26 Abstract

27 Background

28 Rodent malaria parasites (RMPs) serve as tractable tools to study malaria parasite 29 biology and host-parasite-vector interactions. Plasmodium vinckei is the most 30 geographically widespread of the four RMP species with isolates collected in five 31 countries in sub-Saharan Central Africa between 1940s and 1970s. Several P. 32 vinckei isolates are available but are relatively less characterized compared to other 33 RMPs thus hampering its exploitation as rodent malaria models. We have generated 34 a comprehensive resource for *P. vinckei* comprising of high-quality reference 35 genomes, genotypes, gene expression profiles and growth phenotypes for ten P. 36 vinckei isolates. This also allows for a comprehensive pan-genome analysis of the 37 reference-quality genomes of RMPs.

38

39 **Results**

40 Plasmodium vinckei isolates display a large degree of phenotypic and genotypic 41 diversity and potentially constitute a valuable resource to study parasite virulence 42 and immunogenicity. The *P. vinckei* subspecies have diverged widely from their 43 common ancestor and have undergone genomic structural variations. The 44 subspecies from Katanga, P. v. vinckei, is unique among the P. vinckei isolates with 45 a smaller genome size and a reduced multigene family repertoire. P. v. vinckei 46 infections provide good schizont yields and is amenable to genetic manipulation, 47 making it an ideal vinckei group parasite for reverse genetics. Comparing P. vinckei 48 genotypes reveal region-specific selection pressures particularly on genes involved 49 in mosquito transmission. RMP multigene family expansions observed in P. 50 chabaudi and P. vinckei have occurred in their common ancestor prior to speciation.

- 51 The erythrocyte membrane antigen 1 (*ema1*) and *fam-c* families have considerably
- 52 expanded among the lowland forests-dwelling *P. vinckei* parasites with, however,
- 53 most of the *ema1* genes pseudogenised. Genetic crosses can be established in *P*.
- 54 *vinckei* but are limited at present by low transmission success under the
- 55 experimental conditions tested in this study.
- 56

57 Conclusions

We observe significant diversity among *P. vinckei* isolates making them particularly useful for the identification of genotype-phenotype relationships. Inclusion of *P. vinckei* genomes provide new insights into the evolution of RMPs and their multigene families. *Plasmodium vinckei* parasites are amenable to experimental genetic crosses and genetic manipulation, making them suitable for classical and functional genetics to study *Plasmodium* biology.

68

69 Background

Rodent malaria parasites (RMPs) serve as tractable models for experimental genetics and as valuable tools to study malaria parasite biology and host-parasitevector interactions [1-4]. Between 1948 and 1974, several rodent malaria parasites were isolated from wild thicket rats (shining thicket rat - *Grammomys poensis* or previously known as *Thamnomys rutilans*, and woodland thicket rat - *Grammomys surdaster*) and infected mosquitoes in sub-Saharan Africa and were adapted to

76 laboratory-bred mice and mosquitoes. The isolates were classified into four species, 77 namely, Plasmodium berghei, Plasmodium yoelii, Plasmodium chabaudi and 78 Plasmodium vinckei. Plasmodium berghei and P. yoelii are sister species forming the 79 classical berghei group, whereas P. chabaudi and P. vinckei form the classical 80 vinckei group of RMPs [5-7]. Plasmodium chabaudi has been used for studying drug 81 resistance, host immunity and immunopathology in malaria [8-12]. Plasmodium yoelii 82 and *P. berghei* are extensively used as tractable models to study liver and mosquito 83 stages of the parasite [13, 14]. Efficient transfection techniques [15-18] have been 84 established in all three RMPs and they are widely used as *in vivo* model systems for 85 large scale functional studies [19-22]. Reference genomes for these three RMP 86 species are available [23, 24]. Recently, the quality of these genomes has been 87 significantly improved using next-generation sequencing [11, 25, 26].

88

89 P. vinckei is the most geographically widespread RMP species, with isolates 90 collected from many locations in sub-Saharan Africa (Figure 1A). Subspecies 91 classifications were made for 18 P. vinckei isolates in total based on parasite 92 characteristics and geographical origin, giving rise to five subspecies; P. v. vinckei 93 (Democratic Republic of Congo), P. v. petteri (Central African Republic), P. v. lentum 94 (Congo Brazzaville), P. v. brucechwatti (Nigeria) and P. v. subsp. (Cameroon) [27-95 32]. Blood, exo-erythrocytic and sporogonic stages of a limited number of isolates of 96 the five subspecies have been characterized; P. v. vinckei line 67 or CY [33], P. v. 97 petteri line CE [28], P. v. lentum line ZZ [29, 31], P. v. brucechwatti line 1/69 or DA 98 [30, 34] and several parasite lines of P. v. subsp. [35]. Enzyme variation studies [5, 99 36] and multi-locus sequencing data [6, 7] have indicated that there is significant 100 phenotypic and genotypic variation among *P. vinckei* isolates.

101 The rodent malaria parasites isolated from Cameroon in 1974 by J. M. Bafort are 102 currently without subspecies names, being designated as P. yoelii subsp., P. vinckei 103 subsp. and P. chabaudi subsp.. We now present the full genome sequence data of 104 isolates from these subspecies and show they form distinct clades within their parent 105 species. Therefore, we propose the following subspecies names; Plasmodium yoelii 106 cameronensis, from the country of origin; Plasmodium vinckei baforti, after J. M. 107 Bafort, the original collector of this subspecies; and Plasmodium chabaudi 108 esekanensis, from Eséka, Cameroon, the town from the outskirts of which it was 109 originally collected.

- 110
- 111 Very few studies have employed *P. vinckei* compared to the other RMP species
- 112 despite the public availability of several *P. vinckei* isolates
- 113 (http://www.malariaresearch.eu/content/rodent-malaria-parasites). P. v. vinckei v52
- and *P. v. petteri* CR have been used to study parasite recrudescence [37],
- 115 chronobiology [38] and artemisinin resistance [39]. They are also the only isolates for
- 116 which draft genome assemblies with annotation are available as part of the Broad
- 117 Institute *Plasmodium* 100 Genomes initiative
- 118 (https://www.ncbi.nlm.nih.gov/bioproject/163123).
- 119
- 120 A high-quality reference genome for *P. vinckei* and detailed phenotypic and
- 121 genotypic data are lacking for the majority of *P. vinckei* isolates hindering wide-scale
- 122 adoption of this RMP species in experimental malaria studies.
- 123
- 124 We now present a comprehensive genome resource for *P. vinckei* comprising of 125 high-quality reference genomes for five *P. vinckei* isolates (one from each

subspecies) and describe the genotypic diversity within the *P. vinckei* clade through the sequencing of five additional *P. vinckei* isolates (see Figure 1A inset). With the aid of high-quality annotated genome assemblies and gene expression data, we evaluate the evolutionary patterns of multigene families across all RMPs and within the subspecies of *P. vinckei*.

131

We also describe the growth and virulence phenotypes of these isolates and show that *P. vinckei* is amenable to genetic manipulation and can be used to generate experimental genetic crosses.

135

Furthermore, we sequenced the whole genomes of seven isolates of the subspecies
of *P. chabaudi* (*P. c. esekanensis*) and *P. yoelii* (*P. y. yoelii*, *P. y. nigeriensis*, *P. y. killicki* and *P. y. cameronensis*) in order to resolve evolutionary relationships among

139 RMP isolates.

140

The data presented here enable the use of the *P. vinckei* clade of parasites for laboratory-based experiments driven by high-throughput genomics technologies and will significantly expand the number of RMPs available as experimental models to understand the biology of malaria parasites.

145

146 **Results**

147 Plasmodium vinckei isolates display extensive diversity in virulence

We followed the infection profiles of ten *P. vinckei* isolates in CBA/J mice (five biological replicates per group) to study their virulence traits. Some of these isolates were available as uncloned lines and so were first cloned by limiting dilution 151 (Additional File 1). As reported previously [40], *P. vinckei* parasites are 152 morphologically indistinguishable from each other, prefer to invade mature 153 erythrocytes, are largely synchronous during blood stage growth and display a 154 characteristically rich abundance of haemozoin crystals in their trophozoites and 155 gametocytes (Figure 1B).

156

157 Parasitaemia was determined daily to measure the growth rate of each isolate and

158 host RBC density and weight were measured as indications of "virulence" (harm

159 to the host) (Figure 1C, Additional file 2 and 3).

160

161 The P. v. vinckei isolate PvvCY, was highly virulent and reached a parasitaemia of 162 $89.4\% \pm 1.4$ (standard error of mean; SEM) on day 6 post inoculation of 1 x 10^6 163 blood stage parasites intravenously, causing host mortality on that day. Both strains 164 of *P. v. brucechwatti*, *Pvb*DA and *Pvb*DB, were virulent and killed the host on day 7 165 or 8 post infection (peak parasitaemia of around 70%). The P. v. lentum parasites 166 Pv/DS and Pv/DE, were not lethal and were eventually cleared by the host immune 167 system, with PvIDS's clearance more prolonged than that of PvIDE (parasitaemia clearance rates; $Pv/DS = 10.35 \text{ %day}^{-1}$; SE = 1.105; p-value of linear fit =0.0025; 168 *PvI*DE = 16.46 %day⁻¹; SE = 3.873; p-value =0.023). The *P. v. petteri* isolates 169 PvpCR and PvpBS reached peak parasitaemia along similar timelines (6-7 dpi), but 170 171 PvpCR was virulent (peak parasitaemia = 60.35 % ± 2.38 on day 6) and could 172 sometimes kill the host while *Pvp*BS maintained a mild infection.

173

174 Of the three isolates of *P. vinckei baforti*, *Pvs*EL and *Pvs*EE were similar in their 175 growth profiles and their perceived effect on the host, while in contrast, *Pvs*EH was

highly virulent, causing host mortality at day 5, the earliest among all *P. vinckei*parasites.

178

179 RBC densities reduced during the course of infection proportionally to the rise in 180 parasitaemia in all the *P. vinckei* infection profiles studied. There were differences, 181 however, in the patterns of host weight loss. Mild infections by P. v. lentum isolates 182 (maximum weight loss in $Pv/DE = 0.43 \text{ mg} \pm 0.41 \text{ and } Pv/DS = 1.77 \text{ mg} \pm 0.38$), *P. v.* 183 petteri BS (0.58 mg \pm 0.22) and *P. v. baforti* EE (1.66 mg \pm 0.31, 0.09 mg \pm 0.56) did 184 not cause any significant weight loss in mice, whereas the virulent strains, P. v. 185 petteri CR (4.04 mg \pm 0.18), P. v. brucechwatti isolates (pvbDA = 3.5 mg \pm 0.39 and 186 $pvbDB = 2.05 \text{ mg} \pm 1.68$) caused around a 20% decrease in weight. Virulent strains 187 PvvCY (1.74 mg ± 0.15) and PvsEH (0.52 mg ± 0.13) did not cause any significant 188 weight loss during their infection before host death occurred.

