## 47 Abstract:

48

49 Distributed population codes are ubiquitous in the brain and pose a challenge to 50 downstream neurons that must learn an appropriate readout. Here we explore the possibility that this learning problem is simplified through inductive biases 51 52 implemented by stimulus-independent noise correlations that constrain learning 53 to task-relevant dimensions. We test this idea in a set of neural networks that 54 learn to perform a perceptual discrimination task. Correlations among similarly 55 tuned units were manipulated independently of overall population signal-to-noise ratio in order to test how the format of stored information affects learning. Higher 56 57 noise correlations among similarly tuned units led to faster and more robust learning, favoring homogenous weights assigned to neurons within a functionally 58 59 similar pool, and could emerge through Hebbian learning. When multiple 60 discriminations were learned simultaneously, noise correlations across relevant 61 feature dimensions sped learning whereas those across irrelevant feature dimensions slowed it. Our results complement existing theory on noise 62 63 correlations by demonstrating that when such correlations are produced without degradation of signal-to-noise ratio, they can improve readout learning by 64 65 constraining it to appropriate dimensions.

66 67

## 68 Introduction:

69

70 The brain represents information using distributed population codes in which 71 particular feature values are encoded by large numbers of neurons. One 72 advantage of such codes is that a pooled readout across many neurons can 73 effectively reduce the impact of stimulus-independent variability (noise) in the 74 firing of individual neurons (Pouget et al., 2000). However, the extent to which 75 this benefit can be employed in practice is constrained by noise correlations, or 76 the degree to which stimulus-independent variability is shared across neurons in 77 the population (Averbeck et al., 2006). In particular, positive noise correlations 78 between neurons that share the same stimulus tuning can reduce the amount of 79 decodable information in the neural population (Averbeck et al, 2006; Moreno-80 Bote et al., 2014; Hu et al., 2014). Despite their detrimental effect on encoding, noise correlations of this type are reliably observed, even after years of training 81 82 on perceptual tasks (Cohen and Kohn, 2011). Furthermore, noise correlations 83 between neurons are dynamically enhanced under conditions where two neurons 84 provide evidence for the same response in a perceptual categorization task 85 (Cohen and Newsome, 2008), raising questions about whether they might serve 86 a function rather than simply reflecting a suboptimal encoding strategy.

87

88 At the same time, learning to effectively read out a distributed code also poses a 89 significant challenge. Learning the appropriate weights for potentially tens of

90 thousands of neurons in a low signal-to-noise regime is a difficult, high-91 dimensional problem, requiring a very large number of learning trials and 92 entailing considerable risk of "over fitting" to specific patterns of noise across the 93 neural populations encountered during learning trials. Nonetheless, people and 94 animals can rapidly learn to perform perceptual discrimination tasks, albeit with 95 performance that does not approach theoretically achievable levels (Hawkey et 96 al., 2004; Stringer et al., 2019). In comparison, deep neural networks capable of 97 achieving human level performance typically require a far greater number of 98 learning trials than would be required by humans and other animals (Tsividis et 99 al., 2017). This raises the question of how brains might implement inductive 100 biases to enable efficient learning in high dimensional spaces.

101

102 Here we address open questions about noise correlations and learning by

103 considering the possibility that noise correlations facilitate faster learning.

104 Specifically, we propose that noise correlations aligned to task relevant

105 dimensions could reduce the effective dimensionality of learning problems,

106 thereby making them easier to solve. For example, perceptual stimuli often

107 contain a large number of features that may be irrelevant to a given

108 categorization. At the level of a neural population, individual neurons may differ in

109 the degree to which they encode task irrelevant information, thus making the

110 learning problem more difficult. In principle, noise correlations in the relevant

dimension could reduce the effects of this variability on learned readout. Such an

explanation would be consistent with computational analyses of Hebbian learning

113 rules (Oja, 1982), which can both facilitate faster and more robust learning

114 (Krotov and Hopfield, 2019), and in turn may induce noise correlations. We

propose that faster learning of an approximate readout is made possible through low dimensional representations that share both signal and noise across a large

117 neural population. In particular, we hypothesize that representations

118 characterized by enhanced noise correlations among similarly tuned neurons can

improve learning by focusing adjustments of the readout onto task relevantdimensions.

121

122 We explore this possibility using neural network models of a two-alternative 123 forced choice perceptual discrimination task in which the correlation among 124 similarly tuned neurons can be manipulated independently of the overall 125 population signal-to-noise ratio. Within this framework, noise correlations, which 126 can be learned through Hebbian mechanisms, speed learning by forcing learned 127 weights to be similar across pools of similarly tuned neurons, thereby ensuring 128 learning occurs over the most task relevant dimension. We extend our framework 129 to a cued multidimensional discrimination task and show that dynamic noise

130 correlations similar to those observed in vivo (Cohen and Newsome, 2008),

131 speed learning by constraining weight updates to the relevant feature space. Our

132 results demonstrate that when information is extrinsically limited, noise

133 correlations can make learning faster and more robust by controlling the

- 134 dimensions over which learning occurs.
- 135
- 136

## 137 Methods:

138 Our goal was to understand the computational principles through which 139 correlations in the activity of similarly tuned neurons affect the speed with which downstream neurons could learn an effective readout. Previous work has 140 141 demonstrated that manipulating noise correlations while maintaining a fixed 142 variance in the firing rates of individual neurons leads to changes in the 143 theoretical encoding capacity of a neural population (Averbeck et al., 2006; 144 Moreno-Bote et al., 2014). To minimize the potential impact of such encoding 145 differences, we took a different approach; rather than setting the variance of 146 individual neurons in our population to a fixed value, we set the signal-to-noise 147 ratio of our population to a fixed value. Thus, our approach does not ask how 148 maximum information can be packed into a given neural population's activity, but 149 rather how the strategy for packing a *fixed* amount of information in a population 150 affects the speed with which an appropriate readout of that information can be 151 learned. We implement this approach in three neural networks described in more 152 detail below.

## 153 Learning readout in perceptual learning task

154 Simulations and analyses for a simple perceptual discrimination task were 155 performed with a simplified and statistically tractable two-layer feed-forward 156 neural network (figure 3A). The input layer consisted of two pools of 100 units 157 that were each "tuned" to one of two motion directions (left, right). On each trial 158 normalized firing rates for the neural population were drawn from a multivariate 159 normal distribution that was specified by a vector of stimulus-dependent mean 160 firing rates (signal: +1 for preferred stimulus, -1 for non-preferred stimulus) and a 161 covariance matrix. All elements of the covariance matrix corresponding to 162 covariance between units that were "tuned" to different stimuli were set to zero. 163 The key manipulation was to systematically vary the magnitude of diagonal 164 covariance components (eq. noise in the firing of individual units) and the "same 165 pool" covariance elements (eg. shared noise across identically tuned neurons) while maintaining a fixed level of variance in the summed population response for 166 167 each pool:

$$\sigma_{pool}^2 = n\sigma_{unit}^2 + n(n-1)Cov(within pool)$$
 Eq. 1

168 Where  $\sigma_{pool}^2$  is the variance on the sum of normalized firing rates from neurons 169 within a given pool, n is the number of units in the pool and the within pool 170 covariance (*Cov*(*within pool*)) specifies the covariance of pairs of units

belonging to the same pool. The signal-to-noise ratio (signal/ $\sigma_{pool}^2$ ) for each pool was fixed to one. Given this constraint, the fraction of noise that was shared across neurons within the same pool was manipulated as follows:

