22 **Abstract**

23

24 Exploration of oxygen-depleted marine environments has consistently revealed novel
25 microbial taxa and metabolic capabilities that expand our understanding of microbial
26 evolution and ecology. Marine blue holes are shallow karst formations characterized by
27 low oxygen and high organic matter content. They are logistically challenging to sample,
28 and thus our understanding of their biogeochemistry and microbial ecology is limited.
29 We present a metagenomic characterization of Amberjack Hole on the Florida
30 continental shelf (Gulf of Mexico). Dissolved oxygen became depleted at the hole's rim
31 (32 m water depth), remained low but detectable in an intermediate hypoxic zone (40-75
32 m), and then increased to a secondary peak before falling below detection in the bottom
33 layer (80-110 m), concomitant with increases in nutrients, dissolved iron, and a series of
34 sequentially more reduced sulfur species. Microbial communities in the bottom layer
35 contained heretofore undocumented levels of the recently discovered phylum
36 Woesearchaeota (up to 58% of the community), along with lineages in the bacterial
37 Candidate Phyla Radiation (CPR). Thirty-one high-quality metagenome-assembled
38 genomes (MAGs) showed extensive biochemical capabilities for sulfur and nitrogen
39 cycling, as well as for resisting and respiring arsenic. One uncharacterized gene
40 associated with a CPR lineage differentiated hypoxic from anoxic zone communities.

41 Overall, microbial communities and geochemical profiles were stable across two
42 sampling dates in the spring and fall of 2019. The blue hole habitat is a natural marine
43 laboratory that provides opportunities for sampling taxa with under-characterized but
44 potentially important roles in redox-stratified microbial processes.

45

46 **Introduction**

47

48 Blue holes are subsurface caverns found in karst bedrock environments. They formed
49 during climatic periods when low sea levels exposed the bedrock to weathering, and
50 subsequently became submerged as sea levels rose (1). Marine blue holes differ from
51 anchialine blue holes, such as those found in the Bahamas and the Yucatán peninsula,
52 as they do not have freshwater layers and are not exposed to the atmosphere.
53 Anchialine blue holes can be highly stratified, with anoxic and sulfidic bottom waters (2–
54 4) and microbial communities distinct from other marine and freshwater systems (5–8).
55 However, data on true marine blue holes are limited. A recent study on the Yongle Blue
56 Hole, the deepest known marine blue hole with a bottom depth of 300 m, found the
57 water column became anoxic around 100 m with increases in hydrogen sulfide,
58 methane, and dissolved inorganic carbon below that depth (9). This and two additional
59 studies also found that microbial communities in the Yongle Blue Hole were notably
60 different from those of the surrounding pelagic water column, with anoxic layers in the
61 hole dominated by taxa linked to sulfur oxidation and nitrate reduction (9–11). Further,
62 deep blue hole waters may be resistant to mixing with waters outside the hole,
63 especially in regions with limited seasonal variation or water mass intrusion. These
64 observations suggest the potential for blue holes to harbor novel microbial lineages as a
65 consequence of both unique geochemistry and environmental isolation.

66

67 Locations of 18 blue holes have been recorded in offshore waters on the west Florida
68 shelf; however, many more may exist but remain undiscovered due to a lack of
69 systematic survey ((12); J. Culter, unpublished data). According to anecdotal reports
70 from recreational divers and fishers, the rims of these holes feature dense communities
71 of corals, sponges, and other invertebrates, in contrast with the more barren sandy
72 bottom of the surrounding shelf. Commercially and recreationally valuable fishes also
73 congregate at the rims. The presence of high biomass has led to speculation that blue
74 holes could represent offshore sources of groundwater-derived nutrients transported via
75 extensions of the Floridan aquifer (13). However, unlike for some of the nearshore blue
76 holes (12), no measurements of groundwater discharge have been made in the offshore
77 blue holes. Elevated nutrient levels at these sites have broad relevance for coastal
78 ecology in the Gulf of Mexico, particularly as they may fuel phytoplankton blooms
79 (14,15). Indeed, the west coast of Florida experiences frequent and intense harmful
80 algal blooms (HABs). While numerous nutrient sources have been identified as potential

81 HAB triggers, the relative importance of these sources remains geographically
82 unconstrained and our knowledge of what drives HABs is by no means complete (16–
83 18).

84
85 Gulf of Mexico blue holes may be chemically stratified and devoid of oxygen. In one of
86 the only biological studies of these features, Garman et al. (2011) explored Jewfish
87 Sink, a coastal blue hole near Hudson, Florida. Oxygen concentrations fell from near
88 saturation at the rim (~2 m water depth) to zero around 20 m water depth and remained
89 below detection all the way to the bottom of the hole (~64 m water depth), with the
90 anoxic layer further characterized by pronounced sulfide accumulation with depth. A
91 clone library of 16S rRNA genes from microbial mats in the hole revealed a
92 taxonomically rich community (338 operational taxonomic units, including 150 bacterial
93 and 188 archaeal taxa), with sequences closely related to those from low-oxygen
94 habitats including deep-sea sediments, salt marshes, cold seeps, and whale falls (6).
95 These sequences represent taxa linked to a range of metabolisms, including
96 dissimilatory sulfur, methane, and nitrogen cycling (both oxidative and reductive). This
97 study also reported dense and chemically variable clouds of particulates within the hole;
98 these included iron-sulfide minerals, suggesting the potential for microbial-metal
99 interactions in the water column.

100
101 This work, alongside evidence from the South China Sea sites (9), suggests marine
102 blue holes are biogeochemically complex features and potential hotspots for microbial
103 diversity. Indeed, oxygen-depleted marine water columns have been rich targets for
104 exploring novel microbial processes. Within the past five years alone, studies in these
105 systems have shed new light on microbial processes of arsenic respiration (19), cryptic
106 sulfur (20) and oxygen cycling (21), low-oxygen adapted nitrification (22) and
107 denitrification (23), and anaerobic methane oxidation (24). Moreover, oxygen-depleted
108 waters are expanding worldwide (25), making it critical to understand how oxygen
109 concentration impacts microbially regulated nutrient and energy budgets, and how these
110 impacts vary among sites. Most microbes in these systems are uncultivated and
111 phylogenetically divergent from better-studied relatives. Many of these taxa remain
112 unclassified beyond the phylum or class level and likely represent lineages uniquely
113 adapted to low-oxygen conditions. In lieu of cultivation, metagenomic analysis enables
114 exploration of both the taxonomy and function of microbial players in blue holes and
115 similar low-oxygen environments.

116
117 Here, we used metagenomics to describe the microbial ecosystem in a marine blue hole
118 on the west Florida shelf. To help interpret microbial processes, we also present a
119 comprehensive electrochemistry-based analysis of redox chemical speciation.
120 Amberjack (AJ) Hole lies ~50 km west of Sarasota, Florida at a water depth of 32 m.