189

190 *Plasmodium vinckei* reference genome assembly and annotation

191 High-guality reference genomes for five P. vinckei isolates, one from each 192 subspecies; P. v. vinckei CY (PvvCY), P. v. brucechwatti DA (PvbDA), P. v. lentum 193 DE (Pv/DE), P. v. petteri CR (PvpCR) and P. v. baforti EL (PvsEL) were assembled 194 from single-molecule real-time (SMRT) sequencing. PacBio long reads of 10-20 195 kilobases (kb) and with a high median coverage of >155X across the genome 196 (Additional File 1) enabled *de novo* assembly of each of the 14 chromosomes as 197 single unitigs (high confidence contig) (see Table 1). PacBio assembly base call 198 errors were corrected using high-quality 350bp and 550bp insert PCRfree Illumina 199 reads. A small number of gaps remain in the assemblies, but these are mainly 200 confined to the apicoplast genomes and to the PvsEL and Pv/DE genomes that were

assembled from 10kB-long PacBio reads instead of 20kB. The *Pvp*CR and *Pvv*CY assemblies, with each chromosome in one piece, are a significant improvement over their existing fragmented genome assemblies (available through PlasmoDB v.30).

204

205 Plasmodium vinckei genome sizes range from 19.2 to 19.5 Mb except for PvvCY 206 which has a smaller genome size of 18.3 Mb, similar to that of P. berghei (both 207 isolates are from the same Katanga region). While we were not able to resolve the 208 telomeric repeats at the ends of some of the chromosomes, all the resolved 209 telomeric repeats had the RMP-specific sub-telomeric repeat sequences 210 CCCTA(G)AA. The mitochondrial and apicoplast genomes were ~6Kb and ~30 kb 211 long respectively, except for the apicoplast genomes of *Pvp*CR and *Pvs*EL for which 212 we were able to resolve only partial assemblies due to low read coverage (see 213 Additional File 4).

214

215 Gene models were predicted by combining multiple lines of evidence to improve the 216 quality of those predictions. These include publicly available P. chabaudi gene 217 models, de novo predicted gene models and transcript models from strand-specific 218 RNA-seq data of different blood life cycle stages. Consensus gene models were then 219 manually corrected through comparative genomics and visualization of mapped 220 RNAseq reads. As a result, we annotated 5,073 to 5,319 protein-coding genes, 57-221 67 tRNA genes and 40-48 rRNA genes in each P. vinckei genome. Functional and 222 orthology analyses with the predicted P. vinckei proteins showed that the core 223 genome content in *P. vinckei* parasites is highly conserved among the species and 224 are comparable to other rodent and primate malaria species.

225

226 *Plasmodium vinckei* genome assemblies reveal novel structural variations

227 Comparative analysis of *P. vinckei* and other RMP genomes shows that *P. vinckei* 228 genomes exhibit the same high level of synteny seen within RMP genomes, but with 229 a number of chromosomal rearrangements. These events can be identified by 230 breaks in synteny (synteny breakpoints- SBPs) observed upon aligning and 231 comparing genome sequences.

232

233 We aligned *P. vinckei* and other RMP genomes to identify synteny blocks between 234 their chromosomes. Similar to previous findings in RMP genomes [26, 41] (Additional 235 file 12A), we observed large scale exchange of material between non-homologous 236 chromosomes, namely three reciprocal translocation events and one inversion 237 (Figure 2A, Additional File 5 and 12). A pan-vinckei reciprocal translocation of 238 \sim 0.6Mb (with 134 genes) and \sim 0.4 Mb (with 99 genes) long regions between 239 chromosomes VIII and X was observed between P. vinckei and P. berghei (whose 240 genome closely resembles that of the putative RMP ancestor [41]). Within the P. 241 vinckei subspecies, two reciprocal translocations separate P. v. petteri and P. v. 242 *baforti* from the other three subspecies. One pair of exchanges (~1 Mb and ~0.55) 243 Mb) was observed between chromosomes V and XIII, and another smaller pair 244 (~150Kb and ~70Kb) between chromosomes V and VI. These events have left the 245 Chromosomes V of PvvCY-PvbDA-PvlDE and PvpCR-PvsEL groups with only a 246 ~ 0.15 Mb region of synteny between them, consisting of 48 genes while the 247 remaining 304 genes have been rearranged with chromosome VI and XII.

248

There also exists a small, PvvCY-specific inversion of a ~100 kb region in chromosome XIV. All the synteny breakage points (SBPs) were verified manually

and were supported by PacBio read coverage ruling out the possibility of a misassembly at the breakpoint junctions. The SBPs in chromosomes V and VI were near rRNA units, loci previously described as hotspots for such rearrangement events [42, 43].

255

A pan-RMP phylogeny reveals high genotypic diversity within the *P. vinckei* clade

In order to re-evaluate the evolutionary relationships among RMPs, we first inferred a well-resolved species-level phylogeny that takes advantage of the manually curated gene models in eight available high-quality RMP genomes representing all RMPs. A maximum-likelihood phylogeny tree was inferred through partitioned analysis using RAxML, of a concatenated protein alignment (2,281,420 amino acids long) from 3,920 single-copy, conserved core genes in eleven taxa (eight RMPs, *P. falciparum*, *P. knowlesi* and *P. vivax*; see Figure 2B and Additional File 6).

265

In order to assess the genetic diversity within RMP isolates, we sequenced 266 267 additional isolates for four P. vinckei subspecies (PvbDB, PvlDS, PvpBS, PvsEH and 268 PvsEE), P. yoelii yoelii (Pyy33X, PyyCN and PyyAR), P. yoelii nigeriensis (PynD), P. 269 yoelii killicki (PykDG), P. yoelii subsp. (PysEL) and P. chabaudi subsp. (PcsEF) 270 (Additional File 1). This, along with existing sequencing data for 13 RMP isolates 271 (from [26, 44]), were used to infer an isolate-level, pan-RMP maximum likelihood 272 phylogeny based on 1,010,956 high-quality SNPs in non-subtelomeric genes that 273 were called by mapping all reads onto the PvvCY reference genome (Figure 2C and 274 Additional File 7). Both phylogenies were well-resolved with robust 100% bootstrap 275 support obtained for the amino-acid based phylogeny and 78% or higher bootstrap

support for the SNPs-based phylogeny (majority-rule consensus tree criterion was
satisfied at 50 bootstraps for both the phylogenies).

278

Both protein alignment-based and SNP-based phylogenies show significant divergence among the *P. vinckei* subspecies compared to the other RMPs. All *P. vinckei* subspecies have begun to diverge from their common ancestor well before sub-speciation events within *P. yoelii* and *P. chabaudi*. The Katangan isolate, *P. v. vinckei*, has undergone significant divergence from the common *vinckei* ancestor and is the most diverged of any RMP subspecies sequenced to date.

285

Plasmodium v. brucechwatti has also diverged significantly, while the divergence of *P. v. lentum* is comparable to that of *P. y. nigeriensis*, *P. y. kilicki* and *P. c. subsp.* from their respective putative ancestors. Genetic diversity within *P. v. petteri* and *P. v. baforti* isolates are similar to that observed within *P. yoelii* and *P. chabaudi* isolates while *P. v. lentum* and *P. v. brucechwatti* isolates have exceptionally high and low divergences respectively.

292

Our robust phylogeny based on a comprehensive set of genome-wide sequence variations confirms previous estimates of RMP evolution based on isoenzyme variation [5] and gene sequences of multiple housekeeping loci [6, 7], except for the placement of *P. y. nigeriensis* D which we show to be diverged earlier than *P. y. kilicki* DG (supported by a bootstrap value of 100).

298

299 Molecular evolution within *P. vinckei* isolates

Using SNP data (Additional file 7), we then assessed the differences in selection pressure on the geographically diverse *P. vinckei* isolates by calculating the genewise Ka/Ks ratio as a measure of enrichment of non-synonymous mutations in a gene (signifying positive selection). We first compared the Katangan isolate (*Pvv*CY) from the highland forests in the DRC with the non-Katangan isolates from the lowland forests elsewhere.

306

We made pairwise comparisons of the four non-Katangan *P. vinckei* subspecies with *P. v. vinckei* which revealed several genes under significant positive selection (Figure 3C). Notably, we identified three genes involved in mosquito transmission, namely, a gamete-release protein (GAMER), a secreted ookinete protein (PSOP25) and a thrombospondin-related anonymous protein (TRAP), featuring in all Katangan/non-Katangan subspecies comparisons.

313

GAMER (PVVCY_1202630 being the representative ortholog in *P. v. vinckei*) had high Ka/Ks values in all comparisons (except for *P. v. vinckei- P. v. brucechwatti*) and is essential for gamete egress [45]. PSOP25 (PVVCY_1102000) and TRAP (PVVCY_1305250) showed high Ka/Ks values in all comparisons and are essential for ookinete maturation [46] and sporozoite infectivity of mosquito salivary glands and host hepatocytes [47] respectively.

320

321 Several exported proteins and surface antigens were also identified to have 322 undergone positive selection. PVVCY_0100120 has a circumsporozoite-related 323 antigen PFAM domain (PF06589) and is a conserved protein found in all RMPs

except *P. berghei.* PVVCY_1200100 is merozoite surface antigen, p41 [48] that is
 secreted following invasion [49].

326

To assess presence of geographic location-specific selection pressures among the lowland forest isolates, *P. v. brucechwatti*, *P. v. lentum* and *P. v. baforti* were compared with *P. v. petteri* CR from the CAR. To see if similar selection pressures have acted on other RMP species, we also analysed the *P. yoelii* and *P. chabaudi* isolates from these regions that we had sequenced in this study.

332

333 Several exported and rhoptry-associated proteins were identified as been under 334 positive selection in each comparison but in contrast to comparisons with P. v. 335 vinckei, there was no overlap of positively selected genes among the non-Katangan 336 isolates. However, we identified a conserved rodent malaria protein of unknown 337 function (PVVCY_0501990) that seems to be under significant positive selection with 338 high Ka/Ks values (ranging from 2.14 to 4.39) in all P. vinckei comparisons except P. 339 v. petteri - P. v. baforti. The P. yoelii ortholog of this protein was also positively 340 selected among P. y. yoelii, P. y. nigeriensis and P. y. killicki but was not under 341 selection within the *P. y. yoelii* isolates, signifying region-specific selection pressures.