174

$$\sigma_{unit}^2 = \frac{\sigma_{pool}^2}{n+n(n-1)\phi} \quad Eq.2$$

175

176

 $Cov(within pool) = \phi \sigma_{unit}^2 Eq.3$ 

#### 177

178 Where  $\phi$  reflects the fraction of noise that is correlated across units, which we refer to in the text as noise correlations. Noise correlations ( $\phi$ ) were manipulated 179 180 across values ranging from 0 to 0.2 for simulations. Note that, since  $\phi$  appears in 181 the denominator of equation 2, adding noise correlations while sustaining a fixed population signal-to-noise ratio leads to lower variance in the firing rates of single 182 183 neurons, differing from previous theoretical assumptions (compare figure 2a&b). 184 The input layer of the neural network was fully connected to an output layer 185 composed of two output units representing left and right responses. Output units 186

composed of two output units representing left and right responses. Output units
 were activated on a given trial according to a weighted function of their inputs:

189

$$F_{output} = wF_{input} Eq.4$$

190

191 Where  $F_{output}$  is a vector of firing rates of output units,  $F_{input}$  is a vector of firing 192 rates of the input units, and w is the weight matrix. Firing of an individual output 193 unit can also be written as a weighted sum over input unit activity: 194

$$F_j = \sum_{i=1}^{200} w_{i,j} F_i \quad Eq.5$$

where  $F_j$  reflects the firing of the j<sup>th</sup> output unit,  $F_i$  reflects the firing of the i<sup>th</sup> input unit, and  $w_{i,j}$  reflects the weight of the connection between the i<sup>th</sup> input unit and

the j<sup>th</sup> output unit. Actions were selected as a softmax function of output firing
 rates:

199

$$p(A_j) = \frac{e^{\beta F_j}}{\sum_k e^{\beta F_k}} \quad Eq.6$$

where  $\beta$  is an inverse temperature, which was set to a relatively deterministic value (10000). Learning was implemented through reinforcement learning of weights to the selected output neuron (subscripted j below):

$$\Delta w_{i,i} = \alpha \delta F_i \quad Eq.7$$

Where  $F_i$  is the normalized firing rate of the i<sup>th</sup> input neuron,  $\delta$  is the reward 204 prediction error experienced on a given trial [+0.5 for correct trials and -0.5 for 205 206 error trials], and  $\alpha$  is a learning rate (set to 0.0001 for simulations in figure 2). The 207 network was trained to correctly identify two stimuli (each of which was preferred 208 by a single pool of input neurons) over 100 trials (the last 20 trials of which were 209 considered testing). Simulations were repeated 1000 times for each level of  $\phi$ 210 and performance measures were averaged across all repetitions. Mean accuracy 211 per trial across all simulations was convolved with a Gaussian kernel (standard 212 deviation = 0.5 trials) for plotting in figure 2b. Mean accuracy across the final 20 213 trials was used as a measure of final accuracy (figure 2e). Statistics on model 214 performance were computed as Pearson correlations between noise correlations 215  $\phi$  and performance measures across all simulations and repetitions.

216

## 217 Hebbian learning of noise correlations in three layer network

218

219 We extended the two-layer feed-forward architecture described above to include 220 a third hidden layer in order to test whether Hebbian learning could facilitate 221 production of noise correlations among similarly tuned neurons (figure 4A). The 222 input layer was fully connected to the hidden layer, and each layer contained 200 223 neurons. In the input layer, neurons were tuned (100 leftward, 100 rightward) as 224 described above, with  $\phi$  set to zero (eq. no noise correlations). Weights to the 225 hidden layer were initialized to favor one-to-one connections between input layer 226 units and hidden layer units by adding a small normal random weight perturbation 227 (mean=0, standard deviation = 0.01) to an identity matrix. During learning, 228 weights between the input and hidden layer were adjusted according to a 229 normalized Hebbian learning rule:

$$\Delta W = \alpha_{hebb} F_1' F_2 \quad Eq.8$$

231

232 Where  $F'_1$  is a normalized vector of firing rates corresponding to the input layer and  $F_2$  is a normalized vector of firing rates corresponding to the hidden layer 233 units. The learning rate for Hebbian plasticity ( $\alpha_{hebb}$ ) was set to 0.00005 for 234 235 simulations in figure 4. The model was "trained" over 100 trials in the same 236 perceptual discrimination task described above and an additional 100 trials of the 237 task were completed to measure emergent noise correlations in the hidden layer. 238 Noise correlations were measured by regressing out variance attributable to the 239 stimulus on each trial, and then computing the Pearson correlation of residual 240 firing rate across each pair of neurons for the 100 testing trials (figure 4B&C). 241

242 Learning readout in multiple discrimination task

243 In order to test the impact of contextual noise correlations on learning (Cohen 244 and Newsome, 2008), the perceptual discrimination task was extended to include 245 two dimensions and two interleaved trial types: one in which an up/down 246 discrimination was performed (vertical), and one in which a right/left 247 discrimination was performed (horizontal). Each trial contained motion on the 248 vertical axis (up or down) and on the horizontal axis (left or right), but only one of these motion axes was relevant on each trial as indicated by a cue. 249 250 251 In order to model this task we extended our two-layer feed-forward network to 252 include 4 populations of input units, 4 output units, and 2 task units (figure 5A).

Each population of 100 input units encoded a conjunction of the movement
directions (up-right, up-left, down-right, down-left). On each trial, the mean firing
rate of each input unit population was determined according to their tuning
preferences:

257

258

259

 $\mu = V + H \quad Eq.9$ 

260 Where V was +1/-1 for trials with the preferred/anti-preferred vertical motion 261 direction H was +1/-1 for trials with the preferred/anti-preferred horizontal motion 262 direction. Firing rates for individual neurons were sampled from a multivariate 263 Gaussian distribution with mean  $\mu$  and a covariance matrix that depended on trial 264 type (vertical versus horizontal) and the level of same pool, relevant pool, and 265 irrelevant pool correlations.