121 Like Jewfish Sink, AJ is conical in shape, with a narrow rim (25 m diameter) and a wider
122 floor (approximately 100 m diameter; Curt Bowen, personal communication). Water
123 depth at the floor ranges from 110 m at the edge to 90 m at the center, where a debris
124 pile of fine-grained sediment has accumulated. Our knowledge of AJ, like that of other
125 marine blue holes, is limited and based primarily on exploration by a small number of
126 technical divers. The hole's shape and depth present a challenge for SCUBA, as well as
127 for instrumentation or submersibles. During two expeditions in May and September
128 2019, we used a combination of technical divers and Niskin bottles to sample water
129 column microbial communities. These collections spanned oxygenated waters at the
130 rim, an anoxic but non-sulfidic intermediate layer, and a bottom layer rich in reduced
131 sulfur compounds. Our results reveal a system that is highly stratified, apparently stable
132 between timepoints, and phylogenetically diverse, with high representation by
133 uncultivated and poorly understood taxa. The results suggest marine blue holes may
134 serve as unique natural laboratories for exploring redox-stratified microbial ecosystems,
135 while highlighting a need for future biogeochemical exploration of other blue holes and
136 similar habitats.

137

138 **Results**

139

140 *Sampling scheme*

141

142 We sampled physical, chemical, and biological features of Amberjack Hole in May and
143 September 2019. The May data set included one conductivity, temperature, and depth
144 (CTD) profile with a coupled dissolved oxygen sensor, along with water column samples
145 for chemical analyses (5 depths) and microbial community sequencing (11 depths,
146 including 5 from within the hole). These samples were collected via a combination of
147 diver bottle water exchange, hand-cast Niskin bottles, and automated Niskin sampling
148 on a rosette (Table S1). The CTD profile was acquired by attaching a combined CTD
149 and optical dissolved oxygen sensor to an autonomous lander deployed for 24 hours to
150 measure sediment respiratory processes and fluxes (data not included in this study).
151 The lander was positioned at 106 m water depth on the slope of the debris pile; the
152 deepest May water sample was acquired by a diver at this depth.

153

154 In September, improved sampling design resulted in higher spatial resolution for all
155 water column parameters. We obtained two CTD profiles and eight samples from within
156 the hole for microbiome analysis. All September water samples were acquired by hand-
157 cast Niskin bottles, with the deepest sample from 95 m, the presumed peak of the
158 debris pile. In contrast to the May sampling, all water sampling in September was
159 performed on the day of the CTD casts, ensuring that chemical and biological

160 measurements were temporally coupled. We therefore focus primarily on September
161 results (below), with exceptions where noted.

162

163 *Water column physical and chemical profiles*

164

165 Amberjack Hole was highly stratified (Fig. 1). Salinity increased sharply by one PSU
166 between the overlying water column (35.2) and the blue hole water mass (~30 m, 36.2).
167 Within the hole, salinity decreased slightly with depth (maximum difference 0.4 PSU)
168 until 75 m and then increased to ~36 PSU at the bottom. Dissolved oxygen decreased
169 sharply upon entry into the hole, from 100% saturation at the rim (32 m) to less than 5%
170 saturation by 40 m (Fig. 1B). Oxygen then increased gradually to a secondary maximum
171 of 40% at 75 m, before dropping to near 0% (anoxia) below 80 m.

172

173 Dissolved inorganic nitrogen (nitrate (NO_3^-) + nitrite (NO_2^-), or NO_x) spiked between 40
174 and 70 m from 0 to ~12 μM in May and nearly 17 μM in September, while ammonium
175 (NH_4^+) and phosphate (PO_4^{3-}) increased sharply below 80 m (Fig. 1C). Bottom water
176 nutrient concentrations were higher in September than in May, with NH_4^+ reaching
177 nearly 50 μM and PO_4^{3-} exceeding 8 μM . Particulate nutrients (N, P, and carbon (C))
178 and chlorophyll *a* concentrations were seemingly less variable throughout the water
179 column in May compared to September (Fig. S2), although this pattern may be an
180 artifact of the lower sampling resolution. In September, particulate nutrients and
181 chlorophyll *a* spiked at the hole opening (between 30 and 40 m) with P at 0.1 μM , N at
182 1.2 μM , C at 11 μM , and chlorophyll *a* at nearly 1.5 $\mu\text{g/L}$. Particulate nutrients remained
183 low deeper in the water column with the exception of P, which spiked again to 0.14 μM
184 at 80 m. Particulate C and N also increased slightly below 80 m (Fig. S2).

185

186 Coinciding with anoxia, ferrous iron (Fe(II)_d) increased from 16 μM to 187 μM between
187 70 and 80 m, respectively. With increasing depth, sequentially more reduced sulfur
188 compounds were observed (Fig. 1D):

189 a) at 85 m, $\text{S}_2\text{O}_3^{2-}$ (thiosulfate, sulfur (S) in the +II oxidation state), reached a
190 maximum of 264 μM ;

191 b) at 90 m, S(0), representing either S_8 (i.e. elemental sulfur, S in the 0 oxidation
192 state) or most S within polysulfide (S_x^{2-} , e.g. S_4^{2-} or S_8^{2-}), in filtered (< 0.7 μm) and
193 unfiltered water reached 126 μM and 599 μM , respectively; and

194 c) at 95 m (deepest sample), combined $\Sigma\text{S(-II)}$ (i.e. either as hydrogen sulfide (HS^-),
195 polysulfide (S_x^{2-}), or both) reached a maximum of 61 μM .

196 Due to analytical uncertainties associated with the voltammetric quantification scheme,
197 the $\Sigma\text{S(-II)}$ as presented may contribute redundantly to both (b) and (c) from a sulfur
198 mass balance perspective. Only 6% of the S(-II) signal in the 95 m sample is lost upon
199 filtering through 0.7 μm GFF filters (not shown), compared to 93 -100% losses in the 85

200 and 80 m samples, respectively, suggesting that the deepest waters are probably
201 enriched in true hydrogen sulfide (HS^-). Indeed, significant HS^- is fluxing from sediments
202 as revealed by benthic flux and pore water measurements (data not shown).

203
204 Notably, the zone of $\text{S}(0)$ (i.e. elemental sulfur) accumulation between 80 and 90 m was
205 marked by a spike in turbidity (Fig. 1B). In addition, particulate P was elevated
206 concomitantly with Fe_d and Fe(II)_d between 70 and 80 m (Fig. 1D and S2). The latter
207 suggests the presence of particulate or colloidal minerals and associated adsorption
208 sites (e.g., Fe oxide colloids).

209
210 The May sampling resulted in a single data point from a depth of 85 m, which showed
211 levels of $19.8 \pm 2.3 \mu\text{M S}_2\text{O}_3^{2-}$, $93 \mu\text{M } \Sigma\text{S(-II)}$, and no $\text{S}(0)$, similar to the September
212 measurements from that depth.