342

A 28kDa ookinete surface protein (P28; PVVCY_0501540) seem to be under positive selection in the Nigerian *P. v. brucechwatti* as it features in both *P. v. vinckei* - *P. v. brucechwatti* and *P. v. brucechwatti* - *P. v. petteri* comparisons. The protein is also seen positively selected among corresponding Nigerian and Central African Republic *P. yoelii* isolates (*P. y. nigeriensis – P. y. yoelii*). A protein phosphatase

348 (PPM8) has also undergone positive selection in all three RMP species between

349 CAR and Congo isolates (*P. c. chabaudi- P. c. adami* comparison from [26]).

350

351 Evolutionary patterns within the RMP multigene families

352 We were able to accurately annotate members of the ten RMP multigene families in 353 the P. vinckei genomes owing to the well-resolved sub-telomeric regions in the 354 Pacbio assemblies and manually curated gene models (see Table 1 and Additional 355 file 8). Copy numbers within multigene families (exceptions were the *pir*, *etramp* and 356 lysophospholipase families) in the Katangan isolate, P. v. vinckei were strikingly 357 lower than other *P. vinckei* subspecies, similar to *P. berghei*. Multigene family sizes 358 in the four non-Katangan P. vinckei subspecies were similar to P. chabaudi except 359 for expansion in the *ema1* and *fam-c* multigene families (Figure 3A).

360

361 Next, we inferred maximum likelihood-based phylogenies for the ten multigene 362 families, in order to identify structural differences amongst their members and to 363 determine family evolutionary patterns across RMP species and P. vinckei 364 subspecies (Figure 3B, Additional file 3 and 4). Overall, we identified robust clades 365 (with bootstrap value >70) that fell into the following categories, i) pan-RMP, with 366 orthologous genes from the four RMP species (dark grey), ii) berghei group, with 367 genes from P. berghei and P. yoelii alone, iii) vinckei group, with genes from P. 368 chabaudi and any or all P. vinckei subspecies, iv) P. vinckei, with genes only from P. 369 vinckei subspecies and v) non-Katangan, with genes from all P. vinckei subspecies 370 except P. v. vinckei.

371

In general, a high level of orthology was observed between *P. chabaudi* and *P. vinckei* genes forming several *vinckei* group clades (marked in orange in Figure 3) in contrast to more species-specific clades of paralogous genes being formed in *P. berghei* and *P. yoelii*. Thus, family expansions in *P. chabaudi* and *P. vinckei* seem to have occurred in the common *vinckei* group ancestor prior to speciation.

We rebuilt the phylogenetic trees for *pir*, *fam-a* and *fam-b* families in order to see if the previously defined clades [25, 26] were also maintained in *P. vinckei*. Overall, we were able to reproduce the tree structures for the three families using the ML method with *P. vinckei* gene family members now added to them.

381

382 For *pirs*, we obtained four long-form and eight short-form clades as in [26] (Additional 383 file 9, tree 10) albeit with lower bootstrap support, possibly due to our overly stringent 384 automated trimming of the sequence alignment (see Methods). With a few 385 exceptions, P. vinckei pir genes majorly populated two clades - L1 and S7 and a 386 subclade S1g. These clades, previously shown to be P. chabaudi-dominant, hold 387 equal or near equal proportions of P. vinckei pirs too. The only other P. chabaudi-388 dominant clade, L4, remains as a completely P. chabaudi-specific gene expansion. 389 No P. vinckei species- or subspecies-specific clades are evident except for two 390 subclades that could be inferred as PvvCY-specific expansions within L1 and S7 391 (marked i and ii in Additional file 9, tree 10). Speciation of *P. vinckei* subspecies from 392 their common ancestor seems to have been accompanied by gene gain in L1 and S7 393 clades and gene loss in S1g subclade. There is an almost linear increase of around 394 20 genes in PvvCY, PvbDA and PvlDE in clade L1 pirs and a near doubling of clade 395 S7 pirs in *Pvp*CR.

396

397 The fam-a and fam-b phylogenies (Additional file 9, tree 3 and 4 respectively) show 398 that previously identified ancestral lineages [25] are maintained in *P. vinckei* too. The 399 addition of *P. vinckei* genes resolved the ancestral clade of internal fam-a genes in 400 chromosome 13 further into several well-supported vinckei group clades and a 401 berghei group clade (marked as A in Additional file 9, tree 3). The 19 other fam-a 402 clades and five fam-b clades consisting of positionally conserved orthologous genes 403 are also conserved in P. vinckei (pan-RMP clades marked with * in Additional file 9, 404 tree 3 and 4). The fam-a family has expanded in the non-Katangan P. vinckei 405 subspecies through independent events of gene duplication in their common 406 ancestor giving rise to several non-Katangan clades (marked as B in Additional file 9, 407 tree 3). There is only a moderate *P. vinckei*-specific expansion in *fam-b* giving rise to 408 three clades (marked as A in Additional file 9, tree 4) that includes PvvCY genes too, 409 pointing to gene duplications in the P. vinckei common ancestor. In both the 410 phylogenies, species and subspecies-specific gene duplication events within the 411 vinckei group are rare but do occur (marked as i-iv in Additional file 9, tree 3 and 4).

412

413 The fam-d multigene family is present as a single ancestral copy in P. berghei 414 internally on chromosome IX but is expanded into a gene cluster in the same loci in 415 P. yoelii (5 genes) and P. chabaudi (21 genes). Similar expansions have occurred in 416 P. vinckei subspecies and phylogenetic analysis shows the presence of six robust 417 clades within this family (Additional file 9, tree 6). Clade I is clearly the ancestral 418 clade from which all other fam-d genes have been derived as it consists of the single 419 P. berghei gene and its orthologs in other RMPs, positionally conserved to be the 420 outermost gene of the *fam-d* cluster in each RMP.

421

422 While the fam-d family in P. yoelii is completely a product of paralogous expansion 423 within Clade I, the fam-d families in the vinckei group seem to have expanded via 424 five ancestral lineages forming clades II-VI. A subset of orthologs in Clade II (marked 425 with * in Additional file 9, tree 6) are positionally conserved among vinckei group 426 parasites, located immediately after the fam-d ancestral copy and could therefore 427 represent the Clade II ancestral gene in the vinckei group common ancestor. PvvCY 428 has a smaller fam-d repertoire of 6 genes derived from only three of the five vinckei 429 group lineages (Clade II, IV and VI), apart from the conserved ancestral copy.

430

431 ML-based trees for haloacid dehalogenase-like hydrolase (hdh), putative reticulocyte 432 binding proteins (p235) and lysophospholipases (lpl) have generally well-resolved 433 topologies with robust bootstrap support for their nodes and some clades contain 434 syntenic orthologous genes (clades marked with * in Additional file 9, trees 7, 8 and 435 9) to member genes in P. falciparum, for example, PfHAD2, PfHAD3, PfHAD4 and 436 *Pf*RH6. Poor bootstrap support was obtained for the *etramp* tree (Additional file 9, 437 tree 2), however clades were identified for some members including uis3, uis4 and 438 etramp10.2.

439

In order to assess the general level of expression of multi-gene family members in blood stage parasites, we superimposed blood-stage RNAseq data onto the phylogenetic trees. Life stage specific expression of multigene family members in five RMPs – *P. berghei* (rings, trophozoites, schizonts and gametocytes) [26], *P. chabaudi* and *P. v. vinckei* (rings, trophozoites and schizonts) [50], *P. v. petteri* and *P. v. lentum* (rings, trophozoites and gametocytes) and mixed blood stage

expression levels in *P. yoelii* [44], *P. v. brucechwatti* and *P. v. baforti* were assessed
(Additional File 10).

448

449	The level of gene transcription was designated low for genes with normalized FPKM
450	(Fragments Per Kilobase of transcript per Million mapped reads) less than 36,
451	medium if between 36 and 256 and high for genes with FPKM above 256. Both the
452	levels and life stage specificity of gene expression within the various clades were
453	generally conserved across the RMPs signifying that orthologs in structurally distinct
454	clades might have conserved functions across the different RMPs. In general, the
455	proportion of transcribed genes in all multigene families in P. vinckei was similar to
456	that observed in P. chabaudi and slightly higher than P. berghei and P. yoelii
457	(excluding the families with only one or two P. berghei or P. yoelii members).
458	

459 The erythrocyte membrane antigen 1 and *fam-c* sub-telomeric multigene 460 families are expanded in non-Katangan *P. vinckei* parasites.

461 The erythrocyte membrane antigen 1 (EMA1) was first identified and described in P. 462 chabaudi and is associated with the host RBC membrane [51]. These genes encode 463 for a \sim 800 aa long protein and consist of two exons; a first short exon carrying a 464 signal peptide followed by a longer exon carrying a PcEMA1 protein family domain 465 (Pfam ID- PF07418). The gene encoding EMA1 is present only as a single copy in P. 466 yoelii or as two copies in *P. berghei* but has expanded to 14 genes in *P. chabaudi*. 467 We see similar gene expansions of 15 to 21 members in the four non-Katangan P. 468 vinckei parasites (PvbDA, Pv/DE, PvpCR and PvsEL; Figure 3A and Additional file 469 3). However, almost half of these genes are pseudogenes with a conserved SNP 470 (C>A) at base position 14 that introduces a TAA stop codon (S5X) within the signal

471 peptide region, followed by a few more stop codons in the rest of the gene (see 472 Additional File 12B). Apart from one or two cases, the S5X mutation is found in all 473 pseudogenes belonging to the *ema1* family and is *vinckei*-specific (it is not present in 474 the single *P. chabaudi* pseudogene).

475

476 A ML-based phylogeny inferred for the 99 ema1 genes was in general well-resolved 477 with robust branch support for most nodes (see Figure 3B). Four distinct vinckei 478 group-specific clades (Clade I to IV), two vinckei-specific clades (Clade IV and V) 479 and a non-Katangan P. vinckei - specific clade (VI) with good basal support 480 (bootstrap value of 75-100) were identified. Clade I-IV each consist of ema1 genes 481 positionally conserved across P. chabaudi and all five P. vinckei subspecies (in 482 chromosomes I, VII, IX and X respectively) and are actively transcribed during blood 483 stages.

484

Of the two *P. berghei ema1* genes, one forms a distal clade with the single *P. yoelii* gene while the other is paraphyletic within Clade IV, pointing to presence of two *ema1* loci in the common RMP ancestor, one of which was possibly lost during speciation of *P. yoelii*. All seven *Pvv*CY *ema1* genes are found within clades I to V with gene duplication events in Clade III and V.

