October 16, 2020

Since emerging in late 2019, SARS-CoV-2 has caused a global pandemic, and it may become an endemic human pathogen. Understanding the impact of environmental conditions on SARS-CoV-2 viability and its transmission potential is crucial to anticipating epidemic dynamics and designing mitigation strategies. Ambient temperature and humidity are known to have strong effects on the environmental stability of viruses1, but there is little data for SARS-CoV-2, and a general quantitative understanding of how temperature and humidity affect virus stability has remained elusive. Here, we characterise the stability of SARS-CoV-2 on an inert surface at a variety of temperature and humidity conditions, and introduce a mechanistic model that enables accurate prediction of virus stability in unobserved conditions. We find that SARS-CoV-2 survives better at low temperatures and extreme relative humidities; median estimated virus half-life was more than 24 hours at 10 °C and 40 % RH, but approximately an hour and a half at 27 °C and 65 % RH. Our results highlight scenarios of particular transmission risk, and provide a mechanistic explana-
tion for observed superspreading events in cool indoor environments such as food processing plants. Moreover, our model predicts observations from other human coronaviruses and other studies of SARS-CoV-2, suggesting the existence of shared mechanisms that determine environmental stability across a number of enveloped viruses.

In order for viruses to transmit from one host to the next, virions must remain viable (infectious) in the period between release from the transmitting host and uptake by the recipient host. Virus environmental stability thus determines the potential for surface (fomite) transmission and for mid-to-long range transmission through the air. Empirical evidence suggests that virus environmental stability strongly depends on ambient temperature and humidity; examples among viruses that infect humans include influenza viruses\(^1\), norovirus\(^2\), human seasonal coronaviruses\(^3\), and the zoonotic coronaviruses SARS-CoV-1\(^4\) and MERS-CoV\(^5\).

Emerging evidence suggests that the novel zoonotic coronavirus SARS-CoV-2—causative agent of the COVID-19 pandemic—also varies in its environmental stability as a function of temperature and humidity\(^6,7\), but the joint effect of these two factors remains unclear. Moreover, despite years of research on virus environmental stability, there do not exist mechanistically motivated quantitative models for virus inactivation as a function of both temperature and humidity. This makes it difficult to generalize from any given experiment to unobserved conditions, or to real-world settings. Existing predictive models for the environmental stability of SARS-CoV-2\(^6,8\) and other viruses\(^9\) are phenomenological regression models that do not model the underlying biochemical mechanisms of inactivation. This limits both our insight into the underlying process of virus inactivation and our ability to extrapolate reliably to unobserved conditions.

We measured the environmental stability of SARS-CoV-2 virions suspended in cell culture medium deposited onto a polypropylene plastic surface at nine environmental conditions: three relative humidities (RH; 40%, 65%, and 85%) at each of three temperatures (10 °C, 22 °C, and 27 °C). We chose temperatures to reflect the temperatures encountered outdoors in late winter (10 °C), indoors in climate-controlled environments (22 °C), and outdoors in summer (27 °C), and chose RH values that reflect temperate atmospheric conditions in both winter and summer.

We quantified infectious virus titer over time and estimated virus decay rates and corresponding half-lives in each condition using a simple Bayesian regression model (see Methods). We quantified the evaporation of the suspension medium and compared virus stability during the
sample evaporation phase—while substantial water loss was ongoing—to virus stability after a quasi-equilibrium phase was reached—when further evaporation was not evident over the timescale of the experiment.

We then created a mechanistic biochemical model of virus decay kinetics, drawing upon existing hypotheses for how temperature and humidity affect the inactivation chemistry of virus particles in microdroplets\textsuperscript{1,10}. We fit this mechanistic model to our SARS-CoV-2 data, and used it to predict observations from other human coronaviruses and other studies of SARS-CoV-2, in addition to unobserved temperature and humidity conditions.

**Empirical patterns of virus decay**

Our data suggest that SARS-CoV-2 environmental persistence could vary meaningfully across the range of temperatures and humidities individuals encounter in daily life, with posterior median [95\% credible interval] half-lives as long as 27 h [20, 39] (10\(^\circ\)C, 40\% RH) and as short as 1.5 h [1.1, 2.1] (27\(^\circ\)C, 65\% RH) during the quasi-equilibrium phase (Fig. 1a, Extended Data Table 1).

Minimal virus decay occurred during the evaporation phase (Fig. 1a, Extended Data Fig. 2), when excess water was present. Estimated half-lives were long but exact values were highly uncertain, as the small amount of absolute virus inactivation during the brief evaporation phases, combined with the noise involved in sampling and titration, limits our inferential capacity. Posterior median evaporation phase half-lives were 42 h [11, 330] at 10\(^\circ\)C, 12 h [4.5, 160] at 22\(^\circ\)C, and 5.8 h [2.1, 130] at 27\(^\circ\)C (Extended Data Table 1).