213 214 *Microbial community composition*

215
216 16S rRNA gene amplicon sequencing yielded 12,692 to 118,397 reads per sample after
217 filtering for quality (Table S1). Water column microbial communities differed significantly
218 based on depth grouping (PERMANOVA $p=0.016$), partitioning into shallow (0-32 m,
219 oxic zone above the hole), middle (40-70 m, hypoxic zone), and deep (80-106 m, anoxic
220 zone) groups (Fig. 2A). The shallow group was characterized by the ubiquitous
221 cyanobacteria *Synechococcus* and *Prochlorococcus*, as well as several clades of the
222 heterotrophic alphaproteobacterium SAR11 (particularly clade Ia) (Figure 2B).
223 Cyanobacteria were absent below 32 m in both May and September. The middle water
224 column featured high frequencies of *Nitrosopumilus* sp., a member of the ammonia-
225 oxidizing Thaumarchaeota, as well as members of the sulfur-oxidizing family
226 *Thioglobaceae* (Fig. 2B). Other groups, composing 1-10% of the community in this
227 depth zone, included Marine Group II and III Thermoplasmata (formerly MGII/III
228 Euryarchaeota) and members of the family *Gimesiaceae* (phylum Planctomycetes).

229
230 The anoxic and sulfidic deep water column was dominated by Woesearchaeota of the
231 DPANN superphylum. Woesearchaeota represented 33% - 56% of all sequences below
232 75 m in both May and September and were comprised of 74 sequence variants (SVs),
233 with two SVs representing between 84% (May 85 m) and 99% (September 90 m) of the
234 total Woesearchaeotal fraction. Other well-represented groups included *Nitrosopumilus*
235 sp, *Thioglobaceae* (SUP05 clade), and a member of the phylum Bacteroidota (formerly
236 Bacteroidetes) associated with hydrothermal vents ("Bacteroidetes VC2.1 Bac22" in the
237 SILVA database) (Fig. 2B). While Shannon diversity was similar among depth groups,
238 Simpson diversity was ~50% higher in the deep compared to the middle and shallow
239 groups (Fig. S3).

240
241 Depth patterns in community composition were highly similar between May and
242 September. The most abundant taxa showed only minor differences in frequency
243 between these months, with a few exceptions (Fig. 3). Marine Group II
244 Thermoplasmatota reached 12% relative abundance in the middle hypoxic zone in
245 September while in May this taxon never exceeded 1%; in contrast, Marine Group III
246 peaked at around 6% in May and in September only reached about half that level. In
247 May, *Thioglobaceae* frequency increased steadily below 30 m to peak at >10% of the
248 community in the deep anoxic zone. In contrast, *Thioglobaceae* was not detected in the
249 anoxic zone in September. Rather, *Arcobacter* sp. (represented by a single SV) spiked
250 at 80 m in September to nearly 10% of the community. In all other samples, this taxon
251 never exceeded 0.5% at any sampled depth. The 80 m depth was not sampled in May.

252 253 *Metagenomes and MAG taxonomy*

254
255 We obtained four metagenomes from two depths in both May and September. These
256 represent communities at 60 m (both months) in the hypoxic (~15% O₂ saturation) and
257 *Nitrosopumilus*-dominated zone, and at 106 m (May) and 95 m (September) in the
258 anoxic, sulfidic, and Woesearchaeota-dominated zone. Sequencing and assembly
259 results are provided in Table S2. Metagenome binning involving data from all samples
260 yielded 31 high-quality, non-redundant MAGs representing a diverse array of microbial
261 taxa (Table 1). These included eight archaeal MAGs, seven of which were generated
262 from the 60 m samples, including six belonging to the phylum Thermoplasmatota and
263 one belonging to *Nitrosopumilus* (Thaumarchaeota). The deep metagenomes yielded
264 two MAGs classified as members of the superphylum Patescibacteria, part of the
265 Candidate Phyla Radiation, one of which contained a 16S rRNA gene SV classified as
266 *Ca. Uhrbacteria*. The only archaeal MAG from the deep samples was classified as a
267 member of the order Woesearchaeota. This MAG contained a 16S rRNA gene with
268 100% nucleotide identity to the most abundant SV recovered in amplicon sequencing of
269 the bottom water communities (Table 1, Table S3). Queries against the Genome
270 Taxonomy Database (GTDB; using MAG single-copy core genes) and SILVA database
271 (using the 16S rRNA gene SV) classified this MAG as belonging to the order
272 “Woesearchaeia” in the phylum Nanoarchaeota. However, this classification is outdated,
273 as “Woesearchaeia” has recently been given the phylum-level designation
274 Woesearchaeota (26). Only nine MAGs had a reference genome in GTDB that
275 exceeded the minimum alignment fraction (65%); the remainder had no known close
276 relative (Table 1).

277
278 Three MAGs representing the highest amplicon frequencies (from all recovered MAGs)
279 were placed in phylogenies with closely related taxa, confirming their taxonomic

280 assignments (based on GTDB and SILVA) as members of the Woese archaeota (Fig. 4),
281 *Nitrosopumilus* (Fig. S4), and *Thioglobaceae* (SUP05 clade) (Fig. S5). The two taxa
282 most closely related to the Woese archaeotal MAG are both from oxygen minimum zones
283 in the Arabian Sea, with the next most closely related taxa from an iron-rich hot spring
284 and freshwater. The phylogeny shows Woese archaeotal MAGs from a wide range of
285 environments interspersed across branches, providing weak support for clustering
286 according to habitat type (Fig. 4). The AJ *Nitrosopumilus* MAG was most closely related
287 to a MAG from a cold seep sponge, and relatively distantly removed from the nearest
288 cultured *Nitrosopumilus* isolate (Fig. S4). The AJ SUP05 MAG was most closely related
289 to a clade of eight *Thioglobaceae* spp. MAGs from hydrothermal vents, and next-most
290 closely related to genomes associated with deep-sea invertebrates (Fig. S5).

291 292 *Functional annotation*

293
294 Based on analysis of all metagenome contigs (prior to MAG binning), broad functional
295 categories (KEGG 'subgroup2' level) separated the 60 m samples from both deep
296 samples (Fig. S6). Among the categories with a 5-fold or greater difference in frequency
297 between the sample sets was the KEGG category 'ECM-receptor interaction,' which
298 contained only two annotated genes (Fig. S7). Notably, a single gene (KO number
299 K25373, annotated as the eukaryotic protein dentin sialophosphoprotein) occurred at
300 much higher frequency in the deep samples relative to the 60 m samples. BLASTP
301 queries against the NCBI nr database linked this sequence to hypothetical proteins from
302 genomes of the candidate phylum Uhrbacteria (CPR), although these proteins shared
303 only 30% amino acid identity with the gene in our data. This gene was identified in one
304 of the two MAGs (BH28) classified as Patescibacteria (CPR), to which the Uhrbacteria
305 belong. Other categories driving the sample separation included ethylbenzene
306 degradation, bacterial chemotaxis, and o-glycan biosynthesis (Fig. S6).

307
308 Although they were not among the most differentiating categories, sulfur and nitrogen
309 metabolism categories also differed in frequency between the depths (Fig. 5). These
310 included genes for both assimilatory and dissimilatory metabolism. Some of the most
311 pronounced differences in sulfur metabolism involved the dissimilatory thiosulfate
312 (*phsA/psrA*) and sulfite (*dsrAB*) reductases, both of which were enriched in deep
313 metagenomes. Sulfur metabolism genes enriched in the 60 m metagenomes also
314 included *dmdABCD*, which encode enzymes for the catabolism of
315 dimethylsulfoniopropionate (DMSP).