490

Family expansion in *P. chabaudi* is mainly driven by gene duplication giving rise to *P. chabaudi*-specific clades. In contrast, family expansion within non-Katangan *P. vinckei* parasites is mainly driven by expansion of pseudogenized *ema1* genes (41 genes). Except for some *P. v. brucechwatti*-specific gene expansions, the

495 pseudogenes do not form subspecies-specific clades suggesting that the expansion

496 must have occurred in their non-Katangan *P. vinckei* common ancestor.

497

Gene expression data shows that the members of the *P. vinckei*-specific Clade IV are heavily transcribed during blood stages but most *ema1* pseudogenes that share ancestral lineage with Clade IV are very weakly transcribed. Taken together, a core repertoire of conserved *ema1* genes arising from 4-5 independent ancestral lineages are actively transcribed during blood stages of *P. vinckei* and *P. chabaudi*. The *ema1* multigene family expansion in *P. vinckei* is largely due to duplications of *ema1* pseudogenes, all carrying a S5X mutation and lacking transcription.

505

506 The fam-c proteins are exported proteins characterized by pyst-c1 and pyst-c2 507 domains, first identified in *P. yoelii* [42]. There is a considerable expansion of this 508 family in the non-Katangan P. vinckei strains resulting in 59 to 65 members, twice 509 that of *Pvv*CY and other RMPs. The *fam-c* genes are exclusively found in the sub 510 telomeric regions and are composed of two exons and an intron, of which the first 511 exon is uniformly 80 bps long (with a few exceptions). fam-c proteins are 512 approximately 100-200 amino acids long, and more than one third of the proteins in 513 P. vinckei contain a transmembrane domain (75.5%) and a signal peptide (88.9%) 514 but most of them lack a PEXEL-motif (motif was detected in only 4% of the genes 515 compared to 24% in other RMPs).

516

517 An ML-based tree of all *fam-c* genes in the eight RMP species shows the presence 518 of four distinctly distal clades (marked as A in Figure 3B) with robust basal support 519 (96-100). Two of them are pan-RMP and two are *vinckei* group-specific, each

520 consisting of *fam-c* genes positionally conserved across the member subspecies 521 (taking into account the genome rearrangement between chromosome V and VI 522 within the *vinckei* clade). Most members of these clades show medium to high gene 523 expression during asexual blood stages.

524

525 The remainder of the tree's topology does not have good branch support (<70) with 526 the exception of some terminal nodes, but it does demonstrate the significant 527 expansion of this gene family within non-Katangan *P. vinckei* parasites (clades 528 shaded in blue).

529

530 There is evidence of significant species- and subspecies-specific expansions with 531 striking examples in P. yoelii, P. chabaudi and in P. v. brucechwatti (marked i, ii and 532 iii in Figure 3B respectively), though they do not form well-supported clades. Most 533 fam-c genes in P. yoelii seem to have originated from such independent P. yoelii -534 specific expansion events. P. chabaudi and P. v. vinckei fam-c genes are found 535 more widely dispersed throughout the tree suggesting divergence of this family in the 536 vinckei group common ancestor. On the other hand, subspecies-wise distinctions 537 among the non-Katangan P. vinckei fam-c genes are less resolved as they form both 538 paralogous and orthologous groups between the four subspecies with several 539 ortholog pairs strongly supported by bootstrap values.

540

Thus, *fam-c* gene family expansion in the non-Katangan *P. vinckei* subspecies seems to have been driven by both gene duplications in their common ancestor and subspecies-specific gene family expansions subsequent to subspeciation. Around half of the *fam-c* genes have detectable transcripts in asexual or sexual blood

stages. Most of the transcribed genes have medium (36<FPKM<256) or high-level
expression (FPKM > 256) and blood-stage specific expression data for *P. chabaudi*and *P. v. vinckei* show peak transcription among the asexual blood stages at ring
and schizont stages.

549

550 Genetic crossing can be performed between *P. vinckei* isolates

551 The availability of several isolates within each *P. vinckei* subspecies with varying

552 growth rates and wide genetic diversity makes them well-suited for genetic studies.

553 Therefore, we attempted genetic crossing of the two *P. vinckei baforti* isolates,

554 PvsEH and PvsEL, that displayed differences in their growth rates. Optimal

555 transmission temperature and vector stages were initially characterized for *P. v.*

556 baforti EE, EH and EL. Each isolate was inoculated into three CBA mice and on day

557 3 post infection, around 100 female A. stephensi mosquitoes were allowed to

558 engorge on each mouse at different temperatures - 21°C, 23°C and 26°C. All three

559 *P. v. baforti* isolates were able establish infections in mosquitoes at 23°C and 26°C,

560 producing at least 50 mature oocysts on day 15 post-feed, but failed to transmit at

561 21°C (Figure 1A (a) and Additional file 6). Four to five oocysts of 12.5-17.5 μm

562 diameter were observed at day 8 post-feed in the mosquito midgut and around a

563 hundred mature oocysts of 50 um diameter could be observed at day 15 post-feed.

564 Some of these mature oocysts had progressed into sporozoites but only a very few

565 appeared upon disruption of the salivary glands.

566

567 To perform a genetic cross between *Pvs*EH and *Pvs*EL, a mixed inoculum containing 568 equal proportions of *Pvs*EH and *Pvs*EL parasites was injected into CBA mice and a 569 mosquito feed was performed on both day 3 and day 4 post-infection to increase the

570 chances of a successful transmission (Additional 7 B). For each feed, around 160 571 female *A. stephensi* mosquitoes were allowed to take a blood meal from two 572 anaesthetized mice at 24°C for 40 minutes without interruption.

573

Upon inspection of mosquito midguts for the presence of oocysts on day 9 post-feed, 100% infection was observed (all midguts inspected contained oocysts) for both day 3 and day 4 feeds. Around 25-100 oocysts were found per midgut in day 3 fed mosquitoes and 5-40 oocysts per midgut in day 4 fed mosquitoes. On day 12 postfeed, mature oocysts and also a high number of sporozoites were found in the midguts, but upon disrupting the salivary glands on day 20 post-feed, only a few sporozoites were found in the suspension.

581

582 Sporozoites from day 3 and 4 fed mosquitoes were injected into ICR mice (D3 and 583 D4 respectively) and five days later, both mice became positive for blood stage 584 parasites. In order to confirm that a genetic cross has taken place, four clones were 585 obtained from D4 by limiting dilution to screen for presence of both PvsEH and 586 PvsEL alleles within the chromosomes. Based on the SNPs identified between 587 *Pvs*EH and *Pvs*EL, we amplified 600 to 1,000 bp regions from polymorphic genes on 588 both ends of the 14 chromosomes that contained isolate-specific SNPs and 589 performed Sanger sequencing of the amplicons (primer sequences in Additional file 590 6).

591

592 Both *Pvs*EL-specific (11) and *Pvs*EH-specific (17) markers were found in the 28 593 markers sequenced (one marker, PVSEL_0600390, could not be amplified). Also, 594 four chromosomes clearly showed evidence of chromosomal cross-over since they

595 contained markers from both isolates (see Figure 4A), thus confirming a successful 596 *P. vinckei* genetic cross. However, all four clones had the same pattern of 597 recombination which suggests that the diversity of recombinants in the cross-598 progeny was low and a single recombinant parasite might have undergone 599 significant clonal expansion.

600

601 *P. vinckei* parasites are amenable to genetic manipulation

602 We asked if *P. vinckei* parasites can be genetically modified by applying existing

- transfection and genetic modification techniques routinely used in other RMPs.
- 604 Plasmodium v. vinckei CY was chosen to test this because the isolate naturally
- 605 established a synchronous infection in mice and reaches a high parasitaemia, which
- results in an abundance of schizonts for transfection. We aimed to produce a PvvCY
- 607 line that constitutively expresses GFPLuc (green fluorescent protein- firefly
- 608 luciferase) fusion protein, similar to those produced in *P. berghei* and *P. yoelii* [52,
- 53]. A recombination plasmid, *pPvvCY-Δp230p-gfpLuc*, was constructed to target
- and replace the dispensable wildtype P230p locus in *P. v. vinckei* CY
- 611 (PVVCY_0300700) with a gene cassette encoding for GFPLuc and a *hdhfr*
- 612 selectable marker cassette (Figure 4B).
- 613
- Transfection of purified *Pvv*CY schizonts with 20 μg of linearized p*Pvv*CY-Δp230p-
- 615 gfpLuc plasmid by electroporation, followed by marker selection using
- 616 pyrimethamine yielded pyrimethamine-resistant transfectant parasites (PvGFP-
- 617 Luc_{con}) on day 6 after drug treatment. Stable transfectants were cloned by limiting
- dilution and plasmid integration in these clones was confirmed by PCR. Constitutive
- 619 expression of GFPLuc in PvGFP-Luc_{con} asexual and sexual blood stage parasites

620 was confirmed by fluorescence live cell imaging (Figure 4C). GFPLuc expression in

621 PvGFP-Luc_{con} oocysts was confirmed by fluorescence imaging of mosquito midguts

- 622 7 days after blood meal.
- 623

624 **Discussion**

Of the four RMP species that have been adapted to laboratory mice, *P. berghei*, *P. yoelii* and *P. chabaudi* have been extensively used to investigate malaria parasite biology. Adopting these RMPs as tractable experimental models has been facilitated by continuous efforts in characterizing their phenotypes, sequencing their genomes and establishing protocols for parasite maintenance, genetic crossing and genetic modification. Here, we extend these efforts to *Plasmodium vinckei*.

631

We have systematically studied ten *P. vinckei* isolates and produced a comprehensive resource of their reference genomes, transcriptomes, genotypes and phenotypes to help establish *P. vinckei* as a useful additional experimental model for malaria.

636 Enzyme variation and molecular phylogeny studies indicate that the five subspecies 637 of *P. vinckei* have diverged significantly from each probably due to the geographical 638 isolation of these parasites in different locations around the African Congo basin. 639 This diversity calls for a reference genome for each subspecies in order to capture 640 large-scale changes in their genomes such as chromosomal structural variations and 641 gene copy number variations that might have played a role in their subspeciation. To 642 accurately capture these events, we used a combination of Pacbio and Illumina 643 sequencing that allowed us to produce an end-to-end assembly of P. vinckei 644 chromosomes. This, coupled with manual curation of the predicted gene models, led

to the creation of five high-quality reference genomes for *P. vinckei* that are a
significant improvement to the existing fragmented genomes available for *P. v. vinckei* and *P. v. petteri*.