Overall, measured virus decay became markedly faster as temperature increased across all humidities, with decay at 27\(^\circ\)C roughly five to ten times faster than decay at 10\(^\circ\)C. Across temperatures, virus decay exhibited a U-shaped dependence on RH: roughly two to five times faster at 65\% RH than at 40\% and 100\% RH (Fig. 1a).
**Fig. 1** Inactivation kinetics and estimated half-life of SARS-CoV-2 on an inert surface as a function of temperature and relative humidity (RH). (a) Example of medium evaporation and virus inactivation as a function of time since deposition; experiments at 27°C and 85% shown. Inactivation proceeds in two phases: an evaporation phase during which water mass is lost from the sample to evaporation and a quasi-equilibrium phase once the sample mass has plateaued. Light blue vertical line shows posterior median estimated time that quasi-equilibrium was reached. Top plot: medium evaporation. Dots show measured masses. Square shows measured final (quasi-equilibrium) mass; plotted at 24 h for readability. Lines are 10 random draws from the posterior for the evaporation rate; horizontal section of line reflects the reaching of quasi-equilibrium (measured final mass). Bottom plot: virus inactivation. Points show posterior median estimated titers in log_{10} TCID_{50}/mL for each sample; lines show 95% credible intervals. Black dotted line shows the approximate single-replicate limit of detection (LOD) of the assay: 100 TCID_{50}/mL media. Three samples collected at each time-point. Lines are 10 random draws per measurement from the posterior distribution for the inactivation rates estimated by the simple regression model (see Methods). (c) Measured virus half-lives. Violin plots show posterior distribution of estimated half-lives, plotted on a logarithmic scale. Dots show posterior median value. Color indicates temperature. Measurements at 40%, 65%, and 85% reflect decay kinetics once the deposited solution has reached quasi-equilibrium with the ambient air. Estimated half-lives for the evaporation phase that occurs prior to quasi-equilibrium are plotted to the right, since conditions during this phase are mainly dilute, and thus analogous to high RH quasi-equilibrium conditions. (b) Schematic of hypothesized effects of temperature and relative humidity on duration of virus viability. Virus half-lives are longer at lower temperatures, regardless of humidity, because inactivation reaction kinetics proceed more slowly. Relative humidity affects virus half-life by determining quasi-equilibrium solute concentration in the droplet containing the virus. Above the efflorescence relative humidity (ERH), solutes are concentrated by evaporation. The lower the ambient humidity, the more water evaporates, the more concentration occurs, and the faster inactivation reactions proceed. Below the ERH, solutes effloresce, forming crystals. Half-lives are thus not particularly sensitive to changes in sub-ERH relative humidity, and half-lives even slightly below the ERH may be substantially longer than half-lives slightly above it.
Many viruses, including SARS-CoV-2, exhibit exponential decay on surfaces and in aerosols\textsuperscript{1,6,11}. We drew upon known principles of droplet chemistry and its potential effects on virus inactivation chemistry (Fig. 1b) to create a minimal mechanistic model incorporating the effects of both temperature and relative humidity on exponential decay rates.

We model temperature dependence with the Arrhenius equation, which describes a reaction rate $k$ as a function of an activation energy $E_a$, an asymptotic high-temperature reaction rate $A$, the universal gas constant $R$, and the absolute temperature $T$:

$$ k = A \exp \left( - \frac{E_a}{RT} \right) $$

Prior work has found Arrhenius-like temperature dependence for virus inactivation on surfaces and in aerosols for many viruses\textsuperscript{12}, including human coronaviruses\textsuperscript{13}.

Mechanistic principles of virus inactivation as a function of humidity have been more elusive, but recent work has suggested that relative humidity affects virus inactivation by controlling evaporation and thus governing the solute concentrations in a droplet containing virions\textsuperscript{1,10}. In more humid environments, evaporation is slower and some water remains. In less humid environments, evaporation is faster and little or no water remains (Fig. 1b).

When released from infected hosts, virions are found in host bodily fluids, whereas viral inactivation experiments are typically conducted in cell culture medium containing amino-acids and electrolytes, in particular sodium chloride (NaCl)\textsuperscript{14,15}. Prior work has found that higher quasi-equilibrium solute concentrations are associated with faster virus inactivation rates\textsuperscript{16,17}. The simplest explanation for this is that the measured solute concentration is a direct proxy for the concentration of the reactants governing the inactivation reaction. Thus ambient humidity affects the reaction rate by setting the quasi-equilibrium concentrations of the reactants that induce inactivation of the virus.