266

In order to create a covariance matrix, we stipulated a desired standard error of the mean for summed population activity (SEM=20 for simulations in figure 5) and determined the summed population variance that would correspond to that value ( $\sigma_{pool}^2$ ). We then determined the variance on individual neurons that would yield this population response under a given noise correlation profile as follows:

$$\sigma_{unit}^2 = \frac{\sigma_{pool}^2}{n + n(n-1)\phi_{same} + n^2\phi_{relevant} - n^2\phi_{irrelevant}} \quad Eq.10$$

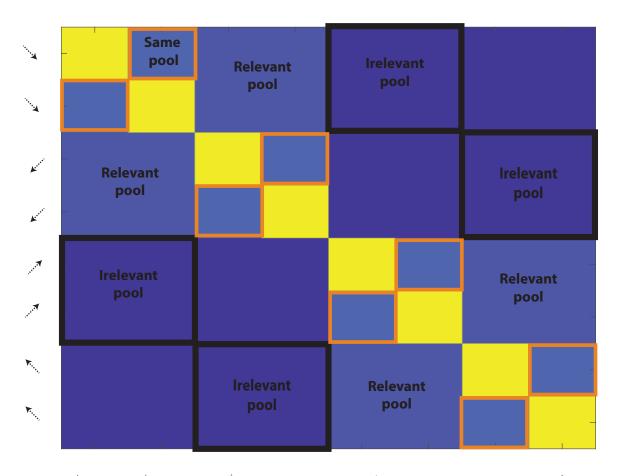

273

Where  $\phi_{same}$  is the level of same pool correlations (range: 0-0.2 in our 274 simulations),  $\phi_{relevant}$  is the level of relevant pool correlations (range: 0-0.2 in our 275 simulations),  $\phi_{irrelevant}$  is the level of irrelevant pool correlations (range: 0-0.2 in 276 our simulations. Note that increasing the same pool or in pool correlations 277 278 reduces the overall variance in order to preserve the same level of variance on 279 the task relevant dimension in the population response, but that increasing 280 irrelevant pool correlations has the opposite effect. Covariance elements of the 281 covariance matrix were determined as follows: 282

 $Cov(same \ pool) = \phi_{same}\sigma_{unit}^2 \quad Eq. 11$  $Cov(relevant \ pool) = \phi_{relevant}\sigma_{unit}^2 \quad Eq. 12$  $Cov(irrelevant \ pool) = \phi_{irrelevant}\sigma_{unit}^2 \quad Eq. 13$ 

283 Variance and covariance values above were used to construct a covariance

matrix for each trial type (vertical/horizontal) as depicted in figure 1.

#### **Covariance matrix: vertical trials**

. منظر 285 286 A. Figure 1: Schematic of covariance matrix for two-dimensional motion discrimination task. 287 Same pool correlations are controlled by covariance elements between neurons with identical 288 tuning (orange boxes). Relevant pool correlations are controlled by covariance elements between 289 neurons that are similarly tuned to the task-relevant feature. Task irrelevant correlations are 290 controlled by covariance elements between neurons that are similarly tuned to the task-irrelevant 291 feature. The covariance matrix shown here is for a vertical trial – on a horizontal trial the irrelevant 292 pool and relevant pool locations would be reversed. Covariance elements for pairs of neurons 293 that differed in tuning on both dimensions were set to zero. Each input population has been 294 depicted as two units here for presentation purposes. Background color reflects the case where 295 same pool correlations = 0.2 and relevant pool correlations = 0.1.

296

297

298 Output units corresponded to the four possible task responses (up, down, left, 299 right) and were activated according to a weighted sum of their inputs as

300 described previously. Task units were modeled as containing perfect information

301 about the task cue (vertical versus horizontal) and were modeled to completely

302 inhibit the responses of the irrelevant output units. Decisions were made on each

303 trial by selecting the output unit with the highest activity level. Weights to chosen

304 output unit were updated using the same reinforcement learning procedure

305 described in the two alternative perceptual learning task.

- 306
- 307

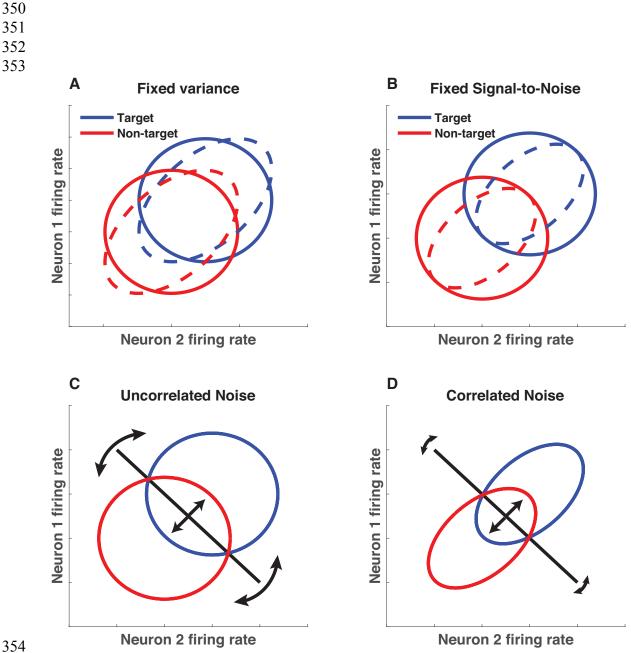

## 308 Results:

309

310 We examine how noise correlations affect learning in a simplified neural network 311 where the appropriate readout of hundreds of weakly tuned units is learned over 312 time through reinforcement. In order to isolate the effects of noise correlations on 313 learning, rather than their effects on other factors such as representational 314 capacity, we consider population encoding schemes at the input layer that can be 315 constrained to a fixed signal-to-noise ratio. This assumption differs from previous 316 work on noise correlations where the *variance* of the neural population is 317 assumed to be fixed and covariance is changed to produce noise correlations, thereby affecting the representational capacity of the population (figure 2A; 318 319 (Averbeck et al., 2006; Moreno-Bote et al., 2014)). Under our assumptions, a 320 fixed signal-to-noise ratio can be achieved for any level of by scaling the variance 321 (figure 2B; equations 1-3), or, alternately scaling the magnitude of the signal (not 322 shown). While we do not discount the degree to which noise correlations affect 323 the encoding potential of neural populations, we believe that in many cases the 324 relevant information is limited by extrinsic factors (eq. the stimulus itself, or 325 upstream neural populations providing input (Beck et al., 2012; Kanitscheider et 326 al., 2015)). Under such conditions, reducing noise correlations can increase 327 information only until it saturates because all of the available incoming 328 information is encoded. Beyond that, increasing encoding potential is not 329 possible as it would be tantamount to the population "creating new information" 330 that was not communicated by inputs to the population. Therefore, our framework 331 can be thought of as testing how best to format limited available information in a 332 neural population in order to ensure that an acceptable readout can be rapidly 333 and robustly learned.

334

335 We propose that within this framework, noise correlations of the form that have 336 previously been shown to limit encoding are beneficial because they constrain 337 learning to occur over the most relevant dimensions. In general, a linear readout 338 can be thought of as hyperplane serving as a classification boundary in an N 339 dimensional space, where N reflects the number of neurons in a population. 340 Learning in such a framework involves adjustments of the hyperplane to minimize 341 classification errors. The most useful adjustments are in the dimension that best 342 discriminates signal from noise (central arrows in figure 2C&D), but adjustments 343 may also occur in dimensions orthogonal to the relevant one (such as "twisting" 344 of the hyperplane depicted by curved arrows in figure 2C&D) that could 345 potentially impair performance, or slow down learning. Our motivating hypothesis 346 is that by focusing population activity into the task relevant dimension, noise 347 correlations can increase the fraction of hyperplane adjustments that occur in the 348 task relevant dimension (figure 2D), thus reducing the effective dimensionality of 349 readout learning.