316
317 Blue hole MAGs encoded a diverse suite of metabolisms (Table 2). We detected genes
318 involved in both reductive and oxidative pathways of dissimilatory sulfur and nitrogen
319 cycling, arsenic respiration, methylotrophy, and carbon monoxide metabolism, among

320 others. One MAG (BH25) is one of only two reported members of the Bacteroidota
321 (formerly Bacteroidetes) phylum potentially capable of dissimilatory sulfur metabolism,
322 with the other represented by a MAG from a hot spring (27). Most MAGs (23 out of 31)
323 contained genes involved in arsenic resistance. Genes for arsenic respiration were
324 detected in three MAGs, with two occurrences of arsenite oxidase gene *aioA* (BH16,
325 Actinobacterial order *Microtrichales*, and BH24, alphaproteobacterial order
326 *Rhodospirillales*) and one of arsenate reductase gene *arrA* (BH30, Desulfobacterota
327 taxon *NaphS2*) (Fig. S8). The latter had 82% amino acid identity with a gene from
328 another *NaphS2* strain isolated from anoxic sediment in the North Sea (DSM:14454);
329 this gene is annotated in the FunGene database as *arrA*. Other MAG-affiliated proteins
330 included nitrous oxide reductase (*nosZ*, in four MAGs representing three phyla), carbon
331 monoxide dehydrogenase (*cooFS*, in BH30 (*NaphS2*, phylum Desulfobacterota)), and
332 the ammonia and methane monooxygenases *amoAB* (in BH19, *Nitrosopumilus*) and
333 *pmoAB* (in BH9 (family *Methylomonadaceae*, Gammaproteobacteria) (Table 2). BH9
334 also contained several other genes involved in C1 metabolism including *mxuD*, *mch*,
335 *mtdAB*, and *fae* (data not shown).

336
337 The Woesearchaeotal MAG (BH21) was notable for its small size (679 Kbp, with 67%
338 (CheckM) and 73% (anvi'o) completion values). As with other Woesearchaeotal
339 genomes, genes for several core biosynthetic pathways were missing, including those
340 for glycolysis/gluconeogenesis, the citric acid cycle, and the pentose phosphate
341 pathway. Genes linked to glyoxylate and glycarboxylate metabolism and fructose and
342 mannose metabolism were detected, along with the carbamate kinase *arcC*; however,
343 no full energetic pathway could be reconstructed.

344
345 Only one MAG (BH24, order *Rhodospirillales*) contained genes for the full denitrification
346 pathway ($\text{NO}_3 \rightarrow \text{N}_2$). Other MAGs had the potential to perform individual steps:
347 $\text{NO}_3 \rightarrow \text{NO}_2$, seven MAGs; $\text{NO}_2 \rightarrow \text{NO}$, six MAGs; $\text{NO} \rightarrow \text{N}_2\text{O}$, six MAGs; and $\text{N}_2\text{O} \rightarrow \text{N}_2$,
348 three MAGs (Table 2).

349
350 *Microscopy and cell counts*

351
352 Microscopy-based cell counts (prokaryotes) ranged from 5×10^6 to 7×10^6 cells/mL
353 within the hole (data available only from September), almost an order of magnitude
354 lower than counts above the hole (30 m sample; Fig. S9). Counts were lowest at 80 m,
355 the depth of the observed turbidity spike.

356
357 **Discussion**

358

359 Oxygen-deficient marine water columns are crucial habitats for understanding
360 ecosystem function under oxygen limitation and across gradients of redox substrates,
361 representing conditions that are predicted to expand substantially in the future (25).
362 Moreover, these systems have been a critical resource for discoveries of novel
363 microbial diversity and unforeseen linkages between chemical cycles (19–24). While in
364 recent years these discoveries have been facilitated by community DNA, RNA, and
365 protein sequencing, most oxygen-depleted waters have not yet been characterized,
366 either from an -omics perspective or via cultivation-dependent methods. This is due
367 partly to the fact that these systems are challenging to sample and span a gradient of
368 environmental conditions. For example, the Pacific oxygen minimum zones (OMZs) are
369 anoxic through several hundreds of meters of the water column, cover hundreds of
370 square kilometers of open ocean, and are relatively unaffected by processes in the
371 underlying sediment (28). Microbial communities in these systems, especially those
372 along the peripheries, presumably have periodic exchange with microbial communities
373 outside the OMZ, for example via eddy intrusion, storms, or offshore transport (20). In
374 contrast, we describe a very different oxygen-deficient zone with intense but apparently
375 stable stratification. We show that the semi-enclosed blue hole environment exhibits a
376 physiochemical profile and microbial community both similar to but also remarkably
377 distinct from that of other oxygen-deficient water columns.

378
379 Amberjack Hole is characterized by an oxygen profile unlike that of most OMZs, with a
380 secondary oxygen peak around 75 m where dissolved oxygen rose to 43% saturation
381 before dropping back to zero (Fig. 1). In open ocean OMZs, oxygen profiles are typically
382 unimodal, with concentrations falling along an upper oxycline, staying hypoxic or anoxic
383 through a core layer, and then gradually increasing below the core as organic
384 substrates are depleted with depth and microbial respiration slows (29,30). In AJ, the
385 secondary oxygen peak at 75 m represents either a decline in net oxygen consumption
386 driven by decreased microbial respiration, a transport-related phenomenon that affects
387 oxygen supply, or both. Exchange of water between the offshore aquifer and blue hole
388 water column could affect oxygen dynamics within the hole. However, the water
389 discharging from the aquifer would be either saline connate water or saline water
390 traveling long distances through the aquifer (13,31,32). As such, it is unlikely that
391 oxygen would remain at levels to increase oxygen to 43% saturation. Alternatively,
392 oxygen may come into the hole by the sinking of dense (high σ_T , Fig 1B) oxygenated
393 marine waters that intrude onto the shelf. Such an event could occur episodically during
394 storms but has not been observed for this system. Turnover via severe cooling of
395 overlying waters, or potentially upwelling and spilling of water from off the shelf, is
396 presumably rare, and turnover by storm events unlikely. Indeed, preliminary
397 calculations, assuming only wind-driven mixing and based on the potential energy
398 anomaly (33), suggest that full turnover of the AJ water column would require wind

399 speeds of 488 mph blowing for 36 hours in conjunction with 2 m/s surface current
400 velocities in the same direction (Navid Constantinou, personal communication). Thus,
401 the observed stratification and oxygen profile may be consistent across seasons and
402 result in a stable bottom layer that is biologically isolated from the surrounding pelagic
403 environment.