648

649 Comparative synteny analysis between *P. vinckei* and other RMP genomes reveals 650 structural variations at both the species and the subspecies levels. Assuming that 651 the observed variations have occurred only once, a putative pathway of genome 652 rearrangements during RMP evolution can be inferred. No rearrangements have 653 occurred during *P. berghei* and *P. yoelii* speciation and their genomes are likely to be 654 identical to the RMP ancestor [41]. A reciprocal translocation between chromosomes 655 VIII and X has accompanied the speciation of *P. vinckei*, and this is mutually 656 exclusive from the reciprocal translocation between chromosome VII and IX that has 657 occurred during P. chabaudi speciation. Following this, there has been a small 658 inversion in chromosome X during the subspeciation of P. v. vinckei and 659 translocations between chromosomes V, VI and XIII during the subspeciation of P. v. 660 petteri (which are then carried over to P. v. baforti).

661

662 We generated additional sequencing data for several *P. vinckei* isolates and made 663 available at least two genotypes per P. vinckei subspecies (except for P. v. vinckei 664 for which only one isolate is available) so as to facilitate future studies that might 665 employ *P. vinckei* parasites to study phenotype-genotype relationships. Similarly, we 666 also supplemented the existing genotype information for other RMPs by sequencing 667 several isolates from additional subspecies of P. chabaudi and P. yoelii. Our data 668 thus comprises of genotypes from sympatric species from each region of isolation 669 allowing us to re-evaluate the genotypic diversity and evolution among RMP isolates.

670

671 A genome-wide SNP-based phylogeny shows that the divergences between different 672 subspecies are proportional to the level of isolation of the habitat for all RMP 673 species. Plasmodium vinckei, P. yoelii and P. chabaudi isolates from sites in 674 Cameroon have very similar genotypes to their counterparts in the Central African 675 Republic denoting similar evolutionary pressures and perhaps the presence of gene 676 flow across these regions, while isolates from Brazzaville (Congo) are more 677 diverged probably due to the different environmental conditions in these locations 678 [40].

679

680 Subspecies from West Nigeria and the DRC are highly diverged compared to 681 subspecies from the rest of Africa. The distinctiveness of P. berghei and P. v. 682 vinckei, both from the DRC is most likely due to climactic and host-vector differences 683 in the highland forests of Katanga. Highland forests are an altitude of 1000-7000 m 684 with mean temperature of 21C whereas the lowland forests lie at an altitude less 685 than 800m with a mean temperature of 25 C. Different host-vector systems are 686 prevalent in the lowland forests (Grammomys poensis (previously known as 687 Thamnomys rutilans) - specific mosquito species unknown) and the highland 688 Katangan forests (Grammomys surdaster - Anopheles dureni millecampsi). The 689 associated selection pressures seem to have mainly influenced their transmission, 690 as reflected by their lower optimal transmission temperatures and the high Ka/Ks 691 ratios observed for three proteins that play critical functions in this process. Recently, 692 several more rodent host and mosquito vector species have been identified in the 693 forests of Gabon [54] implying that a diverse set of host-vector systems could have 694 existed for RMPs. Thus, diversification of RMP species into several subspecies

within these isolated ecological niches might have been driven by evolutionary forces
resulting from the diverse host, vector and environmental conditions experienced at
each locale.

698

Malaria parasite genomes contain several highly polymorphic multigene families located in the sub-telomeric chromosomal regions that encode a variety of exported proteins involved in processes such as immune evasion, cytoadherence, nutrient uptake and membrane synthesis. Multigene families are thought to have evolved rapidly under the influence of immune and other evolutionary pressures resulting in copy number variations and rampant sequence reshuffling that ultimately leads to phenotypic plasticity in *Plasmodium*.

706

707 Previously, phylogenetic analyses of pir, fam-a and fam-b genes from three RMP 708 species have shown that structurally distinct genes exist within these families 709 forming robust clades with varied levels of orthology/paralogy. Identifying sub-710 families that have structurally diversified within the multigene families can help to 711 better understand their functions and to this end, we constructed phylogenetic trees 712 for the ten multigene families with genes from all four RMP species. Due to the scale 713 of the analysis, we applied automated trimming to our alignments and limited our 714 tree inference method to maximum likelihood. While this resulted in poor bootstrap 715 values for some clades in the pir, fam-a and fam-b trees compared to previous 716 phylogenetic analyses [25, 26], our method was able to retrieve similar tree 717 topologies to those previously inferred and in general produced trees with good 718 nodal support for the rest of the multigene families.

719

720 Robust pan-RMP clades identified in our study represent ancestral lineages 721 consisting of structural orthologs that perform conserved functions across all RMPs 722 and will be useful for future work with these families. We show that certain ancestral 723 lineages can expand in a particular species or subspecies in response to selective 724 pressures resulting in distinct evolutionary histories for each family. For example, the 725 pir family expansion is mostly species-specific and driven by frequent gene 726 conversion after speciation, whereas the expansion of the fam-a gene repertoire 727 seems to have occurred initially in the RMP ancestor followed by species-specific 728 expansions.

729

Inclusion of *P. vinckei pirs* in the RMP *pir* family phylogeny show that *P. vinckei pirs* do not form independent clades of their own and instead populate three *P. chabaudi*dominant clades. This suggests that some of the *pir* clades were established earlier on when the classical *vinckei* and *berghei* group of parasites split from their common RMP ancestor resulting in *vinckei* group-specific clades like L1, S7 and S1g.

735

736 Similarly, the addition of *P. vinckei* genes resolved the ancestral clade of internal 737 fam-a genes into several well-supported vinckei group clades and a berghei group 738 clade. We observe similarly high level of orthology between P. chabaudi and P. 739 vinckei genes in other multigene families forming several vinckei group clades in 740 contrast to more species-specific clades of paralogous genes in P. berghei and P. 741 yoelii. For example, within the fam-d family, five ancestral lineages can be identified 742 in the *vinckei* group as opposed to only one paralogous *P. yoelii*-specific expansion 743 within the berghei group. Taken together, it seems that family expansions in P. 744 chabaudi and P. vinckei have occurred in the common vinckei group ancestor prior

to speciation and that multigene families have evolved quite differently across the *vinckei* and *berghei* groups of RMPs. These might be related to the striking
differences in the basic phenotypes of these two groups of parasites.

748

749 We also observed size expansions in the *ema1* and *fam-c* families within the non-

750 Katangan *P. vinckei* parasites, all being isolates from the lowlands around the Congo

751 Basin. *Ema1* family expansions seem to be specific to lowlands dwelling *vinckei*

group parasites as they are expanded in both non-Katangan *P. vinckei* and *P.*

753 chabaudi. However, unlike P. chabaudi, the duplicated gene members in non-

754 Katangan *P. vinckei* are all pseudogenized by a S5X mutation effectively rendering

the functional repertoire to be just 6-8 genes, similar to highlands dwelling Katangan

756 P. v. vinckei. Thus, it could be speculated that even under similar selective

757 pressures, *ema1* family expansions contribute to parasite fitness in *P. chabaudi* but

may not be required for the survival of sympatric *P. vinckei* parasites. The *P. vinckei*

759 *ema1* pseudogenes could still serve as silent donor genes that recombine into

functional variants to bring about antigenic variation [55]. In the case of the *fam-c*

gene family, the expansion is specific to non-Katangan *P. vinckei* subspecies since

762 P. chabaudi, P. yoelii and P. v. vinckei all have similar repertoire sizes. The

responsions seem to be driven by gene duplications initially in their non-Katangan

common ancestor and again after subspeciation.

765

The effect of the difference in habitats is even more pronounced in the Katangan

parasite, *P. v. vinckei*. It has a smaller genome and a compact multigene family

repertoire reminiscent of the only other Katangan isolate, *P. berghei* and its genetic

distance from other members of the *P. vinckei* clade is in the same order of

770 magnitude as that between separate species within the RMPs. The reduced

771 multigene family repertoire mainly consists of members belonging to pan-RMP or

vinckei-group specific ancestral lineages making it an ideal vinckei group parasite to

- study the localization and function of variant proteins.
- 774
- 775 We tested whether *Pvv*CY was amenable to genetic manipulation using standard

transfection protocols already established for other RMPs. We were able to

successfully knock-in a GFP-luciferase fusion cassette to *Pvv*CY to produce a GFP-

Luc reporter line for *P. v. vinckei*, following a transfection protocol routinely used for

modifying *P. yoelii* in our lab [44, 56]. We were able to visualise GFP-positive

780 parasites during different blood stages and in oocysts thus confirming stable GFPLuc

expression. We were unable to visualise other life stages (sporozoites and liver

stages) due to our failure to produce viable salivary gland sporozoites in this

783 parasite.

784

785 The transfection of *P. chabaudi* has been challenging due to its slow proliferation 786 rate and schizont sequestration resulting in low merozoite yield, thus necessitating 787 optimized transfection protocols. In contrast, *Plasmodium v. vinckei* reaches high 788 parasitaemia without being immediately lethal to the host (90% parasitaemia on day 789 6) and is highly synchronous yielding a large number of schizonts. A predominant 790 population of schizonts appear near midnight in P. v. vinckei infections, at which 791 point, they can be Percoll-purified from exsanguinated blood and transfected with 792 DNA.

793

794 *P. vinckei* and *P. chabaudi*, while being distinct species, share several

characteristics that are common among *vinckei* group RMPs, such as a predilection
for mature erythrocytes, synchronous infections and the sequestration of schizonts
from peripheral circulation [33, 37, 57-59]. Thus, *P. v. vinckei* can serve as an ideal
experimental model for functional studies targeting these aspects of parasite biology.

The availability of several RMP isolates with phenotypic differences aids their use in study of parasite fitness and transmission success in mixed infections [60, 61] and for the identification of genes involved in parasite virulence, strain-specific immunity, drug resistance and host-cell preference using genetic crosses [44, 62-64]. With this in mind, we studied the virulence of ten *P. vinckei* isolates to identify differences in their growth rate and their effect on the host.

806

Some of these isolates have been previously characterized [40], but we systematically profiled additional representative isolates for each subspecies (where available) under comparative conditions in the same host strain. We identified pairs of isolates with contrasting virulence phenotypes within two *P. vinckei* subspecies – *P. v. petteri (Pvp*CR and *Pvp*BS) and *P. v. baforti (Pvs*EH and *Pvs*EL or *Pvs*EE). These isolate pairs would be ideal candidates for studies utilising genetic crossing to identify genetic *loci* linked to virulence using Linkage Group Selection [44].