355

#### 356 Figure 2: Modeling noise correlations in under extrinsic constraint on signal-to-noise

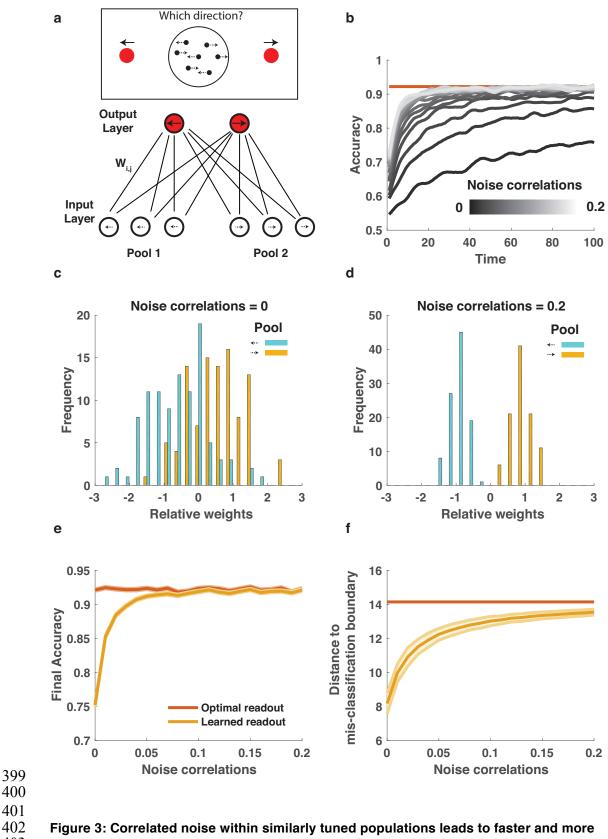

357 ratio. A) Previous work has modeled noise correlations by assuming that population variance is 358 fixed and that covariance is manipulated to produce noise correlations. Under such assumptions, 359 the firing rate of two similarly tuned neurons is plotted in the absence (solid) or presence (dotted) 360 of information-limiting noise correlations. B) Here we assume that the signal-to-noise ratio of the 361 neural population is limited to a fixed value such that noise correlations between similarly tuned 362 neurons do not affect theoretical performance. Thus, the percent overlap of blue (target) and red 363 (non-target) activity profiles does not differ in the presence (dotted) or absence (solid) of noise 364 correlations. C&D) Under this assumption, noise correlations among similarly tuned neurons 365 could compress the population activity to a plane orthogonal to the optimal decision boundary,

thereby minimizing boundary adjustments in irrelevant dimensions (C) and maximizing boundary
 adjustments on relevant ones (D).

368

369 370 In order to test this hypothesis, we constructed a fully connected two-layer feed-371 forward neural network in which input layer units responded to one of two 372 stimulus categories (pool 1 & pool 2) and each output unit produced a response 373 consistent with a category perception (left/right units in figure 3A). On each trial, 374 the network was presented with one stimulus at random, and input firing for each 375 pool was drawn from a multivariate Gaussian with a covariance that was 376 manipulated while preserving the population signal-to-noise ratio. Output units 377 were activated according to a weighted average of inputs and a response was 378 selected according to output unit activations. On each trial, weights to the 379 selected action were adjusted according to a reinforcement learning rule that 380 strengthened connections that facilitated a rewarded action and weakened 381 connections that facilitated an unrewarded action (Law and Gold, 2009). 382 383 Noise correlations led to faster and more robust learning of the appropriate 384 stimulus-response mapping. All neural networks learned to perform the requisite 385 discrimination, but neural networks that employed correlations among similarly 386 tuned neurons learned more rapidly (figure 3B). After learning, networks that 387 employed such noise correlations assigned more homogenous weights to input 388 units of a given pool than did networks that lacked noise correlations (compare 389 figure 3C&D). This led to better trained-task performance (figure 3E; Pearson 390 correlation between noise correlations and test performance: R = 0.29, p < 10e-50) and greater robustness to adversarial noise profiles (figure 3F; R = 0.81, p < 0.81391 392 10e-50) in the networks that employed noise correlations. Critically, these 393 learning advantages emerged despite the fact that optimal readout of all 394 networks achieved similar levels of performance and robustness (figure 3E&F. 395 compare optimal readout across conditions). 396

- 397
- 398

robust learning of a perceptual discrimination. A) A two-layer feed-forward neural network was designed to solve a two alternative forced choice motion discrimination task at or near

405 perceptual threshold. Input layer contains two pools of neurons that provide evidence for alternate 406 percepts (eq. leftward motion versus rightward motion) and output neurons encode alternate 407 courses of actions (eq. saccade left versus saccade right). Lavers are fully connected with 408 weights randomized to small values and adjusted after each trial according to rewards (see 409 methods). B) Average learning curves for neural network models in which population signal-to-410 noise ratio in pools 1 and 2 were fixed, but noise correlations (grayscale) were allowed to vary 411 from small (dark) to large (light) values. C&D) Weight differences (left output - right output) for 412 each input unit (color coded according to pool) after 100 timesteps of learning for low (C) and high 413 (D) noise correlations. E) Accuracy in the last 20 training trials is plotted as a function of noise 414 correlations for learned readouts (orange) and optimal readout (red). Lines/shading reflect 415 Mean/SEM. F) The shortest distance, in terms of neural activation, required to take the mean 416 input for a given category (eg. left or right) to the boundary that would result in misclassification is 417 plotted for the final learned (orange) and optimal (red) weights for each noise correlation condition 418 (abscissa). Lines/shading reflect Mean/SEM.

419 420

421

422 Given that noise correlations implemented in our previous simulation, like those 423 observed in the brain, depended on the tuning of individual units, we tested 424 whether such noise correlations might be produced via Hebbian plasticity. 425 Specifically, we considered an extension of our neural network in which an 426 additional intermediate layer is included between input and output neurons (figure 427 4a). Input units were again divided into two pools that differed in their encoding, 428 but variability was uncorrelated across neurons within a given pool. Connections 429 between the input layer and intermediate layer were initialized such that each 430 input unit strongly activated one intermediate layer unit, and shaped over time 431 using a Hebbian learning rule that strengthened connections between co-432 activated neuron pairs. Despite the lack of noise correlations in the input layer of 433 this network (figure 4b; mean[std] in pool residual correlation = 0.0015[0.10]), 434 neurons in the intermediate layer developed tuning-specific noise correlations of 435 the form that were beneficial for learning in the previous simulations (figure 4c; 436 mean[std] in pool residual correlation = 0.55[0.07]; t-test on difference from input 437 layer correlations t = 443, dof = 19800, p < 10e-50). 438 439