The exact quasi-equilibrium state reached will depend on the solutes present, since different solutes depress vapor pressure to different degrees. In electrolyte solutions like bodily fluids or cell culture media, efflorescence is also important. Below a threshold ambient humidity—the efflorescence relative humidity (ERH)—electrolytes effloresce out of solution, forming a crystal
For NaCl solutions at standard temperature and pressure, the ERH is around 45\%\textsuperscript{18}. Below the ERH, inactivation may proceed differently, since the reaction no longer occurs in solution. The notable U-shape of virus inactivation as a function of relative humidity, observed in our data (Fig. 1a) and elsewhere in the literature\textsuperscript{16}, including for coronaviruses\textsuperscript{19,20}, could be explained by this regime shift around the ERH (Fig. 1b).

To quantify these effects, we model virus inactivation at quasi-equilibrium on inert surfaces as a chemical reaction with first-order reaction kinetics; that is, the quantity of virus is the limiting reactant, and the concentrations of other reactants are assumed to be approximately constant over time. At constant temperature and humidity, the quantity of virus should then exhibit exponential decay. During the evaporation phase prior to quasi-equilibrium, reactants are less concentrated and decay is expected to be slower, as observed from our data (Fig. 1a). If small initial droplet sizes are used—as in real-world depositions (predominantly < 10 µL\textsuperscript{21–23}) and in some experiments—evaporative quasi-equilibration should be near instant, and so inactivation should follow the kinetics at quasi-equilibrium. Larger droplets, such as those used in our experiments, will take more time to equilibrate (depending on temperature and humidity), allowing us to distinguish the quasi-equilibrium phase from the evaporation phase.

We partition inactivation at quasi-equilibrium into two humidity regimes, solution and effloresced, according to whether the ambient RH is above the ERH (solution) or below (effloresced). In either case, we approximate virus inactivation as a first-order reaction with rate $k_{\text{sol}}$ or $k_{\text{eff}}$, respectively. We use an ERH of 45\%, meaning that 40\% experiments are in the effloresced regime and 65\% and 85\% experiments are in the solution regime.

We model the inactivation rates $k$ using two Arrhenius equations defined by different activation energies $E_a$ and asymptotic high-temperature reaction rates $A$. In solution conditions, we further modulate $k_{\text{sol}}$ by a quasi-equilibrium “concentration factor” $\frac{[S_{\text{eq}}]}{[S_0]}$: how concentrated the solution has become at quasi-equilibrium $[S_{\text{eq}}]$ relative to its initial state $[S_0]$. Additional details are provided in the Supplementary Information (SI), section 1. Given our assumption of first-order kinetics, an n-fold increase in the non-virion reactant concentrations should translate directly into an n-fold increase in the inactivation rate.

$$k_{\text{eff}} = A_{\text{eff}} \exp \left( -\frac{E_{a_{\text{eff}}}}{RT} \right)$$

(2)
We estimated $A_{\text{eff}}$, $A_{\text{sol}}$, $E_{a}^{\text{eff}}$, and $E_{a}^{\text{sol}}$ from our data, constraining all to be positive. We treated evaporation phase data as governed by $k_{\text{sol}}$, with a dynamic value of the concentration factor $[S_{\text{eq}}(t)]/[S_{0}]$ (SI section 1.4). We computed the quasi-equilibrium concentration factor $[S_{\text{eq}}]/[S_{0}]$ in two ways: using measurements from our evaporation experiments (measured concentration fit) and with a theoretically motivated curve fit to our virological data (modeled concentration fit, Extended Data Fig. 8). See SI section 2.5.3 for details.
**Fig. 2** | Estimated titers and mechanistic model fit for SARS-CoV-2 stability on polypropylene at quasi-equilibrium. Points show posterior median estimated titers in log_{10}TCID\(_{50}\)/mL for each sample; lines show 95% credible intervals. Time-points with no positive wells for any replicate are plotted as triangles at the approximate single-replicate limit of detection (LOD) of the assay—denoted by a black dotted line at 10^{0.5} TCID\(_{50}\)/mL media—to indicate that a range of sub-LOD values are plausible. Three samples collected at each time-point. X-axis shows time since quasi-equilibrium was reached, as measured in evaporation experiments. Lines are random draws (10 per sample) from the joint posterior distribution of the initial sample virus concentration and the mechanistic model predicted decay rate; the distribution of lines gives an estimate of the uncertainty in the decay rate and the variability of the initial titer for each experiment. Density plots above each box show posterior distribution of virus half-life according to the model for the given condition; point under the density shows the posterior median half-life and line shows a 95% credible interval. Parameters from the measured concentration model fit.
Model fitting and prediction of unobserved conditions