814

Since *P. vinckei* subspecies have significantly diverged from each other, isolates within the same subspecies are more likely to recombine than isolates from different subspecies. However, intra-specific hybrids between *P. v. petteri* and *P. v. baforti* may also be possible (as demonstrated earlier in *P. yoelii* [65]) since these two

819 subspecies are closely related (see Figure 2C). However, difficulties in transmitting 820 P. vinckei parasites have been reported previously with either the gametocytes 821 failing to produce midgut infections or sporozoites failing to invade the salivary 822 glands or infections resulting in non-infective sporozoites [27, 30, 35]. Repeated 823 attempts to create a cross between two P. vinckei baforti isolates failed to produce 824 any detectable recombinants due to low frequency of mosquito transmission [35]. 825 Here, we renewed these efforts with different P. vinckei isolates to see if we could 826 establish a *P. vinckei* genetic cross. Two attempts were made to create a *pvp*CR X 827 *pvp*BS cross and further two attempts were made to create a *pvs*EL X *pvs*EH cross. 828 However, in all attempts the sporozoites failed to optimally invade the salivary glands 829 and we managed to isolate only a few in the P. v. subsp cross, subsequently 830 obtaining a cross progeny in mice. While we were able to demonstrate a successful 831 genetic cross by showing the presence of alleles from both isolates in the cross 832 progeny, the recombinant diversity was quite low probably due to the transmission 833 bottleneck. We are currently further investigating the optimal conditions for 834 transmitting *P. vinckei*.

835

836 **Conclusions**

In this study, we have created a comprehensive resource for the rodent malaria parasite *Plasmodium vinckei*, comprising of five high-quality reference genomes, and blood stage-specific transcriptomes, genotypes and phenotypes for ten isolates. We have employed state-of-the-art sequencing technologies to produce largely complete genome assemblies and highly accurate gene models that were manually polished based on strand-specific RNA sequencing data. The unfragmented nature of our genome assemblies allowed us to characterize structural variations within *P. vinckei*

subspecies, which, to the best of our knowledge, is the first time that large-scale
genome re-arrangements have been found among subspecies of a *Plasmodium*species.

847

848 The biological or phenotypic significance, if any, of such alterations are poorly 849 understood, but it seems likely that they may drive speciation through the promotion 850 of reproductive isolation of species or subspecies. Through our extensive 851 sequencing efforts, we have generated genotype data for seventeen RMP isolates 852 comprising of five P. vinckei, four P. yoelii and one P. chabaudi subspecies, thus 853 making at least one genotype available for all subspecies of the RMP that previously 854 lacked any sequencing data. We also systematically characterised the virulence 855 phenotypes of the ten P. vinckei isolates to capture the phenotypic diversity among 856 them. Combined, these efforts will greatly aid genetic linkage studies to resolve 857 genotype-phenotype relationships.

858

859 In order to understand the evolutionary relationships among the RMP isolates, we 860 have carried out a combination of analyses to describe the genotypic diversity 861 molecular evolution of these parasites. While our phylogenies more or less agree 862 with previous biochemical and molecular data-based studies, our reconstruction 863 based on sequence variations on a genome scale provides higher resolution to the 864 divergence estimates. Taking advantage of the high-quality RMP genomes produced 865 from our work and previous studies, we also undertook a comprehensive 866 phylogenetic analysis of multigene families across all RMP species and identify 867 various structurally diversified sub-families with distinct evolutionary histories. This 868 will enable future studies on the critical role of multigene families in parasite

adaptation, and to aid this, we have made searchable and interactive versions of the

870 phylogenies publicly available through the iTOL online tool [66].

871

872 While genome rearrangements have occurred during speciation and sub speciation 873 events, diversification of the multigene families seem to have occurred earlier when 874 the RMPs split into vinckei and berghei groups of parasites. Thus, structural, copy 875 number and nucleotide-level variations among the RMPs have occurred at various 876 points during the evolution of RMPs in response to a variety of evolutionary 877 pressures. The gene expression data from our study, covering specific blood stages 878 for some P. vinckei subspecies, show conserved expression of multigene family 879 members across RMPs. While not comprehensive, it complements existing RMP 880 transcriptomes and will aid functional studies in the P. vinckei model. Taken 881 together, our study provides a comprehensive view of the phenotypic and genotypic 882 diversity within RMPs and functional diversification of the multigene families in 883 response to selection pressures.

884

885 The synchronicity of P. v. vinckei infection and its unique ability to sustain high 886 parasitaemia without killing its host culminating in good schizont yields make this 887 parasite an attractive model for reverse genetics studies, especially those on 888 multigene families owing to its reduced repertoire. We have successfully 889 demonstrated genetic manipulation in P. v. vinckei but encountered difficulties in 890 producing large numbers of recombinant parasites through genetic crossing. 891 Attempts to transmit isolates from three different P. vinckei subspecies in A. 892 stephensi mosquitoes failed in our hands as sporozoites repeatedly failed to infect 893 the salivary glands. Careful optimisation of transmission parameters and serial

894 mosquito passages of the *P. vinckei* parasites might help in improving their

transmission efficiency and could aid genetic linkage studies with these parasites.

896

897

898

899 Methods

900 Parasite lines and experiments using mice and mosquitos

The parasite lines used in this study and their original isolate information are detailed in Supplementary Table 1. Frozen parasite stabilates of cloned or uncloned lines were revived and inoculated intravenously into ICR mice. Five *P. vinckei* isolates (*Pvv*CY, *Pvb*DA, *Pvb*DB, *Pvl*DE and *Pvs*EE) and the *P. yoelii nigeriensis* isolate (*Pyn*D) were uncloned stabilates and were cloned by limiting dilution to obtain clonal parasite lines.

907

Laboratory animal experimentation was performed in strict accordance with the
Japanese Humane Treatment and Management of Animals Law (Law No. 105 dated
19 October 1973 modified on 2 June 2006), and the Regulation on Animal
Experimentation at Nagasaki University, Japan. The protocol was approved by the
Institutional Animal Research Committee of Nagasaki University (permit:
12072610052).

914

915 Six to eight weeks old female ICR or CBA mice were used in all the experiments.916 The

mice were housed at 23°C and maintained on a diet of mouse feed and water. Mice
infected with malaria parasites were given 0.05% para-aminobenzoic acid (PABA)-

919 supplemented water to assist parasite growth.

920

All mosquito transmission experiments were performed using *Anopheles stephensi* mosquitoes were housed in a temperature and humidity-controlled insectary at 24°C and 70% humidity. Mosquito larvae were fed with mouse feed and yeast mixture and adult mosquitoes were maintained on 10% glucose solution supplemented with 0.05% PABA.

926

927 Parasite growth profiling

For each isolate, an inoculum containing 1 X 10⁶ parasitized RBCs was injected intravenously to five CBA mice. Blood smears, haematocrit readings (Beckman Coulter Counter) and body weight readings were taken daily for 20 days or until host mortality to monitor parasitaemia, anaemia and weight loss. Blood smears were fixed with 100% methanol and stained with Geimsa's solution. The average parasitaemia was calculated from parasite and total RBC counts taken at three independent microscopic fields.

935

936 Genomic DNA isolation and whole genome sequencing

Parasitized whole blood was collected from the brachial arteries of infected mice and blood sera was removed by centrifugation. RBC pellets were washed once with PBS and leukocyte-depleted using CF11 (Sigma Cat# C6288) cellulose columns. Parasite pellets were obtained by gentle lysis of RBCs with 0.15% saponin solution. Genomic DNA extraction from the parasite pellet was performed using DNAzol reagent (Invitrogen CAT # 10503027) as per manufacturer's instructions.

943

944 Single-molecule sequencing was performed for five P. vinckei isolates. 5-10 ug of 945 gDNA was sheared using a Covaris g-TUBE shearing device to obtain target sizes of 946 20kB (for PvvCY, PvbDA and PvpCR) and 10kB (for samples PvlDE and PvsEL). 947 Sheared DNA was concentrated using AMPure magnetic beads and SMRTbell 948 template libraries were generated as per Pacific Biosciences instructions. Libraries 949 were sequenced using P6 polymerase and chemistry version 4 (P6C4) on 3-6 SMRT 950 cells and sequenced on a PacBio RS II. Reads were filtered using SMRT portal v2.2 951 with default parameters. Read yields were 352,693, 356,960, 765,596, 386,746 and 952 675,879 reads for PvvCY, PvbDA, Pv/DE, PvpCR and PvsEL respectively totalling 953 around 2.7 to 4.7 Gb per sample. Mean subread lengths ranged from 6.15 to 9.1 kB. 954 N50 of 11.7 kB and 19.2 kB were obtained for 10 and 20 kB libraries respectively.

955

956 PCR-free Illumina sequencing was performed for all RMP isolates. 1-2 ug of DNA 957 was sheared using Covaris E series to obtain fragment sizes of 350 and 550bp. 958 350bp and 550bp PCR-free libraries were prepared using TruSeq PCR-free DNA 959 library preparation kits according to the manufacturer's instructions. Libraries were 960 sequenced on the Illumina HiSeq2000 platform with 2 X 100bp paired-end read 961 chemistry. Read yields ranged from 8-22 million reads for each library (see 962 Additional File 1).

963

964 **Genome assembly and annotation**

Genome assembly from long single molecule sequencing reads was performed
using FALCON (v0.2.1)[67] with length cutoff for seed reads used for initial mapping
set as

2,000bp and for pre-assembly set as 12,000bp. The falcon sense options were set

as- "-min idt 0.70 -min cov 4 -local match count threshold 2 -max n read 200"
and overlap filtering settings were set as "-max diff 240 -max cov 360 -min cov
5 -bestn 10". 28-40 unitigs were obtained and smaller unitigs were discarded as
they were exact copies of the regions already present in the larger unitigs.

PCR-free reads were used to correct base call errors in the unitigs using ICORN2 [68], run with default settings and for 15 iterations. The unitigs were classified as chromosomes based on their homology with *P. chabaudi* chromosomes (GeneDB version 3). In *PvI*DE and *Pvs*EL samples, some of the chromosomes were made of two to three unitigs with overlapping ends which were then fused and the gaps were removed manually. Apicoplast and mitochondrial genomes were assembled from PCR-free reads alone using Velvet assembler [69].

981

Syntenic regions between genome sequences were identified using MUMmer v3.2 [70]. Synteny breakpoints were identified manually and were confirmed not to be misassemblies by verifying that they had continuous read coverage from PacBio and Illumina reads. Artemis Comparison tool [71, 72] and Integrative Genomics Viewer [73] were used for this purpose. The structural variations were illustrated using CIRCOS [74].

De novo gene predictions were made using AUGUSTUS [75] trained on *P. chabaudi* gene models. RNA sequencing reads were mapped onto the reference genome using TopHat [76] to infer splice junctions. AUGUSTUS predicted gene models, junctions.bed file from TopHat and *P. chabaudi* gene models were fed into MAKER [77] to create consensus gene models that were then manually curated based on RNAseq evidence in Artemis Viewer and Artemis Comparison tool [71, 72].