440

441

442

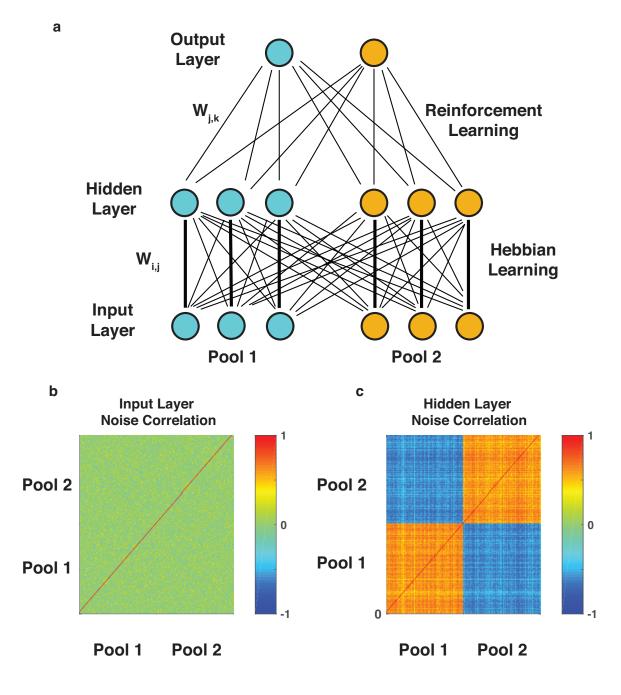

Figure 4: Hebbian learning produces correlations within similarly tuned populations in a
 perceptual discrimination task. A) Three-layer neural network architecture. Input layer feeds
 forward to hidden layer, which is fully connected to an output layer. Input layer provides
 uncorrelated inputs to hidden layer through projection weights that are adjusted according to a
 Hebbian learning rule. B&C) Noise correlations observed in hidden layer units at the beginning
 (B) and end (C) of training.

## 458

459 In order to understand how noise correlations might impact learning in mixed 460 encoding populations, we extended our perceptual discrimination task to include 461 two directions of motion discrimination (eq. up/down and left/right). On each trial, 462 a cue indicated which of two possible motion discriminations should be 463 performed (figure 5A, left; (Cohen and Newsome, 2008)). We extended our 464 neural network to include four populations of one hundred input units, each 465 population encoding a conjunction of motion directions (up-right, up-left, down-466 right, down-left; figure 5A; input layer). Two additional inputs provided a perfectly 467 reliable "cue" regarding the relevant feature for the trial (figure 5A; task units). 468 Four output neurons encoded the four possible responses (up, left, down, right) 469 and were fully connected to the input layer (figure 5A; output layer). Task units 470 were hard wired to eliminate irrelevant task responses, but weights of input units 471 were learned over time as in our previous simulations.

472

473 Learning performance in the two-feature discrimination task depended not only
474 on the level of noise correlations, but also on the type. As in the previous
475 simulation, adding noise correlations to each individual population of identically
476 tuned units led to faster learning of the appropriate readout (Figure 5B&C,

477 compare blue and yellow; Figure 5D&E, vertical axis; mean[std] accuracy across
 478 training: 0.53[0.05] and 0.614[0.08] for minimum (0) and maximum (0.2) in pool

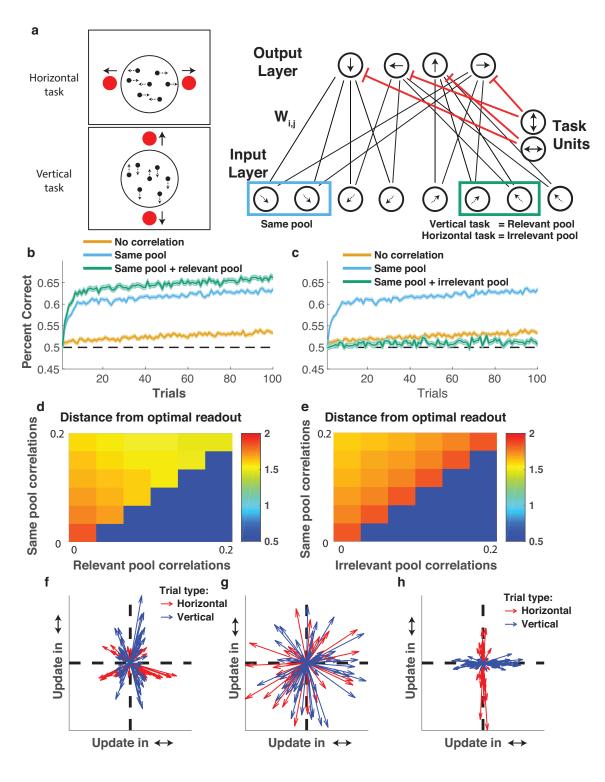

- 479 correlations, t-test for difference in accuracy: t = 95, dof = 19998, p < 10e-50).
- 480

481 However, the more complex task design also allowed us to test whether dynamic 482 trial-to-trial correlations might further facilitate learning. Specifically, correlations 483 that increase shared variability among units that contribute evidence to the same 484 response have been observed previously (Cohen and Newsome, 2008), and 485 could in principle focus learning on relevant dimensions (figure 2C&D) even when 486 those dimensions change from trial to trial. Indeed, adding correlations among 487 separate pools that share the same encoding of the relevant feature (eq. UP on a 488 vertical trial) led to faster learning (figure 5B; mean[std] training accuracy for 489 model with relevant pool correlations: 0.64[0.09], t-test for difference from in pool correlation only model: t = 22, dof = 19998, p < 10e-50) and weights that more 490 491 closely approached the optimal readout (figure 5E, horizontal axis). In contrast, 492 when positive noise correlations were introduced across separate encoding pools 493 that shared the same tuning for the irrelevant dimension on each trial (eg. UP on 494 a horizontal trial) learning was impaired dramatically (figure 5C: mean[std] 495 training accuracy for model with irrelevant pool correlations: 0.51[0.05], t-test for 496 difference from in pool correlation only model: t = -112, dof = 19998, p < 10e-50) 497 and learned weights diverged from the optimal readout (figure 5F, horizontal 498 axis). Model performance differences were completely attributable to learning the 499 readout, as all models performed similarly when using the optimal readout (figure 500 S1).

502 In order to test the idea that noise correlations might focus learning onto relevant 503 dimensions, we extracted weight updates from each trial and projected these 504 updates into a two-dimensional space where the first dimension captured the 505 relative sensitivity to leftward versus rightward motion and the second dimension 506 captured relative sensitivity to upward versus downward motion. In the model 507 where input units were only correlated within their identically tuned pool, weight 508 updates projected in all directions more or less uniformly (figure 5G), and did not 509 differ systematically across trial types (vertical versus horizontal). However, 510 dynamic noise correlations that shared variability across the relevant dimension 511 tended to push weight updates onto the appropriate dimension for a given trial 512 (figure 4F: t-test for difference in the magnitude of updating in up/down and 513 left/right dimensions across conditions [up/down – left/right]: t = 3.4, dof=98, p =514 0.001). In contrast, dynamic noise correlations that shared variability across the 515 irrelevant dimension tended to push weight updates onto the wrong dimension 516 (figure 4H; t-test for difference in the magnitude of updating in up/down and 517 left/right dimensions across conditions [up/down – left/right]: t = -9.5, dof=98, p =518 10e-14). Both of these trends were consistent across simulations, providing an 519 explanation for the performance improvements achieved by relevant noise 520 correlations (projection of learning onto an appropriate dimension) and 521 performance impairments produced by irrelevant noise correlations (projection of 522 learning onto an inappropriate dimension). 523 524 525 526 527