404
405 AJ Hole is also characterized by a subsurface maximum in NO_3^- (nitrate) and/or NO_2^-
406 (nitrite) below the main chemocline (Fig. S2), suggesting that dissolved oxygen is also
407 consumed by nitrification. The decline in NO_x coincides with the second sharp drop in
408 oxygen concentration around 80 m. This drop is followed by the detection of reduced
409 inorganic compounds, consistent with decreasing redox free energy expectations as a
410 function of depth. The presence of $\Sigma\text{S}(-\text{II})$ below 80 m suggests active SO_4^{2-} reduction.
411 Although we detected genes potentially supporting sulfate reduction (e.g., *dsrAB*,
412 *aprAB*), we cannot rule out the potential that the encoded proteins instead catalyze
413 oxidative sulfur metabolism. Indeed, preliminary evidence indicates that $\Sigma\text{S}(-\text{II})$ was
414 generated at millimolar concentrations in the sediments based on pore water profiles,
415 and benthic lander chamber sediment flux measurements in fact show that the
416 sediment-derived $\Sigma\text{S}(-\text{II})$ fluxes (on the order of $10 \text{ mM m}^{-2} \text{ day}^{-1}$) are comprised entirely
417 of acid-volatile, purgeable hydrogen sulfide, $\Sigma\text{H}_2\text{S}$ (Beckler et al., in prep). Thus, it is
418 likely that the reduced sulfur in the deep water column largely originates from benthic,
419 rather than water column, sulfate reduction.

420
421 Reduced sulfur is clearly a key energy source in the deepest layers of the blue hole. We
422 detected high concentrations of sulfur in intermediate redox states, notably S(II) (i.e.
423 thiosulfate, $\text{S}_2\text{O}_3^{2-}$) and S(0) (elemental sulfur), overlying a pronounced zone of S(-II)
424 (hydrogen sulfide) below 80 m. Generally, oxidative sulfur metabolism proceeds with
425 $\text{H}_2\text{S}/\text{HS}^-$ being oxidized to sulfite and sulfate ($\text{SO}_3^{2-}/\text{SO}_4^{2-}$) with S(0) and $\text{S}_2\text{O}_3^{2-}$
426 produced as intermediates (34,35), with the relative completion depending on the pH or
427 on the composition of the microbial community. Here, the peak concentration of $\text{S}_2\text{O}_3^{2-}$
428 was observed at a depth above that of the peak concentration of S(0), suggesting that
429 different steps in the overall oxidation of $\Sigma\text{S}(-\text{II})$ may be performed by various vertically-
430 distributed niches within a complex cycle. We argue that if a single microbial population
431 was performing complete $\text{H}_2\text{S}/\text{HS}^-$ oxidation to SO_4^{2-} (with S(0) or S(+II) as
432 intermediates), these compounds should exhibit similar depth distributions, not
433 stratification.

434
435 The zone of peak reduced sulfur concentration (peak concentrations of all measured
436 sulfur compounds) occurred below 80 m (Fig. 1D) and appeared vertically decoupled
437 from detectable dissolved oxygen, which fell below detection between 74 and 79 m (Fig.
438 1B). This decoupling suggests the anaerobic sulfur oxidation may also proceed with

439 NO_x as a terminal oxidant, as NO_x remained detectable above 90 m and decreased in
440 concentration with depth as reduced sulfur concentrations increased (Fig. 1). Although
441 representing only the deepest, most sulfidic layers of the blue hole, metagenomes
442 contained diverse genes for oxidizing sequentially reduced sulfur compounds, as well
443 as high abundances of genes for each step of the denitrification pathway (Fig. 5).
444 Sulfur-driven denitrification is common in marine OMZs (e.g. (36)), notably in
445 conjunction with gammaproteobacteria of the SUP05 lineage (e.g. (37)). In some cases,
446 we detected both sulfur oxidation and denitrification genes in the same MAG, including
447 in the SUP05 (*Thioglobaceae*) MAG (BH20). We also recovered MAGs encoding only
448 sulfur oxidation proteins or incomplete denitrification pathways (Table 2), a pattern
449 observed in other low oxygen water columns and suggesting the likely cross-feeding of
450 sulfur and nitrogen cycle intermediates between taxa (e.g., (38,39)). However, the zone
451 of stratification of sulfur intermediates, roughly 70-90 m, overlaps with the zone of
452 oxygen availability (down to 80 m) as measured with the fluorometric sensor, which has
453 a detection limit only in the low micromolar range. Thus, it is likely that the community in
454 this depth range consumes both oxygen and oxidized nitrogen species (and potentially
455 other oxidants) for use in sulfur oxidation, with the relative concentrations of oxidants
456 and sulfur intermediates potentially driving the vertical separation of microbial niches.

457
458 Interestingly, the oxic-anoxic transition at 80 m coincided with a sharp spike in turbidity.
459 This spike was not due to an increase in microbial cell counts (Fig. S9). However, at 80
460 m, we recorded a sharp increase (to 10% of total) in the frequency of 16S rRNA genes
461 assigned to *Arcobacter*, a sulfide-oxidizing bacterium known to produce filamentous
462 sulfur at oxic-anoxic interfaces (40). Between 80 and 90 m, 70-83% of the combined
463 elemental sulfur (S(0)) and polysulfide (Σ S(-II)) signal was lost after 0.7 μ m filtration,
464 suggesting that this lost fraction was in fact elemental sulfur, as polysulfide is soluble
465 (41,42). We did not sample at 80 m in May and therefore cannot confirm if the sharp
466 turbidity and *Arcobacter* spikes are stable over time. However, the production of
467 filamentous or other particulate forms of sulfur under microaerophilic conditions is
468 consistent with the observed sulfide and oxygen gradients in both months (Fig. 1).
469 Alternatively, *Arcobacter* may be using NO_x to oxidize S(-II), as has been shown in
470 denitrifying members of the genus (43).

471
472 Other oxidants may also play a role in AJ. Dissolved ferrous iron (Fe(II)) reached a
473 maximum concentration near the turbidity spike at ~80 m, below the zone of peak
474 O₂/NO_x and above the zone of reduced sulfur (Fig. 1D). Further, total dissolved iron
475 (Fe_d), which includes dissolved organically-stabilized Fe(III) and FeS colloids, remained
476 < 300 nM, but increased below 40 m, peaking just above the dynamic reduced sulfur
477 zone (Fig. 1D). These patterns hint at a possible cryptic iron cycle, in which Σ H₂S
478 diffusing upwards is rapidly oxidized by dissolved Fe(III) (44) to form Fe(II), S(0), and

479 $\Sigma S(-II)$. Dissolved Fe(III) may then be recycled by reoxidation of Fe(II) by O_2 , and the
480 S(0)/S(-II) simultaneously oxidized by O_2 or dissolved Fe(III) to form thiosulfate, $S_2O_3^{2-}$.
481 Alternatively, ΣH_2S may first react with Fe(II) to form the detected FeS colloids, which
482 subsequently oxidize to form Fe(II), S(0), and S(-II). Metabolic pathways for iron
483 oxidation (or reduction) are not easy to detect with metagenomic data, as iron
484 metabolism genes play roles in other cellular processes and are therefore suggestive
485 but not diagnostic of iron metabolism (45,46). Nonetheless, additional metagenomic
486 sampling at finer spatial resolution may help identify a role for microbial activity in blue
487 hole iron cycling. The oxidation of iron, however, is rapid even abiotically, and the
488 vertical distribution of iron in this system can partially explain the apparent vertical
489 disconnect between the $\Sigma S(-II)$ and O_2 . Indeed, this phenomenon has been observed in
490 a nearshore Florida hole (6), in which FeS colloids formed at the interface between 30
491 and 50 m. AJ appears to be enriched instead in colloidal S(0), with only nanomolar
492 concentrations of FeS colloids.