Ribosomal RNA (rRNA) and transfer RNA (tRNA) were annotated using RNAmmer
v1.2 [78]. Gene product calls were assigned to *P. vinckei* gene models based on
above identified orthologous groups using custom scripts. Functional domain
annotations were inferred from InterPro database using InterProScan v5.17 [79].
Transmembrane domains were predicted by TMHMMv2.0 [80], signal peptide
cleavage sites by SignalP v4.0 [81], presence of PEXEL/VTS motif detected using
ExportPredv4.0 [82] (with PEXEL score cutoff of 4.3).

1001

1002 Transcriptomics

1003 Total RNA was isolated for four *P. vinckei* isolates (*Pvb*DA, *Pvp*CR, *Pvl*DS and 1004 *Pvs*EL) from mixed blood stages using TRIzol (Invitrogen) following the 1005 manufacturer's protocol. For *Pvp*CR and *Pvl*DS, additionally, total RNA was isolated 1006 from ring, trophozoite and gametocyte enriched fractions obtained using a Nycodenz 1007 gradient.

1008 Strand-specific mRNA sequencing was performed from total RNA using TruSeg 1009 Stranded mRNA Sample Prep Kit LT (Illumina) according to the manufacturer's 1010 instructions. Briefly, polyA+ mRNA was purified from total RNA using oligo-dT 1011 dynabead selection. First strand cDNA was synthesised using randomly primed 1012 oligos followed by second strand synthesis where dUTPs were incorporated to 1013 achieve strand-specificity. The cDNA was adapter-ligated and the libraries amplified 1014 by PCR. Libraries were sequenced in Illumina Hiseq2000 with paired-end 100bp 1015 read chemistry.

1016

1017 Stage-specific RNAseq data for *Pvv*CY's intraerythrocytic growth stages were 1018 obtained from an earlier study [50]. Gene expression was captured every 6 hours

during *Pvv*CY's 24 h IDC with three replicates, of which 6h, 12h and 24h timepoints were used in this study to denote gene expression at ring, trophozoite and schizont stages respectively. Similarly, for *P. chabaudi* AS, gene expression was captured every 3h during its IDC with two replicates in a recent study [56], of which the 5.5h, 11.5h and 23.5 h timepoints on day 2 were chosen to denote ring, trophozoite and schizont stages respectively. *P. yoelii* and *P. berghei* transcriptome data were obtained from [26] and [44] respectively.

1026

1027 SNP calling and molecular evolution analysis

1028 Illumina paired-end reads for a total of 30 RMP isolates produced in this study or

1029 sourced from previous studies (see Additional File 13) were used for SNP calling. In

1030 the case of isolates sequenced in this study, the 350bp fragment size PCR-free

sequencing data was used. First, to produce a high quality pan-RMP SNP dataset

1032 for phylogeny construction, all quality-trimmed reads were mapped onto the PvvCY

1033 reference genome using BWA tool [83] with default parameters. MAPQ values of the

1034 mapped reads were fixed and duplicated reads removed using CleanSam,

1035 FixMateInformation and MarkDuplicates commands in picardtools

1036 (http://broadinstitute.github.io/picard) and only uniquely mapped reads were retained

1037 using samtools with parameter -q 1 (<u>http://www.htslib.org/</u>). Raw SNPs were called

1038 from the mapped reads using samtools mpileup and bcftools with following

1039 parameters- minimum base quality of 20, minimum mapping quality of 10 and ploidy

1040 of 1. SNPs with quality (QUAL) less than 20, read depth (DP) less than 10, mapping

1041 quality (MQ) less than 2 and allele frequency (AF1) less than 80% were removed.

1042 Further, only SNPs present in protein-coding genes were retained and those present

1043 in low-complexity regions (predicted by DustMasker [84]) and sub-telomeric

1044 multigene family members were excluded.

1045

1046 The filtered SNPs from different samples were merged and SNP positions with

1047 missing calls in more than six samples were removed. This filtered high-quality set of

1048 1,020,956 SNP positions were used to infer maximum likelihood phylogeny (see

1049 Additional File 7).

1050

1051 For inferring Ka/Ks ratios between P. vinckei isolates and PvvCY, filtered SNPs 1052 obtained above were merged as before but excluding PvpBS due to its high missing 1053 call rate. Only SNP positions with no missing calls in any sample were retained and 1054 morphed *Pvv*CY onto gene sequences using gatk command 1055 FastaAlternateReferenceMaker [85] to produce isolate-specific gene sequences 1056 which were then used for pairwise sequence comparisons to identify synonymous 1057 and non-synonymous substitutions. Ka/Ks ratios were calculated using KaKs 1058 Calculator [86] and averaged across isolates if more than one was available for a 1059 subspecies.

1060

For comparisons against *P. v. petteri*, *P. yoelii* and *P. chabaudi*, sample reads were mapped onto *Pvp*CR, *P. yoelii* 17X and *P. chabaudi* AS genomes respectively and subsequent steps were followed as before. Similar to *Pvp*BS, *Pys*EL was excluded from Ka/Ks analysis due to high missing rate.

1065

1066 **Phylogenetic analysis**

For constructing species-level phylogenies, orthologous proteins were identified between the five *P. vinckei* genomes, three RMP genomes, *P. falciparum, P. knowlesi* and *P. vivax* genomes using OrthoMCL v2.0.9 [87] with inflation parameter as 1.5, BLAST hit evalue cutoff as $1e^{-5}$ and percentage match cutoff as 50%.

1071

1072 One-to-one orthologous proteins from each of the 3,920 ortholog groups that form 1073 the core proteome were aligned using MUSCLE [88]. Alignments were trimmed 1074 using trimAl [89] removing all gaps and concatenated into a partitioned alignment 1075 using catsequence. An initial RAxML [90] run was performed on individual 1076 alignments to identify best amino acid substitution model under the Akaike 1077 Information Criterion (--auto-prot=aic). These models were then used to run a 1078 partitioned RAxML analysis on the concatenated protein alignment using 1079 PROTGAMMA model for rate heterogeneity.

1080

For constructing isolate-level phylogeny, the vcf files containing high-quality SNPs were first converted to a matrix for phylogenetic analysis using vcf2phylip (<u>https://github.com/edgardomortiz/vcf2phylip</u>). RAxML tree inference was performed using GTRGAMMA model for rate heterogeneity along with ascertainment bias correction (--asc-corr=stamatakis) since we used only variant sites.

1086

1087 Maximum likelihood trees for multigene families were constructed based on 1088 nucleotide sequence alignments of member genes that included intron sequences if 1089 present (except in the case of *pir* family where introns were excluded). Alignments 1090 were performed using MUSCLE with default parameters, frame-shifts edited 1091 manually in AliView [91] followed by automated trimming with trimAl using -gappyout

- 1092 parameter. In all the phylogenies, bootstrapping was conducted until the majority-
- 1093 rule consensus tree criterion (-I autoMRE) was satisfied (usually 150-300 replicates).
- 1094 Phylogenetic trees were visualized and annotated in the iTOL server [66].
- 1095

1096 Plasmid construction and transfection in *P. vinckei*

1097 The p*Pvv*CY-p230p-gfpLuc plasmid was constructed using MultiSite Gateway 1098 cloning

1099 system (Invitrogen). attB-flanked 5'and 3'homology arms were obtained by 1100 amplifying

1101 800bp regions upstream and downstream of PVVCY_0300700. These fragments 1102 were subjected to independent BP recombination with pDONRP4-P1R (Invitrogen) to 1103 generate entry plasmids pENT12-5U and pENT41-3U, respectively. Similarly, the 1104 gfpLuc cassette from pL1063 was amplified and subjected to LR reaction to obtain 1105 pENT23-gfpLuc. BP reaction was performed using the BP Clonase II enzyme mix 1106 (Invitrogen) according to the manufacturer's instructions.

1107

1108 *Plasmodium vinckei vinckei* CY schizont-enriched fraction was collected by 1109 differential centrifugation on 50% Nycodenz in incomplete RPMI1640 medium, and 1110 20 ug of Apal- and Stul-double digested linearized transfection constructs were 1111 electroporated to 1×10^7 of enriched schizonts using a Nucleofector device (Amaxa) 1112 with human T-cell solution under program U-33. Transfected parasites were 1113 intravenously injected into

1114 7-week-old ICR female mice, which were treated by administering pyrimethamine in 1115 the drinking water (0.07 mg/mL) 24 hours later for a period of 4-7 days. Drug 1116 resistant parasites were cloned by limiting dilution with an inoculum of 0.3

1117 parasites/100 uL injected into 10 female ICR mice. Two clones were obtained, and 1118 integration of the transfection constructs was confirmed by PCR amplification with a 1119 unique set of primers for the modified p230p gene locus. Live imaging of parasites 1120 was performed on thin smears of parasite-infected blood prepared on glass slides 1121 stained with Hoechst 33342. Fluorescent and differential interference contrast (DIC) 1122 images were captured using an AxioCam MRm CCD camera (Carl Zeiss, Germany) 1123 fixed to an Axio imager Z2 fluorescent microscope with a Plan-Apochromat 100 x/1.4 1124 oil immersion lens (Carl Zeiss) and Axiovision software (Carl Zeiss). GFP-expressing 1125 P. vinckei oocysts in mosquito midguts were imaged in SMZ25 microscope (Nikon).

1126

1127 Mosquito transmission and genetic crossing of *P. vinckei* parasites

1128 To determine the optimal transmission temperature for *P. vinckei baforti* isolates, 1129 infected CBA mice were anaesthetized on day 3 post-inoculation and ~100 female 1130 Anopheles stephensi mosquitoes (7 to 12 days post emergence) were allowed to 1131 take a blood meal for 30 min without interruption after confirming presence of 1132 gametocytes by microscopy. Three batches of ~100 mosquitoes were fed at three 1133 different temperatures - 21°C, 23°C and 26°C. The fed mosquitoes were maintained 1134 at the feed temperatures and at 70% humidity. To check for presence of 1135 oocysts/sporozoites, mosquitoes were dissected, and their midguts or salivary 1136 glands were suspended in a drop of PBS solution atop a glass slide, covered by a 1137 coverslip and studied under a microscope.