528

529

531 532

533

**Figure 5: Task dependent noise correlations affect learning speed by projecting learning onto specific feature dimensions. A)** A neural network was trained to perform two interleaved motion discrimination tasks (left; (Cohen and Newsome, 2008)). Network schematic (right) depicts two-layer feed-forward network in which each population of input units represents two dimensions of motion (up versus down, and left versus right), and output units produce responses

539 in favor of alternative actions (up, down, left, right). Two additional input units provide cue

540 information that biases output units to produce an output corresponding to the discrimination 541 appropriate on this trial (eq. horizontal or vertical). Noise correlations were manipulated among 1) 542 identically tuned neurons (blue rectangle; same pool), 2) neurons that have similar encoding of 543 the task relevant feature (green rectangle pair in vertical trials; relevant pool), and 3) neurons that 544 have similar encoding of the task irrelevant feature (green rectangle pair in horizontal trials; 545 irrelevant pool). B&C) Learning curves showing accuracy (ordinate) over trials (abscissa) for 546 models 1) lacking noise correlations (orange), 2) containing noise correlations that are limited to 547 neurons that have same tuning for both features (same pool; blue), 3) containing same pool noise 548 correlations along with correlations between neurons in different pools that have the same tuning 549 for the task-relevant feature (in pool+rel pool; green in **B**), and 4) containing in-pool noise 550 correlations along with correlations between neurons in different pools that have the same tuning 551 for the task irrelevant feature (in pool+irrel pool; green in C). D&E) Distance between learned 552 weights and the optimal readout (color) for models that differ in their level of "in pool" correlations 553 (ordinate, both plots), "relevant pool" correlations (abscissa, **D**), and "irrelevant pool" correlations 554 (abscissa, E). F.G.H) Weight updates for example learning sessions were projected into a two 555 dimensional space in which net updates to the relative contribution of vertical motion information 556 (eg. up versus down) is represented on the abscissa and updates to the relative contribution of 557 horizontal motion information (eq. left versus right) is represented on the ordinate. Arrows reflect 558 single trial weight updates and are colored according to the trial type (red = horizontal 559 discrimination, blue = vertical discrimination). Weight updates for a model with only "in pool" 560 correlations look similar across trial types (G), but weight updates for a model with "relevant pool" 561 correlations indicate more weight updating on the relevant feature (F), whereas the opposite was 562 observed in the case of "irrelevant pool" correlations (H).

- 564

## 565 **Discussion:**

566

567 Taken together, our results suggest that in settings where the population signal-568 to-noise ratio is limited by external factors (eq. inputs) and relevant task 569 representations are low dimensional, noise correlations can make learning faster 570 and more robust by focusing learning on the most relevant dimensions. We 571 demonstrate this basic principle in a simple perceptual learning task (figure 3), 572 where beneficial noise correlations between similarly tuned units could be 573 produced through a simple Hebbian learning rule (figure 4). We extended our 574 framework to a contextual learning task to demonstrate that dynamic noise 575 correlations that bind task relevant feature representations facilitate faster 576 learning (figure 5b&d) by pushing learning onto task-relevant dimensions (figure 577 5f). Given the pervasiveness of noise correlations among similarly tuned sensory 578 neurons (Zohary et al., 1994; Maynard et al., 1999; Bair et al., 2001; Averbeck 579 and Lee, 2003; Cohen and Maunsell, 2009; Huang and Lisberger, 2009; Ecker et 580 al., 2010; Gu et al., 2011; Adibi et al., 2013), and that the noise correlations 581 dynamics beneficial for learning in our simulations are similar to those that have 582 been observed in vivo (Cohen and Newsome, 2008), we interpret our results as 583 suggesting that noise correlations between similarly tuned neurons are a feature of neural coding architectures that ensures efficient readout learning, rather than 584 585 a bug that limits encoding potential.

- 586
- 587

588 This interpretation rests on several assumptions in our model. Of particular 589 importance is the assumption that signal-to-noise ratio of our populations is fixed, 590 meaning that our manipulation of noise correlations can focus variance on 591 specific dimensions without gaining or losing information. This assumption 592 reflects conditions in which information is limited at the level of the inputs to the 593 population, for instance due to noisy peripheral sensors (Beck et al., 2012; 594 Kanitscheider et al., 2015). In such conditions, even with optimal encoding, 595 population information saturates at an upper bound determined by the 596 information available in the inputs to the population. Therefore, fixing the signal-597 to-noise ratio enabled us to examine the effect of noise correlations on 598 downstream processes that learn to read-out the population code in the absence 599 of any influence of noise correlations on the quantity of information contained 600 within that population code.

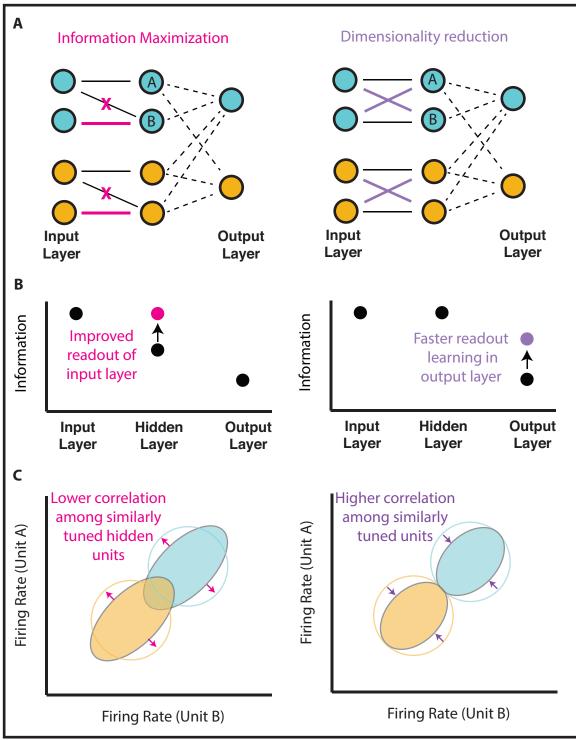

601

602 Previous theoretical work exploring the role of noise correlations in encoding has typically assumed that single neurons have a fixed variance, such that tilting the 603 covariance of neural populations towards or away from the dimension of signal 604 605 encoding would have a large impact on the amount of information that can be 606 encoded by a population (figure 1a; (Averbeck et al., 2006; Moreno-Bote et al., 607 2014)). Such assumptions lead to the idea that positive noise correlations among 608 similarly tuned neurons limit encoding potential, raising the question of why they 609 are so common in the brain (Cohen and Kohn, 2011). In considering the 610 implications of this framework, one important question is: if information encoded 611 by the population can be increased by changing the correlation structure among 612 neurons, where does this additional information come from? In some cases, the 613 neural population in guestion may indeed receive sufficient task relevant 614 information from upstream brain regions to reorganize its encoding in this way, 615 but in other cases it is likely that information is limited by the inputs to a neural population (Kanitscheider et al., 2015; Kohn et al., 2016). In cases where 616 617 incoming information is limited, further increasing representational capacity is not 618 possible, and formatting information for efficient readout is essentially the best 619 that the population code could do. Here we show that the noise correlations that 620 have previously been described as "information limiting" are exactly the type of 621 correlations that format information most efficiently for readout learning under 622 such conditions. 623