Our dataset comprises 9 experimental conditions, each with 7 time-points that span the evaporation and quasi-equilibrium phases. We sought to explain the virus inactivation rates across this entire dataset using our mechanistic model with just 4 free parameters: the effloresced and solution activation energies $E_{a}^{\text{eff}}$ and $E_{a}^{\text{sol}}$ and the asymptotic high-temperature reaction rates $A_{a}^{\text{eff}}$ and $A_{a}^{\text{sol}}$. The mechanistic function used and the constraint on the parameters to be positive means that inactivation rate must increase with temperature and with increasing solute concentration. Remarkably, the fit of the mechanistic model (Fig. 2, Extended Data Figs. 3, 4, 6) is virtually indistinguishable from the fit of the simple regression, which estimates independent exponential decay rates for each condition (Extended Data Figs. 2, 5, see SI section 2.4.1).

We used the mechanistic model to predict SARS-CoV-2 half-life for unobserved temperature and humidity conditions from 0 to 40 °C, and from 0 to 100 % RH. We chose these ranges to reflect environments encountered by human beings in daily life. We did not extrapolate to temperatures below 0 °C since inactivation kinetics may be different when fluid containing the virus freezes. The exact freezing points of suspension medium and human fluids at sea level will depend on solute concentration, but will typically be below the 0 °C freezing point of pure water.

Median predicted SARS-CoV-2 half-life varies by more than three orders of magnitude, from less than half an hour at 40 °C and 46 % RH (i.e., just above the ERH), to more than a month at 0 °C and 100 % RH (Fig. 3a and c). We find good qualitative agreement between model predictions and model-free estimates from our data, including the long half-lives prior to quasi-equilibrium, and the U-shaped effect of humidity on virus half-life is readily explained by the regime-shift at the ERH (Fig. 3a). In particular, half-lives become extremely long at cold temperatures, and at very high RH (corresponding to low solute concentrations; Fig. 3b).

As a stronger test of our model’s validity, we used our estimated $E_{a}$ and $A$ values to make out-of-sample predictions of the half-lives of five human coronaviruses reported from independent studies: four betacoronaviruses (SARS-CoV-2, SARS-CoV-1, MERS-CoV and HCoV-OC43) and one alphacoronavirus (HCoV-229E). We compiled data on the environmental stability of those viruses under conditions ranging from 4 to 95 °C, from 30 to 80 % RH, and on a range of surfaces or bulk media, and computed empirical—model-free—estimates of virus half-lives (Extended Data Tables S1–2).

Where both temperature and RH were available, we compared these model-free estimates to
predictions based on the mechanistic model parameterized with our SARS-CoV-2 data (Fig. 3c, Extended Data Fig. 7). We found striking agreement for half-life estimates both above and below the ERH, and for temperatures ranging from 4 to 37 °C.

To include a broader range of conditions in our out-of-sample model testing, we used our model to predict half-lives observed in all comparable studies by extrapolating from a reference half-life in each study. Predicted half-lives matched observations well across five orders of magnitude (Fig. 3d), despite spanning five virus species and despite important heterogeneities in the data collection process (SI section 3). The two conspicuous outliers, where SARS-CoV-2 half-lives were measured to be substantially shorter than our prediction, correspond to samples exposed to high heat in closed vials24,25 which is known to accelerate virus inactivation26.
Fig. 3 | Extrapolation of human coronavirus half-life from the mechanistic model to unobserved temperatures and humidities and prediction of data from the literature. (a) Predicted half-life as a function of relative humidity according to the modeled concentration fit. Points show posterior median for measured half-lives, estimated without the mechanistic model (i.e. independent estimation of a fixed exponential decay rate for each temperature/humidity combination), lines show a 68 % (thick) and 95 % (thin) credible interval. Dashed line shows the ERH. Estimated evaporation phase half-lives plotted at the right. Colored lines show predicted half-lives as a function of humidity at five temperatures: 0°C, 10°C, 22°C, 27°C, and 40°C. 100 random draws from the posterior distribution are shown at each temperature to visualize uncertainty. Line and point colors indicate temperature. (b) Predicted half-life above the ERH as a function of quasi-equilibrium concentration factor according to the measured concentration fit. Points and lines as in a, but only solution (above ERH) conditions shown. (c) Heatmap showing posterior median predicted half-lives from the modeled concentration fit as a function of temperature and relative humidity. Posterior median estimated half-lives for human coronaviruses from our study and from the literature plotted on top (see also Extended Data Table 2 and Fig. 7). Shape indicates virus; measurements from our own group are shown slightly larger with a slightly thicker outline. (d) Comparison of model-free estimates (x-axis) to model predictions (y-axis) for human coronavirus half-lives. Points show posterior median for measured (horizontal) or predicted (vertical) half-lives and lines show a 68 % (thick) and 95 % (thin) credible interval. Shape indicates virus; only data from the literature are shown.
Discussion

Combining novel data, mathematical modelling, and a meta-analysis of existing literature, we have developed a unified, mechanistic framework to quantify the joint effects of temperature and humidity on virus stability. In particular, our model provides a mechanism for the non-linear and non-monotonic relationship between relative humidity and virus stability previously observed\textsuperscript{16,19,20}. Our work documents and explains the strong dependence of SARS-CoV-2 stability on environmental temperature and relative humidity, and accurately predicts half-lives for five coronavirus species in conditions from 4 to 95°C, and from 30 to 80% RH and in bulk solution.