1138

For genetic crossing, isolates were harvested from donor mice and mixed to achieve a 1:1 ratio and 1 x 10^6 parasites of this mixture was inoculated into four female CBA mice. Three days after inoculation, after confirming the presence of gametocytes,

1142 two infected CBA mice were anaesthetized and placed on two mosquito cages, each 1143 containing around 80 mosquitoes each. Mosquitoes were allowed to feed on the 1144 mice without interruption for 40 minutes at 24°C. A fresh feed was again performed 1145 on the 4th day post-inoculation with the other two CBA mice and two fresh cages of 1146 mosquitoes. 5-10 female mosquitoes from each cage were dissected on the 9th and 1147 12th day after the blood meal to check for presence of oocysts in the mosquito 1148 midguts. Twenty days after the blood meal, the mosquitoes were dissected and the 1149 salivary glands were removed, placed in 0.5-0.7 ml PBS solution and gently 1150 disrupted 1151 to release sporozoites. The suspensions from day 3 and day 4 feeds were injected 1152 intravenously into an ICR mouse each. When the mice were positive for blood-stage 1153 parasites, they were sub-inoculated into ten ICR mice with an inoculum of 0.6 1154 parasites/100uL to obtain clones from the potential cross progeny by limiting dilution. 1155 Eight days post infection, four mice were positive for parasites and these clones 1156 were screened for the presence of both PvsEH and PvsEL alleles within the 1157 chromosomes.

1158

1159 **Declarations**

1160 Ethics approval and consent to participate

1161 Laboratory animal experimentation was performed in strict accordance with the

Japanese Humane Treatment and Management of Animals Law (Law No. 105 dated 1163 19 October 1973 modified on 2 June 2006), and the Regulation on Animal 1164 Experimentation at Nagasaki University, Japan. The protocol was approved by the 1165 Institutional Animal Research Committee of Nagasaki University (permit: 1166 12072610052).

1167

1168 **Consent for publication**

1169 Not applicable

1170 Availability of data and materials

- All genome sequences, gene annotations and sequencing data files generated in
- 1172 this study can be found in ENA Study: PRJEB19355. All the datasets would also be
- available via EuPathDB portal at the time of publication. All parasite resources will be
- 1174 made available to the scientific community via the BEI Resources
- 1175 (https://www.beiresources.org/). Searchable and interactive versions of the
- 1176 phylogeny trees produced in this study can be accessed at
- 1177 <u>https://itol.embl.de/shared/2ICr6w0mdDENs.</u>

1178 **Competing interests**

- 1179 The authors declare that they have no competing interests.
- 1180

1181 Funding

1182 RC was supported by a Grant (JP16K21233) from the Japan Society for the 1183 Promotion of Science. This work was supported by KAUST faculty baseline fund 1184 (BAS/1/1020-01-01) and Competitive Research Fund (URF/1/2267-01-01) to AP.

1185

1186 Authors' contributions

1187 RC and AP conceived the study. AR and RC conducted all rodent and mosquito 1188 experiments. AR, SK and RC conducted genetic cross experiments. AR collected 1189 data and performed all bioinformatic analyses. AR wrote the manuscript and all 1190 authors contributed to it.

1191

1192 Acknowledgements

- 1193 The authors would like to acknowledge the personnel at the Bioscience Core
- 1194 Laboratory (BCL) at King Abdullah University of Science and Technology for their
- 1195 help with next generation sequencing. We acknowledge the contribution of Professor
- 1196 Richard Carter, whose support of this work was crucial to its inception and
- 1197 completion.

1468

1469 **Figure legends**

1470 Figure 1. *Plasmodium vinckei* parasites and their phenotypic characteristics.

1471 A) Rodent malaria parasite species and subspecies and the geographical sites in 1472 sub-Saharan Africa where from which they were isolated (modified from [1]). 1473 Plasmodium vinckei is the only RMP species to have been isolated from five different 1474 locations. Inset: To date, several RMP isolates have been sequenced (black) to aid 1475 research with rodent malaria models. Additional RMP isolates have been sequenced 1476 in this study (red) to cover all subspecies of *P. vinckei* and further subspecies of 1477 Plasmodium chabaudi and Plasmodium yoelii. B) Morphology of different life stages 1478 of P. vinckei baforti EL. R: Ring, ET: early trophozoite, LT: Late trophozoite, S: 1479 Schizont, MG: Male gametocyte, FG: Female gametocyte, O: oocyst and Sp: 1480 Sporozoite. Plasmodium vinckei trophozoites and gametocytes are morphologically 1481 distinct from other RMPs due to their rich haemozoin content (brown pigment). C) 1482 Parasitaemia of ten *P. vinckei* isolates (split into two graphs for clarity) during 1483 infections in mice (n=5) for a 20-day duration. † denotes host mortality. Plasmodium 1484 vinckei isolates show significant diversity in their virulence phenotypes.

1485

Figure 2. Structural variations and genotypic diversity among *Plasmodium vinckei* parasites. A) Chromosomal rearrangements in *P. vinckei* parasites. Pairwise synteny was assessed between the five *P. vinckei* subspecies and *Plasmodium berghei* (to represent the earliest common RMP ancestor). The 14 chromosomes of different RMP genomes are arranged as a Circos plot and the

1491 ribbons (grey) between them denote regions of synteny. Three reciprocal 1492 translocation events (red) and one inversion (blue) accompany the separation of the 1493 different P. vinckei subspecies. A pan-vinckei reciprocal translocation between 1494 chromosomes VIII and X was observed between P. vinckei and other RMP 1495 genomes. Within the P. vinckei subspecies, two reciprocal translocations, between 1496 chromosomes V and XIII, and between chromosomes V and VI, separate 1497 Plasmodium vinckei petteri and P. v. baforti from the other three subspecies. A small 1498 inversion of ~100 kb region in chromosome 14 has occurred in PvvCY alone. B) 1499 Maximum likelihood phylogeny of different RMP species with high-quality reference 1500 genomes based on protein alignment of 3,920 one-to-one orthologs (bootstrap 1501 values of each node are shown). Genomes of three human malaria species-1502 Plasmodium falciparum, Plasmodium vivax and Plasmodium knowlesi were included 1503 in the analysis as outgroups. C) Maximum likelihood phylogenetic tree of all 1504 sequenced RMP isolates based on 1,010,956 high-quality SNPs (bootstrap values of 1505 each node are shown). There exists significant genotypic diversity among the P. 1506 vinckei isolates compared to the other RMPs. All P. vinckei subspecies have begun 1507 to diverge from their common ancestor well before sub-speciation events within 1508 Plasmodium yoelii and Plasmodium chabaudi. Genetic diversity within P. v. petteri 1509 and P. v. baforti isolates are similar to those observed within P. yoelii and P. 1510 chabaudi isolates while P. v. lentum and P. v. brucechwatti isolates have 1511 exceptionally high and low divergences respectively. Genes with significantly high 1512 Ka/Ks ratios in different subspecies-wise comparisons (as indicated by connector 1513 lines), the gene's Ka/Ks ratio averaged across all indicated *P. vinckei* comparisons 1514 and geographical origin of the isolates are shown.

1516 Figure 3. Sub-telomeric multigene family expansions in *Plasmodium vinckei*

1517 parasites. A)

1518 Violin plots show sub-telomeric multigene family size variations among RMPs and 1519 *Plasmodium falciparum.* The erythrocyte membrane antigen 1 and *fam-c* multigene 1520 families are expanded in the non-Katangan P. vinckei parasites (red). Apart from 1521 these families, multigene families have expanded in *P. vinckei* similar to that in 1522 Plasmodium chabaudi. The Katangan isolate PvvCY (purple) has a smaller number 1523 of family members compared to non-Katangan isolates (orange) except for 1524 lysophospholipases, p235 and pir gene families. B) Maximum Likelihood phylogeny 1525 of 99 ema1 (top) and 328 fam-c (bottom) genes in RMPs. Branch nodes with good 1526 bootstrap support (> 70) are marked in red. The first coloured band denotes the 1527 RMP species to which the particular gene taxon belongs to. The heatmap denotes 1528 the relative gene expression among rings, trophozoite, schizont and gametocyte 1529 stages in the RMPs for which data are publicly available. Orange denotes high 1530 relative gene expression and white denotes low relative gene expression, while grey 1531 denotes lack of information. Gene expression was classified into three categories 1532 based on FPKM level distribution- High (black) denotes the top 25% of ranked FPKM 1533 of all expressed genes (FPKM > 256), Low (light grey) is the lower 25% of all 1534 expressed genes (FPKM < 32) and Medium level expression (grey: 32 < FPKM < 256). 1535 "P" denotes pseudogenes, Four vinckei-group (P. chabaudi and P. vinckei 1536 subspecies) specific clades (Clades I-IV; orange), two vinckei-specific clade (Clade 1537 IV and V; purple) and one non-Katangan-specific clade (Clade VI; blue) can be 1538 identified within ema1 family with strong gene expression, maximal during ring 1539 stages. Rest of the family's expansion within non-Katangan P. vinckei isolates are 1540 mainly pseudogenes with weak transcriptional evidence. The fam-c gene phylogeny

1541 shows the presence of four distinctly distal clades (A) with robust basal support (96-1542 100). Of the four clades, two are pan-RMP (grey) and two are *vinckei* group-specific 1543 (orange), each consisting of fam-c genes positionally conserved across the member 1544 subspecies. Most members of these clades show medium to high gene expression 1545 during asexual blood stages. Other well-supported clades can be classified as either 1546 berghei group-specific (two; green), vinckei group-specific (two; orange), P. vinckei -1547 specific (two; purple) or non-Katangan P. vinckei -specific clades (three; blue). There 1548 is evidence of significant species-specific expansion with striking examples in 1549 Plasmodium voelii (i), P. chabaudi (ii) and in P. v. brucechwatti (iii). 1550 1551 Figure 4. Phenotypic variation and genetics in *Plasmodium vinckei* parasites. 1552 A) Schematic of isolate-specific genetic markers detected in clonal line of PvsEL X 1553 PvsEH cross progeny by Sanger sequencing. Genetic markers from both EH (red) 1554 and EL (blue) isolates were detected in the crossed progeny proving successful 1555 genetic crossing. B) Schematic of homologous recombination-mediated insertion of a 1556 gfp-luciferase cassette into the p230p locus in *P. vinckei* CY. C) GFP expression in 1557 different blood stages of PvvCY and luciferase expression of PvvCY oocysts in

1558 mosquito midgut.

1559 **Tables**

Table 1. Genome assembly characteristics of five *Plasmodium vinckei* **reference genomes.** AT-rich *P. vinckei* genomes are 19.2 to 19.5 megabasepairs (Mbps) long except for *Pvv*CY which has a smaller genome size of 18.3 Mb, similar to *Plasmodium berghei.* PacBio long reads allowed for chromosomes to be assembled as gapless unitigs with a few exceptions. Number of genes include partial genes and pseudogenes. Copy numbers of the ten multigene families differ between

the *P. vinckei* subspecies (*ema1*, erythrocyte membrane antigen 1, *etramp*, early
transcribed membrane protein, *hdh*, haloacid dehalogenase-like hydrolase, *lpl*,
lysophospholipases, *p235*, reticulocyte binding protein, *pir*, *Plasmodium* interspersed
repeat protein).