624 Jointly considering these antagonistic perspectives on noise correlations provides 625 a more nuanced view of how neural representations are likely optimized for 626 learning. In order to optimize an objective function, a neural population can 627 reduce correlated noise in task relevant dimensions to increase its 628 representational capacity up to some level constrained by its inputs (Figure 6. 629 left). But once the population is fully representing all task relevant information that 630 has been provided to it, it can additionally optimize representations by pushing as 631 much variance onto task relevant dimensions as possible, thereby affording

632 efficient learning in downstream neural populations (Figure 6, right). In short,

- 633 optimization of a neural population code does not occur in a vacuum, and instead
- 634 depends critically on both upstream (eg. input constraints) and downstream (eg.
- readout) neural populations (Figure 6). In this view, if a neural population is *not*
- 636 fully representing the decision relevant information made available to it, then
- 637 learning could improve the efficiency of representations by reducing rate limiting
- noise correlations as has been observed in some paradigms (Figure 6, left; Gu et
- al., 2011; Ni et al., 2018). In contrast, once available information is fully
- 640 represented, readout learning could be further optimized by reformatting
- 641 population codes such that variability is shared across neurons with similar
- 642 tuning for the relevant task feature, producing the sorts of dynamic noise
- 643 correlations that have been observed in well trained animals (Figure 6, right;
- 644 Cohen and Newsome, 2008).

645 646 Figure 6: Information maximization and dimensionality reduction can be useful for 647 learning under different situations and have opposite effects on noise correlations among 648 similarly tuned units. A) A schematic representation of a three layer neural network in which 649 units provide evidence for one of two categorizations (blue/orange). In the left network, the hidden 650 layer initially has access to information from only one of two independent units in each pool, but 651 weights are subsequently adjusted to increase task-relevant information represented in the 652 hidden layer (pink). In the right network, the hidden layer initially has access to all task-relevant

653 information, but weights are subsequently adjusted to share signal and noise across similarly 654 tuned units to afford dimensionality reduction (purple). Note that the information maximizing 655 weight adjustments (left, pink) increase signal-to-noise ratio in the hidden layer but preserve the 656 variance in firing rate of individual neurons, whereas the dimensionality reducing weight 657 adjustments (right, purple) maintain a fixed signal-to-noise ratio in hidden units, but decrease the 658 variance of individual units by averaging across multiple similarly tuned inputs. Dashed lines to 659 output units reflect weights that need to be learned based on feedback. B) Task relevant 660 information (mutual information between unit activations and stimulus category; abscissa) is 661 depicted for each layer (ordinate). Weight adjustments affording information maximization (left) 662 increase task relevant information in the hidden layer (pink), whereas weight adjustments that 663 afford dimensionality reduction (right) do not affect task-relevant information in the hidden layer 664 itself but instead increase the rate of learning in the output layer, thereby leading to more task-665 relevant information in the output layer (purple). C) Weight adjustments for information 666 maximization (pink in panel A) decrease correlations among hidden units A&B by removing 667 shared input from a single input unit and instead providing independent sources of input to each 668 unit (pink arrows). In contrast, weight adjustments for dimensionality reduction increase noise 669 correlations among hidden units A&B by providing them with the same mixture of information from 670 the two identically tuned input units. We propose that both of these processes play a critical role 671 in learning and that changes in noise correlations across learning will depend critically on which 672 process dominates. As shown in panel B, this will depend critically on whether the neural 673 population in guestion has already fully represented information available from its inputs. In 674 principle, these processes could occur serially, with early learning maximizing information 675 available in intermediate layers (left) and later learning compressing that information into a format 676 allowing rapid readout learning (right).

677 678

679 In addition to key assumptions about an external limitation on signal-to-noise, our 680 modeling included a number of simplifying assumptions that are unlikely to hold 681 up in real neural populations. For example, we consider discrete pools of 682 identically tuned neurons, rather than the heterogeneous populations observed in sensory cortical regions of the brain. A primary goal of our work was to identify 683 684 the computational principles that control the speed at which readout can be 685 learned, and our simplified populations are considerably more tractable and 686 transparent than realistic neural populations. The principles that we identify here 687 are certainly at play in real neural populations, albeit with implications that are far 688 less transparent. We hope that our simplified results pave the way for future work 689 to assess nuances that can emerge in mixed heterogeneous populations, or in 690 more realistic architectures that go beyond the simple feed forward flow of 691 information considered here.

692

# 693 Model predictions

694

Our work shows that noise correlations can focus the gradient of learning onto the most appropriate dimensions. Thus, our model predicts that the degree to which similarly tuned neurons are correlated during a perceptual discrimination should be positively related to performance improvements experienced on subsequent discriminations. In contrast, our model predicts that the degree of correlation between neurons that are similarly tuned to a task irrelevant feature should control the degree of learning on irrelevant dimensions, and thus

702 negatively relate to performance improvements on subsequent discriminations. 703 These predictions are strongest for the earliest stages of learning where weight 704 adjustments are critical for subsequent performance, but they may also hold for 705 later stages of learning, when correlations on irrelevant dimensions, including 706 independent noise channels, could potentially lead to systematic deviations from 707 optimal readout (figure 2f, 4d&e). These predictions could be tested by recording 708 neural responses to a stimulus set that differs across multiple features to 709 characterize both signal-to-noise and correlated variability for each feature 710 discrimination. A strong prediction of our model is that correlated variability within 711 neurons tuned to a given feature should be a predictor of subsequent learning of 712 responses to that feature – above and beyond feature value discriminability. 713 714 One interesting special case involves tasks where the relevant dimension 715 changes in an unsignaled manner (Birrell and Brown, 2000). In such tasks, noise 716 correlations on the previously relevant dimension would, after such an 717 "extradimensional shift", force gradients into a task-irrelevant dimension and thus 718 impair learning performance. Interestingly, learning after extra-dimensional shifts 719 can be selectively improved by enhancing noradrenergic signaling (Devauges 720 and Sara, 1990; Lapiz and Morilak, 2006), which leads to increased arousal 721 (Joshi et al., 2016; Reimer et al., 2016) and decreased cortical pairwise noise 722 correlations in sensory and higher order cortex (Vinck et al., 2015; Joshi and 723 Gold, n.d.). While these observations have been made in different paradigms, our

- model suggests that the reduction of noise correlations resulting from increased
  sustained levels of norepinephrine after an extradimensional shift (Bouret and
  Sara, 2005) could mediate faster learning by expanding the dimensionality of the
  learning gradients (compare figure 5G to 5F) to consider features that have not
  been task-relevant in the past.
- 729
- 730 Relation to attentional effects on noise correlations
- 731

732 In broad strokes, our finding that manipulation of noise correlations can focus 733 variance on specific dimensions is in line with specific models of attention. In 734 particular, noise reduction in task irrelevant dimensions might be considered in 735 the same light that is often cast on suppression of task irrelevant dimensions by 736 attentional mechanisms (Zanto and Gazzaley, 2009), in particular for purposes of 737 accurate credit assignment (Akaishi et al., 2016; Leong et al., 2017). One 738 possibility is that compressed low-dimensional task representations in higher-739 order decision regions (Mack et al., 2019) may pass accumulated decision 740 related information back to sensory regions in order to approximate Bayesian 741 inference (Haefner et al., 2016; Bondy et al., 2018; Lange et al., 2018). As task 742 relevant features are learned, such a process would promote noise correlations 743 between neurons coding those relevant features. In other words, noise 744 correlations may reflect a chosen hypothesis about which feature is relevant for 745 predicting outcomes. Such a signal would be beneficial if it could persist (and

thus preserve correlations between neurons tuned to the same task relevant

feature value) until the time of feedback or reinforcement. Recent work showing
 strengthened noise correlations between similarly tuned neurons during working

memory maintenance suggests that this might very well be the case (Merrikhi et al., 2018).