493
494 The pronounced stratification of blue hole chemistry is consistent with differentiation of
495 microbial communities with depth. In both May and September, microbiome composition
496 varied distinctly among oxic, hypoxic, and anoxic, sulfidic layers (Fig. 2). Shannon
497 diversity was similar among all communities, but Simpson diversity was notably higher
498 in the anoxic depth group (Fig. S3), reflecting the lower evenness of these microbiomes.
499 Surprisingly, the deepest communities were dominated by a recently described archaeal
500 lineage, the Woesearchaeota (47). Woesearchaeota have been detected in a wide
501 variety of biomes, including groundwater, terrestrial and marine sediments, wetlands,
502 deep-sea hydrothermal vents, and hypersaline lakes (48). However, their relative
503 abundance is consistently low, at most ~5% of the total microbial community in any
504 given environment, with the highest proportions observed in freshwater sediments (48)
505 and high-altitude lakes (49). In contrast, Woesearchaeota comprised at least one third
506 of the blue hole microbiome between 75 and 106 meters, reaching a maximum of nearly
507 60% in the anoxic sulfidic layer in September (Fig. 2, Fig. 3). Remarkably, one 16S
508 rRNA sequence variant represented up to 97% (and only two SVs represented up to
509 99%) of all Woesearchaeotal amplicons in each sample, suggesting low intrapopulation
510 diversity. Dominance (>50% of the community) by a single strain variant is relatively
511 uncommon in pelagic marine microbiomes; it is even more rare that such occurrences
512 involve members of the Archaea. The AJ Woesearchaeotal MAG, which contained the
513 dominant 16S rRNA Woesearchaeota amplicon sequence, was 679 Kbp and similar in
514 size to other Woesearchaeotal genomes, which rarely exceed 1 Mbp (47,48). This MAG
515 was most closely related to MAGs from an OMZ in the Arabian Sea (Fig. 5), suggesting
516 the potential for a Woesearchaeotal clade specific to a pelagic, marine, low oxygen
517 niche. At around 70% completion, the AJ MAG did not contain genes of metabolic
518 processes common to marine low oxygen systems, notably dissimilatory sulfur or

519 nitrogen cycling, anaerobic metabolism, or autotrophy. Indeed, consistent with
520 characterizations of other Woesearchaeotal genomes (47,48), AJ Woesearchaeota
521 appear to have limited metabolic capabilities. It is therefore possible that these cells are
522 partnered in a syntrophic relationship with other microbes on which they rely for energy
523 or nutrients, as has been previously suggested (47,48).

524
525 The Woesearchaeotal MAG was one of several novel lineages in the AJ water column.
526 From the deepest samples (95 m and 106 m), recovered MAGs included members of
527 the sulfur-oxidizing SUP05 clade of *Thioglobaceae*, two members of the CPR phylum
528 Patescibacteria, and three members of the phylum Marinimicrobia (SAR406), among
529 others (Table 1). The middle water column (60 m) was also populated by
530 underdescribed taxa, including several lineages of marine Thermoplasmatota and
531 members of the bacterial phyla Planctomycetota and Myxococcota. Only eight out of
532 nineteen MAGs from 60 m had identifiable close representatives in the GTDB,
533 suggesting a high level of taxonomic novelty. Surprisingly, automatic binning did not
534 recover a Thaumarchaeal MAG from the 60 m assembly despite the large fraction of
535 amplicon SVs belonging to the ammonia-oxidizing genus *Nitrosopumilus*. However, a
536 manually binned MAG could be phylogenomically placed in this lineage (Fig. S4) and
537 contained the dominant SV from the amplicon data set, which comprised up to 86% of
538 all *Nitrosopumilus* spp. amplicons. As with the Woesearchaeota, this low level of SV
539 diversity implies population homogeneity. It remains to be determined if this
540 homogeneity is driven by a potential dearth of ecological niches. Indeed, the AJ
541 *Nitrosopumilus* MAG, at 725 Kbp, was estimated to be only 53-63% complete (Table 1,
542 Table S3); its full biochemical potential therefore remains to be characterized. However,
543 in contrast to recently described and putatively heterotrophic Thaumarchaeota (50,51),
544 blue hole *Nitrosopumilus*, like all known members of this genus, contain *amoCAB*
545 encoding ammonia monooxygenase and therefore likely contribute to nitrification in the
546 blue hole.

547
548 The 60 m samples also contained six MAGs belonging to the archaeal phylum
549 Thermoplasmatota. One of these (BH15) could only be placed in the family
550 Thalassoarchaeaceae. The others included four (BH4, BH11, BH12, and BH13) from
551 the Marine Group II lineage, which is one of the four major planktonic archaeal groups
552 (52), and one from the less well-characterized Marine Group III lineage (BH3). The
553 Marine Group II have recently been proposed as an order-level lineage, *Candidatus*
554 Poseidoniales, containing two families delineating the current MGIIa and MGIIb clades
555 (53). Most MGIIa members have been identified from the photic zone, while MGIIb
556 sequences are largely limited to depths below 200 m, although there are exceptions
557 (54). Notably, all AJ MGII MAGs belonged to the MGIIb lineage (Table 1). Several
558 studies have identified genes related to low-oxygen metabolism including reduction of

559 sulfate (55–57) and nitrate (53), suggesting these taxa are more likely to be adapted to
560 microaerophilic or anaerobic conditions. We found a gene for thiosulfate reduction to
561 sulfite (*phsA*) in two of the four MGIIb MAGs (Table 2), but no complete pathways for
562 any forms of anaerobic respiration. Nevertheless, the Marine Group II lineage
563 comprised over 25% (five out of nineteen) of the MAGs recovered from 60 m,
564 suggesting this group as an important component to the hypoxic zone community.