Our findings have direct implications for the epidemiology and control of SARS-CoV-2 and other enveloped viruses. The majority of SARS-CoV-2 clusters have been linked to indoor settings\textsuperscript{27}, suggesting that virus stability in indoor environmental conditions may be an important determinant of super-spreading risk. Our results provide a mechanistic explanation for the many observed SARS-CoV-2 superspreading events in cool indoor environments such as food processing plants, where the typical temperature is around 10°C\textsuperscript{28,29}, or in dry indoor environments such as long-distance flights\textsuperscript{30,31}. Conversely, our results imply that the relative rarity of outdoor SARS-CoV-2 transmission clusters is not readily explained by temperature and humidity effects, since these conditions outdoors during temperate winters should be favorable for the virus. Instead, increased dilution of aerosols and UV light inactivation\textsuperscript{32} may be more important than the effects of temperature and humidity outdoors. In contrast, typical climate-controlled conditions indoors (moderate temperature and low humidity) are favorable for virus stability, and specialized conditions such as those found in food processing plants even more so. Our results highlight the importance of proper personal protective equipment and improved ventilation for protecting workers, particularly in cold indoor settings, and the general transmission risks associated with indoor gatherings.

The effects of temperature and humidity we observe in our data and model are relevant to both fomite and airborne transmission. Prior work has shown that virus decay as a function of RH is similar in droplets on surfaces and suspended aerosols\textsuperscript{10,33}. Various studies of smaller deposited droplets\textsuperscript{34} or aerosols\textsuperscript{3,17,35} have reported similar qualitative patterns to those we observe on an inert surface, with increased decay rates at high temperatures and a U-shaped effect of RH. Furthermore, small particles containing virions can be re-suspended from surfaces by air currents and thus contribute to aerosol transmission\textsuperscript{36}. Re-suspension is further enhanced by procedures
such as high-pressure washing, which is common in food processing plants. While the relative contributions of aerosol and fomite transmission to the epidemiology of SARS-CoV-2 remain uncertain, our results indicate that cold situations present elevated transmission risks for either mode, especially if air is either dry or very humid. It has been speculated, for instance, that chilled or frozen foods might allow for rare but impactful long-range fomite transmission. Our results show that this is conceivable, as there is good empirical and mechanistic support for prolonged virus viability at very low temperatures.

Implications for the seasonality of viral transmission are less certain. It is widely speculated that SARS-CoV-2 transmission will be faster in temperate winters, as occurs with other respiratory viruses. Major seasonal or climate-mediated effects on SARS-CoV-2 epidemiology have yet to be demonstrated; this is expected since population susceptibility and epidemic control measures are more important than seasonality in an early pandemic context. In the future, climatic conditions are likely to affect SARS-CoV-2 epidemiology, but climatic effects on virus stability may not be the dominant mechanism. While virus survival in cold temperatures is often cited as a potential mechanism for respiratory virus seasonality, this effect is confounded with changes in human behaviour and circannual variation in immunity, among other factors.

Our work has implications for the study of virus environmental stability and seasonality more broadly. Whether absolute or relative humidity is more important for influenza stability has been a matter of debate. The answer has proved elusive because it is difficult to disentangle the effects of humidity from those of temperature. Our mechanistic model permits principled disaggregation of those effects, and reveals a strong effect of relative humidity even after accounting for the effects of temperature.

There may thus exist general principles that govern virus inactivation across enveloped viruses, and even more broadly. Similar empirical patterns of temperature and humidity dependence to what we see for SARS-CoV-2 have been observed for other important enveloped RNA viruses, including influenza viruses, paramyxoviruses, rhabdoviruses and retroviruses, suggesting the existence of a shared mechanism. Some enveloped DNA viruses such as herpesviruses and poxviruses and some encapsulated viruses such as polioviruses also show similar empirical behavior. Experiments have found that heat treatment of viruses reduces infectivity principally by degrading surface proteins, lending further support to a chemical model of environmental virus inactivation. We discuss additional practical implications for the empirical study of virus environmental stability in the SI (section 4).
Despite years of research on virus stability as a function of temperature and humidity and plausible hypotheses about the underlying chemistry, proposed mechanisms have lacked explicit quantitative support. By encoding the underlying chemistry into a mathematical model and estimating parameters using modern computational techniques, we provide such support, with critical insights for the control of an ongoing pandemic. Our empirical results provide mechanistic insight into transmission risks associated with cold and climate controlled indoor settings, while our modeling work allows for explicit quantitative comparison of the aerosol and fomite risks in different environments, and suggests that simple, robust general mechanisms govern the viability of enveloped viruses: hotter, more concentrated solutions are favorable to chemical reactions—and therefore unfavorable to viruses.