751

752 One observation that seems at odds with this interpretation is that manipulations 753 of attention that cue a particular location or feature tend to decrease noise 754 correlations among neurons that encode that location or feature (Cohen and 755 Maunsell, 2009; Mitchell et al., 2009; Cohen and Maunsell, 2011; Herrero et al., 756 2013; Doiron et al., 2016). The effects of attentional cuing on noise correlations 757 are dynamic in that cues change from one trial to the next, and contextual, in that 758 noise correlations are reduced most dramatically among neurons that contribute 759 evidence toward the same response in a manner consistent with increasing the 760 amount of task relevant information in the population code (Ruff and Cohen. 761 2014; Downer et al., 2015). Our model does not account for these attentional 762 effects, as we intentionally constrained the signal-to-noise ratio of our neural 763 populations, thereby eliminating any potential changes in information encoding 764 potential. However, we hope that our work motivates future studies to jointly 765 consider the impacts of noise correlations on both learning and immediate 766 performance in order to better understand the potentially competing imperatives 767 that the brain faces in dynamically controlling the correlation structure of its own representations (see (Haimerl et al., 2019) for one attempt to do so). 768

769

- 770771 Origins of useful noise correlations
- 772

773 One important question stemming from our work is how noise correlations 774 emerge in the brain. This guestion has been one of longstanding debate. largely 775 because there are so many potential mechanisms through which correlations 776 could emerge (Kanitscheider et al., 2015; Kohn et al., 2016). Noise correlations 777 could emerge from convergent and divergent feed forward wiring (Shadlen and 778 Newsome, 1998), local connectivity patterns within a neural population (Hansen 779 et al., 2012; Smith et al., 2013), or top down inputs provided separately to 780 different neural populations (Haefner et al., 2016). Here we show that static noise 781 correlations that are useful for perceptual learning emerge naturally from Hebbian 782 learning in a feed-forward network. While this certainly suggests that useful noise 783 correlations could emerge through feed forward wiring, it is also possible to 784 consider our Hebbian learning as occurring in a one-step recurrence of the input 785 units, and thus the same data support the possibility of noise correlations through 786 local recurrence. The context dependent noise correlations that speed learning 787 (figure 4), however, would not arise through simple Hebbian learning. Such 788 correlations could potentially be produced through selective top-down signals 789 from the choice neurons, as has been previously proposed (Wimmer et al., 2015;

790 Haefner et al., 2016; Bondy et al., 2018; Lange et al., 2018). Moreover, top-down 791 input may selectively target neuronal ensembles produced through Hebbian 792 learning (Collins and Frank, 2013). While previous work has suggested that such 793 a mechanism could be adaptive for accumulating information over the course of a 794 decision (Haefner et al., 2016), our work demonstrates that the same mechanism 795 could effectively be used to tag relevant neurons for weight updating between 796 trials, making efficient use of top-down circuitry. Haimerl et al. recently made a 797 similar point, showing that stochastic modulatory signals shared across task-798 informative neurons can serve to tag them for a decoder (Haimerl et al., 2019).

799

# 800 Noise correlations as inductive biases

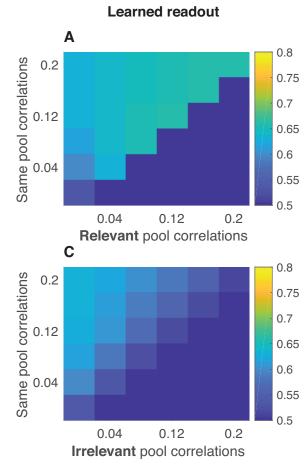

801 802 Artificial intelligence has undergone a revolution over the past decade leading to 803 human level performance in a wide range of tasks (Mnih et al., 2015). However, a 804 major issue for modern artificial intelligence systems, which build heavily on 805 neural network architectures, is that they require far more training examples than 806 a biological system would (Hassabis et al., 2017). This biological advantage 807 occurs despite the fact that the total number of synapses in the human brain, 808 which could be thought of as the free parameters in our learning architecture, is 809 much greater than the number of weights in even the most parameter-heavy 810 deep learning architectures. Our work provides some insight into why this occurs; 811 correlated variability across neurons in the brain constrain learning to specific 812 dimensions, thereby limiting the effective complexity of the learning problem (figure 5F-G). We show that, for simple tasks, this can be achieved using 813 814 Hebbian learning rules (figure 4), but that contextual noise correlations, of the 815 form that might be produced through top-down signals (Haefner et al., 2016), are 816 critical for appropriately focusing learning in more complex circumstances. In 817 principle, algorithms that effectively learn and implement noise correlations might 818 reduce the amount of data needed to train AI systems by limiting degrees of 819 freedom to those dimensions that are most relevant. Furthermore, our work 820 suggests that large scale neural recordings in early stages of learning complex 821 tasks might serve as indicators of the inductive biases that constrain learning in 822 biological systems.

823

824 In summary, we show that under external constraints of task-relevant information. 825 noise correlations that have previously been called "rate limiting" can serve an 826 important role in constraining learning to task-relevant dimensions. In the context 827 of previous theory focusing on representation, our work suggests that neural 828 populations are subject to competing forces when optimizing covariance 829 structures; on one hand reducing correlations between pairs of similarly tuned 830 neurons can be helpful to fully represent available information, but increasing 831 correlations among similarly tuned neurons can be helpful for assigning credit to 832 task relevant features. We believe that this view of the learning process not only 833 provides insight to understanding the role of noise correlations in the brain, but

opens up the door to better understand the inductive biases that guide learning inbiological systems.

- 838 Supplementary figures:

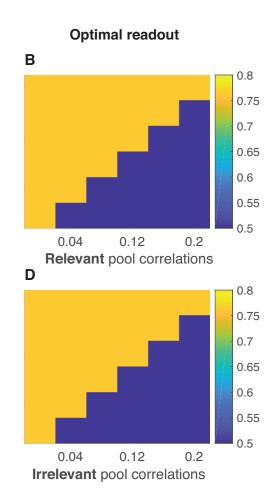

Figure S1: Noise correlations affect speed of learning, but not performance using optimal readout in multiple discrimination task. A) Mean test accuracy (color) of all models spanning the range of in pool correlations (abscissa) and relevant pool correlations (ordinate). B) Mean accuracy of same models using optimal readout, rather than the learned readout. C) Mean test accuracy (color) of all models spanning the range of in pool correlations (abscissa) and irrelevant pool correlations (ordinate). D) Mean accuracy of same models using optimal readout, rather than the learned readout. Note that performance of all models is identical when readout is optimal, rather than learned.