565
566 Metabolic potential differentiated the middle and deep water column communities (Fig.
567 5, Fig. S6). Many of these functions could be linked to MAGs and represented a range
568 of anaerobic metabolisms. Genes for dissimilatory sulfide and sulfite oxidation (or
569 potentially reduction; *dsrAB*, *aprAB*), denitrification (*nar*, *nir*, *nor*, *nos*), and dissimilatory
570 nitrate reduction to ammonia (DNRA, *nrf*) were enriched in deep anoxic samples, but
571 also common in the hypoxic zone (60 m) (Table 2, Fig. 5). Other genes linked to MAGs
572 included *aioAB* and *arrA*, encoding arsenite oxidase and arsenate reductase,
573 respectively (Fig. S8). Reduction of arsenate to arsenite is thought to be an ancient
574 metabolic pathway, originating before oxygenation of the Earth's atmosphere and
575 oceans (58). It has recently been proposed as an important microbial metabolic strategy
576 in oxygen-deficient marine environments, potentially providing arsenite for use as an
577 energy source by other microbes (19). Arsenic concentrations in Amberjack have not
578 been measured. However, the detection of *aioAB* and *arrA*, of which the latter was also
579 detected in unbinned contigs from the deep co-assembly (Fig. S8), as well as genes for
580 arsenic detoxification (*arsCM*) in diverse MAGs (including in the *Nitrosopumilus* MAG
581 described above), suggest a role for arsenic cycling in AJ. Remarkably, one MAG
582 (BH24, *Rhodospirillales*) contained genes for several of these pathways, representing
583 an unusual repertoire of respiration strategies (Table S4). Finally, one of the genes with
584 the largest differences in frequency between 60 m and deep samples encodes an
585 unknown protein previously observed in genomes of *Candidatus* Uhbacteria, one of the
586 groups within the CPR/Patescibacteria (Fig. S7). Two MAGs from this group, which is
587 largely affiliated with freshwater and subsurface aquifer environments, were recovered
588 from the deep samples, and may play as-yet undetermined ecological roles in this
589 unusual microbiome. This hypothesis is supported by the low sequence identity of this
590 protein to similar ones in NCBI.

591 592 **Conclusions**

593
594 The Amberjack Hole water column is potentially highly stable, with complete turnover
595 (driven either by wind or the sinking of cold water masses) unlikely. Thus, AJ
596 microbiomes, particularly those in the deepest layers, potentially have limited
597 connectivity to other marine communities. The extent to which such isolation explains
598 the observed unique community composition or drives divergence of individual microbial

599 lineages remains uncertain. Undoubtedly, the vertical transport, transformation, and
600 stratification of redox active elements - notably sulfur, nitrogen, and iron - also play a
601 significant role in structuring this unusual microbiome. The presumed stability of this
602 community, its high metabolic diversity, and its dominance by understudied microbial
603 taxa, highlight AJ as a model for detecting novel biogeochemical processes under low
604 oxygen. Marine blue holes in general are potentially valuable sites for the study of
605 microbial diversification and linked elemental cycling.

606

607 **Methods**

608

609 *Sampling scheme*

610

611 Sampling was conducted May 15-17 2019 and September 19 2019 using the vessels
612 *R/V William R. Mote* and *R/V Eugenie Clark*. Amberjack Hole is located approximately
613 50 kilometers west of Sarasota, Florida, at 27.28748 N, -83.16139 W. One component
614 of the research involved the deployment of an autonomous benthic lander to the bottom
615 of the hole for 24-48 hours at a time for benthic electrochemistry measurements; these
616 data are not included in this paper. Technical SCUBA divers who guided the lander into
617 and out of the hole also collected water samples (see details below).

618

619 In both May and September, all water samples used for nutrient measurements and
620 microbial DNA preservation were filtered immediately on board. Microbial DNA samples
621 were stored on ice until the return to Mote Marine Laboratory, where they were stored at
622 -20°C. Subsequent nutrient analyses described below were conducted at Mote except
623 where noted.

624

625 *Water column physical parameters and dissolved oxygen*

626

627 During the May sampling, an EXO2 sonde (YSI Inc/Xylem Inc, Yellow Springs, Ohio)
628 was attached to the autonomous lander deployed for 24 hours to the bottom of the hole.
629 The sensor provided extensive data from the surface (1-2 m) and the bottom position
630 (106 m) but low-resolution readings from the water column due to rapid ascent and
631 descent velocities. Dissolved oxygen, temperature, and salinity data were retrieved from
632 the instrument and plotted in R.

633

634 During the fall sampling, an integrated SBE-19plus V2 CTD with an SBE43 DO sensor,
635 WET Labs FLNTUrt chlorophyll and turbidity sensor, Satlantic cosine PAR sensor, and
636 an SBE18 pH sensor (Sea-Bird Electronics Inc) was lowered twice by hand at a rate
637 that provided high-resolution dissolved oxygen, turbidity, salinity, and density data on

638 September 19 2019. CTD casts were performed the same day as water was sampled
639 for microbial DNA and nutrients. Data were retrieved and plotted in R as above.

640
641 SBE data were processed using SBE Data Processing software after compensating for
642 sensor thermal mass, sensor alignment, timing offset (the delay associated with
643 pumped sensors, i.e. conductivity), and changes in instrument velocity (due to ship
644 heave). Data were binned (~0.2 m increments) to smooth data variability. Processed
645 and derived data included temperature (°C), potential temperature (°C), salinity (psu),
646 water density (σ_T in kg/m³), chlorophyll *a* (µg/L based on relative fluorescence), turbidity
647 (NTU), dissolved oxygen (mg/L), O₂ saturation (%), pH, PAR, and Brunt-Väisälä
648 frequency (N = stratification index). Manufacturer recommendations for calibration and
649 service for all sensors were followed.

650

651 *Water column electrochemical measurements*

652

653 Water samples (~10 m vertical resolution) were subject to solid-state Hg/Au
654 voltammetric analyses (59) for measurement of the redox environment, i.e. O₂, Mn(+II),
655 organic-Fe(III) complexes, Fe(II), S(+II) (in the form of S₂O₃⁻), S(0), S_x(-II), and ΣH₂S
656 (S²⁻, HS⁻, H₂S). Briefly, samples collected from the water column at 10 m intervals were
657 carefully transferred via a Tygon (formula 2375) transfer tube line into LDPE bottles
658 while filling from bottom to top to minimize atmospheric oxygen contaminations. Sample
659 bottles remained sealed until analyses and were stored at 4°C. Upon return to the lab
660 (within 4-6 hours of collection), 20 mL of each sample was carefully pipetted into an
661 electrochemical cell (Analytical Instrument Systems, Inc.) holding a custom fabricated
662 Hg/Au amalgam microelectrode working electrode (60), a Pt counter electrode, and a
663 fritted Ag/AgCl reference electrode (with 3 M KCl electrolyte solution). N₂ was gently
664 blown over the top of the solution to minimize mixing with the atmosphere. Within 5
665 minutes, samples were subject to a series of anodic square wave voltammograms
666 (ASWVs), cathodic square wave voltammograms (CSWVs), and linear sweep
667 voltammograms (LSVs) to quantify the above redox analytes (59,61). To analytically
668 distinguish between S(0) and S(-II), which both react at the same potential at an Hg
669 electrode (42), CSWV measurements were repeated after acidification with HCl (final
670 pH < 3) and N₂ sparging of the solution for two minutes to remove free ΣH₂S. This same
671 electrochemical speciation experiment was conducted a second time in separate
672 aliquots that were filtered through 0.7 µm GFF filters directly in the N₂-degassed
673 electrochemical cell (this filter size was selected for future organic carbon analyses).