**Methods**

**Laboratory experiments**

**Viruses and titration**

We used SARS-CoV-2 strain HCoV-19 nCoV-WA1-2020 (MN985325.1)\(^{50}\) for this study. We quantified viable virus by end-point titration on Vero E6 cells as described previously\(^{11,51}\), and inferred posterior distributions for titers and exponential decay rates directly from raw titration data using Bayesian statistical models (see Statistical analyses and mathematical modelling below).

**Virus stability experiment**

We measured virus stability on polypropylene (ePlastics, reference PRONAT.030X24X47S/M) as previously described\(^{11}\). We prepared a solution of Dulbecco’s Modified Eagle Medium (DMEM, a common cell culture medium) supplemented with 2 mM L-glutamine, 2% fetal bovine serum and 100 units/mL penicillin/streptomycin, and containing \(10^5\) TCID\(_{50}\)/mL SARS-CoV-2. Polypropylene disks were autoclaved for decontamination prior to the experiment. We then placed 50 \(\mu\)L aliquots of this SARS-CoV-2 suspension onto the polypropylene disks under nine environmental conditions: three RH (40 %, 65 %, and 85 %) at each of three temperatures (10 °C, 22 °C, and 27 °C). These controlled environmental conditions were produced in incubators (MMM Group CLIMACELL and Caron model 6040) with protection from UV-B or UV-C.
exposure. We prepared 216 disks corresponding to three replicates per eight post-deposition time-points (0, 1, 4, 8, and 24 hours, then daily for 4 days) for the nine conditions. At each time-point, samples were collected by rinsing the disks with 1 mL of DMEM and stored at −80 °C until titration.

Evaporation experiment

We measured the evaporation kinetics of suspension medium under the same temperature and humidity conditions as the virus stability experiments. We placed 50 µL aliquots of supplemented DMEM onto polypropylene disks in a Electro-Tech Systems 5518 environmental chamber. The polypropylene disks were rinsed three times 1M sulfuric acid, ethanol and DI H2O respectively before use. We measured medium mass \( m(t) \) every 5 min for up to 20 h or until a quasi-equilibrium was reached using a micro-balance (Sartorius MSE3.6P-000-DM, readability 0.0010 mg). The chamber of the micro-balance was half-opened to keep air circulating with the environmental chamber. The flow entering the balance chamber decreased the balance accuracy to around 0.010 mg. We measured initial droplet mass \( m(0) \) and final droplet mass \( m(\infty) \) under closed-chamber conditions to increase accuracy.

Statistical analyses and mathematical modelling

We quantified the stability of SARS-CoV-2 under different conditions by estimating the decay rates of viable virus titers. We inferred individual titers using a Bayesian model we have previously described\(^{26}\). Briefly, the model treats titration well infection as a Poisson single-hit process. We inferred raw exponential decay rates by modifying a previously-described simple regression model\(^{26}\) to account for the evaporation phase. See the SI (section 2.4) for model description.

We estimated parameters of our mechanistic models by predicting titers based on those models and then applying the same Poisson single-hit observation process to estimate parameters from the data. See the SI (section 2.5) for a complete description, including model priors.

We estimated evaporation rates and corresponding drying times by modeling mass loss for each environmental condition \( i \) as linear in time at a rate \( \beta_i \) until the final mass \( m(\infty) \) was reached, See the SI (sections 1.2, 2.3) for a full description including model priors.

We drew posterior samples using Stan\(^{52}\), which implements a No-U-Turn Sampler (a form of
Markov Chain Monte Carlo), via its R interface RStan\(^53\).

**Meta-analysis**

To test the validity of our model beyond the measured environmental conditions (i.e., beyond 10–27 °C and 40–85 % RH), we compiled data from 11 published studies on human coronaviruses, including SARS-CoV-2, SARS-CoV-1, MERS-CoV, HCoV-OC43 and HCoV-299E, under 17 temperature-RH conditions. We generated estimates of half-life and uncertainties (Extended Data Table 2) and compared those estimates to the half-lives predicted by the mechanistic model parametrized from our SARS-CoV-2 data. As data on evaporation kinetics were not available, we estimated a unique half-life for each experimental condition, covering both the evaporation and quasi-equilibrium phases. As virus decay during the evaporation phase is expected to be minimal, and the evaporation phase to be short, the estimated half-life can be used as a proxy for the quasi-equilibrium half-life. The complete data selection, extraction and analysis process is detailed in the SI (section 3).

