Dictionary). Empathy will influence the inherent value given to individuals from other species.
Impact (for the purposes of the framework, Eq.1)	Impact refers to any effect that modifies the wellbeing, health or resilience (for non-sentient beings) of an individual, from physical pain to emotional suffering and death (these notions being interrelated, but not equivalent).
Inherent value (our definition)	Value possessed by an individual or collective, accounting for the effects of multiple context-dependent factors (e.g. charisma, anthropomorphism, organismic complexity, neoteny, cultural importance, religion, or parochialism).

Intrinsic value	Value possessed by an individual or collective as defined by a system of moral valuation, such as anthropocentrism, sentientism, biocentrism or ecocentrism. Intrinsic value is context-independent, and based on objective criteria (but the choice of criteria is subjective).
Invasive alien species	"Plants, animals, pathogens and other organisms that are non-native to an ecosystem, and which may cause economic or environmental harm or adversely affect human health" (*Regulation (EU) No 1143/2014 of the European Parliament and of the Council of 22 October 2014 on the prevention and management of the introduction and spread of invasive alien species*).
Moral community	See "Community of moral patients".
Nativism	Value system considering that species that have evolved in a given location have a higher value in this location than species that have evolved somewhere else. In nativism, value varies spatially (Wallach et al., 2018).
Nature despite people	Management conceptual approach aiming at conserving biological diversity (focusing on species and habitats) specifically in response to human impacts on the environment, e.g. sustainable use (Mace, 2014).
Nature for itself	Management conceptual approach aiming at conserving biological diversity (focusing on wilderness and natural habitats) through human exclusion, for example through the creation of parks and protected areas (Mace, 2014).
Nature for people	Management conceptual approach aiming at conserving the components of nature beneficial to humans (focusing on ecosystems and their services) (Mace, 2014).
Neoteny	"The retention of juvenile characteristics in a (sexually) mature organism" (Oxford English Dictionary).
New conservation	Discipline aiming at preserving biological diversity through the conservation of natural elements providing services and contribution to human wellbeing (Kareiva, 2014; Kareiva and Marvier, 2012).

Normative postulate	Value statements that make up the basis of an ethic of appropriate attitudes toward other forms of life (Soulé, 1985).
Parochialism	Ideology in which moral regard is directed "towards socially closer and structurally tighter targets, relative to socially more distant and structurally looser targets", and, by extension, to species phylogenetically, cognitively, or in appearance closer to humans (Waytz et al., 2019).
People and nature	Management conceptual approach considering that humans and nature are interdependent and therefore aiming at achieving compromises in the conservation of nature and human wellbeing (Mace, 2014).
Sentience	The ability to experience phenomenal consciousness, i.e. the qualitative, subjective, experiential, or phenomenological aspects of conscious experience, rather than just the experience of pain and pleasure (Allen and Trestman, 2017).
Sentientism	Value system considering sentient beings as the concern of direct moral obligations (Palmer et al., 2014; Rolston III, 2003).
Speciesism	Value system in which some species are considered to have a higher value than others, for various possible reasons (Singer, 2009). Speciesism is often used to refer to the superiority of humans, which is a specific expression of speciesism as considered in this paper.
Suffering	Negative emotion, sometimes called emotional distress, experienced by sentient beings, and which can result from different causes, including but not limited to physical pain (Dawkins, 2008; Farah, 2008).
Traditional conservation	Discipline aiming at preserving biological diversity through the management of nature, and based on four value-driven normative postulates: "diversity of organisms is good," "ecological complexity is good," "evolution is good," and "biotic diversity has intrinsic value" (Soulé, 1985). Traditional conservation is rooted in ecocentrism.
Utilitarian value	Value given to an individual or collective by humans, based on its utility.
Virtue ethics	Ethical doctrine that emphasizes the virtues, or moral character as the reason for action (Hursthouse and Pettigrove, 2018).

Table 2. List of factors to consider regarding the effects of environmental management actions

from an environmental ethics perspective.

Factor	Influence on variables and outputs in Equations 1 to 5
Biotic interactions	The impact or suffering of individuals from one species can be caused by individuals from another species, either through direct or indirect interactions. Management actions can therefore also have non-trivial indirect impacts on some species.
Capacity to provide ecosystem services	The presence of a specific species may increase the fitness/welfare of other species through the ecosystem services it provides. Since these effects can be difficult to quantify explicitly, the value of such species may be increased in Equations 1 to 4 to account for them.
Discounting rate	Rate at which impacts that occur in the future lose importance.
Impact quantification and commensurability	How the impacts of management actions are quantified is also dependent on value systems, as some impacts (such as death) may be considered incommensurable to others (such as suffering).
Responsibility from previous actions	Previous human actions on certain species, such as reintroduction of domesticated species or the introduction of alien species can change the perception of the public and therefore change the inherent value attributed to these species, or change the morality of an action, in addition to obviously having an impact on these species.
Spatial scale	The spatial scale will change the abundance N and the number of species considered. As a result, a management action that is more beneficial than another at small scale may not be such at a larger scale, and reciprocally. Additionally, the spatial scale can change the inherent value of species, for example under nativism, or because of the range of cultures that are considered.
Temporal scale	The time frame over which the impact or the suffering of individuals is computed can change their values. Management actions may decrease welfare of individuals on the short term, but

	be beneficial on the long term once the ecosystem has stabilised. Similarly, not culling some population may cause less suffering on the short term, but increase it in the future by disrupting ecosystem services, leading to population collapse due to lack of resources, etc.
Uncertainty of impact	The complexity of an ecological system can make the impact of management actions on different species difficult to assess precisely, therefore creating potential errors, especially in the presence of multiple biotic interactions. This may lead to an incorrect estimation of the consequences C.
Uncertainty of value expressions and preferences	Quantifying the value given by a person or a group of people to an individual is difficult, context-dependent, and highly subjective. Sensitivity analyses on the distribution of values can be used to account for such uncertainty.

Figure

Figure 1. Differences between value systems influenced by a) anthropocentrism, b) sentientism, c) biocentrism and d) ecocentrism. Anthropocentrism, sentientism and biocentrism all value individuals intrinsically, but consider different moral communities, i.e. their values depend on the category of species they belong to, with {humans} ∈ {sentient beings} ∈ {all living organisms}. The intrinsic value, in combination with contextual factors, defines the inherent value of an individual. Ecocentrism, in contrast, is not based on individuals, but on ecological collectives, i.e. on species or on species assemblages and ecosystems. Species outside of the moral community may have a utilitarian value for species in the moral community (represented by the arrows), which will be reflected by changes in the impact variable. Note that species can have both an inherent and a utilitarian value. Within the moral community, species may have equal inherent values, but subjective perceptions and different value systems can assign different values to different species. The skewness of the value distribution then indicates the degree or strength of speciesism with respect to the species of reference, assumed here to be the human species, and is influenced by many factors, including charisma, cultural context, etc. Different value systems (or combination of) correspond to different conservation perspectives.