We also included data from SARS-CoV-1 and MERS-CoV collected by our group during previous studies\(^11\). Those data were collected at 22 °C and 40 % on polypropylene using the protocol described previously\(^11\) and similar to the one used to collect the SARS-CoV-2 data. SARS-CoV-1 strain Tor2 (AY274119.3)\(^54\) and MERS-CoV strain HCoV-EMC/2012\(^55\) were used for these experiments. We calculated half-lives for evaporation and quasi-equilibrium phases using the same analysis pipeline used for SARS-CoV-2 (SI section 2.4). These data were used only for out-of-sample prediction testing. We used the obtained evaporation phase half-lives as proxies for the half-life at 100 % RH, as with SARS-CoV-2. See SI section 3.3 for a figure showing model fits (Fig. S22) and a table of estimated half-lives (Table S1).

**Visualization**

We created plots in R using ggplot2\(^56\), ggdist\(^57\), and tidybayes\(^58\), and created original schematics using BioRender.com.

Author contributions

VJM and JOL-S conceived the study. KCY performed the inactivation experiments, with support from TB, RJF, MJM, NvD, and VJM. QH performed the evaporation experiments, with support from PJV and LCM. DHM developed the mechanistic model and conducted statistical and theoretical analysis, with support from JOL-S, AG, FWR, and LCM. DHM wrote analysis code and produced figures and schematics. AG reviewed the literature on coronavirus stability and compiled and prepared data for meta-analysis. DHM and AG wrote the first draft of the paper, which all authors edited.

Additional information

Supplementary Information

Supplementary information for this paper is available online.
Correspondence

Correspondence and requests for materials should be addressed to Dylan H. Morris: dhmorris@princeton.edu.

Data availability

All code and data needed to reproduce results and figures is archived on Github (https://github.com/dylanhmorris/sars-cov-2-temp-humidity/) and on Zenodo (https://doi.org/10.5281/zenodo.4093265), and licensed for reuse, with appropriate attribution/citation, under a BSD 3-Clause Revised License.
Extended data figures

Extended Data Fig. 1 | Evaporation of supplemented Dulbecco’s Modified Eagle Medium (DMEM) as a function of temperature and humidity. Dots show measured masses. Square shows measured final (quasi-equilibrium) mass; actual measurement times for final masses were upon removal of sample from chamber, but for readability they are plotted at 24 h for all experiments. Lines are 100 random draws from the posterior for the evaporation rate; horizontal section of line reflects the reaching of quasi-equilibrium (measured final mass). Transition point between evaporation phase and quasi-equilibrium phase inferred from data (see SI sections 1.2, 2.3). Note that final mass measurement is more accurate than timeseries measurements (see the Evaporation experiment subsection of the Methods).
Extended Data Fig. 2 | Fit of the simple regression model to the evaporation phase (pre-drying) SARS-CoV-2 titer data. Points show posterior median estimated titers in log_{10} TCID_{50}/mL for each sample; lines show 95% credible intervals. Time-points with no positive wells for any replicate are plotted as triangles at the approximate single-replicate limit of detection (LOD) of the assay—denoted by a black dotted line at 10^{0.5} TCID_{50}/mL media—to indicate that a range of sub-LOD values are plausible. Three samples collected at each time-point. x-axis shows time since sample deposition. Lines are truncated at the estimated time quasi-equilibrium was reached. Lines are random draws (10 per sample) from the joint posterior distribution of the initial sample virus concentration and the estimated decay rate; the distribution of lines gives an estimate of the uncertainty in the decay rate and the variability of the initial titer for each experiment.
Extended Data Fig. 3 | Estimated titers and measured concentration model fit for SARS-CoV-2 stability on plastic during the evaporation phase. Points show posterior median estimated titers in log_{10} TCID\(_{50}\)/mL for each sample; lines show 95% credible intervals. Time-points with no positive wells for any replicate are plotted as triangles at the approximate single-replicate limit of detection (LOD) of the assay—denoted by a black dotted line at 10^{0.5} TCID\(_{50}\)/mL media—to indicate that a range of sub-LOD values are plausible. Three samples collected at each time-point. x-axis shows time since sample deposition. Lines are truncated at the estimated time quasi-equilibrium was reached. Lines are random draws (10 per sample) from the joint posterior distribution of the initial sample virus concentration and the mechanistic model predicted decay rate; the distribution of lines gives an estimate of the uncertainty in the decay rate and the variability of the initial titer for each experiment.
Extended Data Fig. 4 | Estimated titers and modeled concentration model fit for SARS-CoV-2 stability on plastic during the evaporation phase. Points show posterior median estimated titers in log_{10} TCID_{50}/mL for each sample; lines show 95% credible intervals. Time-points with no positive wells for any replicate are plotted as triangles at the approximate single-replicate limit of detection (LOD) of the assay—denoted by a black dotted line at 10^{0.5} TCID_{50}/mL media—to indicate that a range of sub-LOD values are plausible. Three samples collected at each time-point. x-axis shows time since sample deposition. Lines are truncated at the estimated time quasi-equilibrium was reached. Lines are random draws (10 per sample) from the joint posterior distribution of the initial sample virus concentration and the mechanistic model predicted decay rate; the distribution of lines gives an estimate of the uncertainty in the decay rate and the variability of the initial titer for each experiment.
Extended Data Fig. 5 | Fit of the simple regression model to the quasi-equilibrium (post-drying) SARS-CoV-2 titer data. Points show posterior median estimated titers in log_{10}TCID_{50}/mL for each sample; lines show 95% credible intervals. Time-points with no positive wells for any replicate are plotted as triangles at the approximate single-replicate limit of detection (LOD) of the assay—denoted by a black dotted line at 10^{1.5} TCID_{50}/mL media—to indicate that a range of sub-LOD values are plausible. Three samples collected at each time-point. x-axis shows time since quasi-equilibrium was reached, as measured in evaporation experiments. Lines are random draws (10 per sample) from the joint posterior distribution of the initial sample virus concentration and the estimated decay rate; the distribution of lines gives an estimate of the uncertainty in the decay rate and the variability of the initial titer for each experiment. Density plots above each box show posterior distribution of virus half-life according to the model for the given condition; point under the density shows the posterior median half-life and line shows a 95% credible interval.
Extended Data Fig. 6 | Estimated titers and modeled concentration model fit for SARS-CoV-2 stability on plastic at quasi-equilibrium. Points show posterior median estimated titers in \(\log_{10}\text{TCID}_{50}/\text{mL}\) for each sample; lines show 95% credible intervals. Time-points with no positive wells for any replicate are plotted as triangles at the approximate single-replicate limit of detection (LOD) of the assay—denoted by a black dotted line at \(10^{0.5}\text{ TCID}_{50}/\text{mL}\) media—to indicate that a range of sub-LOD values are plausible. Three samples collected at each time-point. x-axis shows time since quasi-equilibrium was reached, as measured in evaporation experiments. Lines are random draws (10 per sample) from the joint posterior distribution of the initial sample virus concentration and the mechanistic model predicted decay rate; the distribution of lines gives an estimate of the uncertainty in the decay rate and the variability of the initial titer for each experiment. Density plots above each box show posterior distribution of virus half-life according to the model for the given condition; point under the density shows the posterior median half-life and line shows a 95% credible interval.
Extended Data Fig. 7 | Modeled concentration fit predictions compared to half-lives estimated directly from data. Lines show half-life as a function of relative humidity (x-axis value) and temperature (color) according to the modeled concentration fit. 100 random draws from the posterior distribution are plotted for each of 20 evenly spaced temperatures between 0 and 40 °C. Points show posterior median for measured half-lives for human coronaviruses from our study and from the literature (Extended Data Table 2); lines show a 68% (thick) and 95% (thin) credible interval. Half-lives estimates are model-free (i.e. no mechanistic model; fitting of independent exponential decay rates to each condition). Shape indicates virus; measurements from our own group are shown slightly larger. Estimated evaporation phase half-lives plotted at 100% relative humidity (RH). Grey line shows the efflorescence relative humidity (ERH), 45%.
Extended Data Fig. 8 | Concentration factor at quasi-equilibrium a function of relative humidity, modeled concentration fit. Points show estimates for quasi-equilibrium concentration factor based on empirically measured masses from the evaporation experiments (Extended Data Fig. 1) and the estimated initial solute mass fraction from the modeled concentration fit (see Main Text, Methods). Estimates shown for each temperature (point color) and ambient RH (x-axis value). Vertical lines around the points show a 68% (thick) and 95% (thin) credible interval. Blue curves show model predictions for concentration factor given parameters $α_c$, $α_s$ (Supplementary Information section 1.1, equation 8), and the initial solute mass fraction, all estimated from the measured concentration fit. Each is an independent draw from the joint posterior distribution of the parameters, thus giving a sense of the distribution of possible curves. Vertical dashed line shows the efflorescence relative humidity, 45%. 
Extended data tables

Extended Data Table 1 | Estimated half-lives in hours of SARS-CoV-2 on polypropylene as a function of temperature (T) and relative humidity (RH). Estimated half-lives are reported as posterior median and the middle 95% credible interval.