674

675 *Nutrient, iron, and DIC measurements*

676

677 Water samples were collected for nutrients and included chlorophyll *a*, dissolved
678 ammonium (NH_4^+), dissolved NO_x (nitrate (NO_3) + nitrite (NO_2)), dissolved
679 orthophosphates (PO_4^{3-}), dissolved total and ferrous iron (Fe), dissolved inorganic
680 carbon (DIC) and particulate carbon (C), nitrogen (N), and phosphorous (P). All samples
681 were collected and immediately filtered once shipboard.

682
683 Chlorophyll *a* was measured according to EPA method 445.0 (62). Briefly, samples
684 were filtered through a glass fiber filter until clogging, then stored in the dark until
685 analyses. Prior to analyses, filters were sonicated in 90% acetone to extract chlorophyll
686 from algal cells and then centrifuged for clarification. The fluorescence of the clarified
687 extract was then measured using a fluorometer (Turner 10-AU Fluorometer) with special
688 narrow bandpass filters at an excitation wavelength of 436 nm and an emission
689 wavelength of 680 nm. Analytical quality assurance followed standard laboratory
690 practices assessing precision and accuracy using sample replicates, container blanks,
691 duplicate and spiked analyses with results meeting acceptable levels of precision and
692 accuracy.

693
694 Samples for dissolved NH_4^+ and NO_x were filtered through Pall Supor (PES) 450 47 mm
695 (0.45 μm pore size) membrane filters while samples for particulates were filtered
696 through pre-combusted (450°C, 3h) 47 mm (0.7 μm pore size) Whatman GF/F filters.
697 For particulate carbon and nitrogen, 200 mL was filtered per sample and filters were
698 rinsed with acidified (10% HCl) filtered seawater to remove inorganic carbon. For
699 particulate P, 500 mL was filtered. Samples were then stored on ice until their return to
700 the lab and analyzed within 48 hours (dissolved NH_4^+ and NO_x) or within 28 days
701 (particulates). Analyses for dissolved nutrients followed colorimetric, segmented flow,
702 autoanalyzer techniques on an AA3 with method reference and method detection limits
703 (MDL) as follows: dissolved NH_4^+ ((63); 0.07 μM), dissolved NO_x ((64); 0.07 μM).
704 Particulate phosphorus was analyzed according to (65,66) with in-house modifications
705 for analysis on a segmented flow analyzer and MDLs of 0.03 μM . For particulate carbon
706 and nitrogen, samples were analyzed on a Thermo FlashEA1 1112 Elemental Analyzer
707 with MDLs of 0.2 and 0.1 μM , respectively.

708
709 To measure DIC, samples were immediately poisoned with HgCl_2 and stored until
710 analyses. DIC was analyzed (Apollo AS-C6 DIC Analyzer) following methods by (67).
711 Accuracy and precision of the instrument was regularly monitored using Certified
712 Reference Materials for Seawater CO_2 Measurements (Dickson Laboratory, Scripps
713 Institution of Oceanography, San Diego, CA; Batch #181 and 186).

714
715 Soluble orthophosphates (PO_4^{3-}) were measured spectrophotometrically using the
716 molybdate-blue technique (68).

717
718 Finally, the speciation of iron was obtained by measuring Fe(II) by the ferrozine assay
719 (69) in filtered samples before (dissolved Fe(II)) and after (total dissolved Fe) reduction
720 by hydroxylamine (0.2 M) using a long waveguide spectrophotometric flow cell.
721 Analytical quality assurance follows standard laboratory practices assessing precision
722 and accuracy using sample replicates, container blanks, duplicate and spiked analyses
723 with results meeting acceptable levels of precision and accuracy.

724 725 *Microbial DNA sampling and preservation*

726
727 Water column samples were collected on May 15 and 17 2019 and September 19 2019.
728 In May, 800 mL water was collected by divers from depths of 46 m, 61 m, and 106 m
729 inside the hole. Sterilized Nalgene bottles filled with deionized water were taken down
730 by the divers, opened at the appropriate depth, and DI water was replaced with ambient
731 seawater. Niskin bottles deployed on the CTD rosette also collected 1.9 L samples from
732 depths of 8 m, 15 m, and 23 m above the hole. In May and September, hand-cast
733 Niskin bottles collected 1 L water from 0 m (surface), 30 m, 60 m, and 85 m (May), and
734 from 0 m (surface) to 90 m at 10 m intervals, as well as 85 m and 95 m (September).
735 Samples were filtered onto 0.22 μm Sterivex (MilliporeSigma) filters with a peristaltic
736 pump and preserved with approximately 3 mL DNA/RNA stabilization buffer (25 mM
737 sodium citrate, 10 mM EDTA, 5.3 M ammonium sulfate (pH 5.2)) and stored at -80°C or
738 on dry ice until further processing at Georgia Tech. In September, unfiltered water from
739 the following depths was also preserved (1.4 mL water, 150 μL PBS-buffered
740 formaldehyde) for nucleic acid staining and microscopy and kept frozen at -20°C until
741 processing: 30 m, 50 m, 60 m, 70 m, 80 m, 85 m, 90 m, 95 m.

742 743 *Sequencing library preparation*

744
745 DNA was extracted from each Sterivex cartridge using a custom protocol as described
746 in (70), except for the September surface (0 m) sample which was lost during sample
747 transit to Georgia Tech. Briefly, cells were lysed by flushing out RNA stabilizing buffer
748 and replacing it with lysis buffer (50mM Tris-HCl, 40 mM EDTA, 0.73 M sucrose) and
749 lysozyme (2 mg in 40 mL of lysis buffer per cartridge), then incubating cartridges for 45
750 min at 37°C . Proteinase K was added and cartridges were resealed and incubated for 2
751 h at 55°C . The lysate was removed, and the DNA was extracted once with
752 phenol:chloroform:isoamyl alcohol (25:24:1) and once with chloroform:isoamyl alcohol
753 (24:1). Finally, DNA was concentrated by spin dialysis using Ultra-4 (100 kDA, Amicon)
754 centrifugal filters. Yield was assessed using a Qubit 2.0 dsDNA high-sensitivity assay
755 (Invitrogen, Carlsbad, CA).

756

757 Illumina MiSeq libraries were prepared by amplifying the V4 region of the 16S rRNA
758 gene using the environmental DNA protocol adapted from (71). Briefly, amplicons were
759 generated using Platinum[®] PCR SuperMix (Life Technologies, Carlsbad, CA) with Earth
760 Microbiome Project primers 515FB and 806RB appended with Illumina-specific
761 adapters. Template DNA was diluted to approximately 5 ng/μL for all samples and
762 PCRs were performed in 25-μL reactions using Platinum[®] PCR SuperMix (Life
763 Technologies) (22 μL), BSA (Invitrogen) (1 μL), and 0.5 μL each of forward and reverse
764 primer (10 ng/L stock concentration) with 1 μL template DNA. The thermal cycling
765 protocol consisted of 26 cycles with the following steps: denaturation at 98°C (30 s),
766 followed by 30 cycles of denaturation at 98°C (5 s), primer annealing at 55°C (5 s) and
767 primer extension at 72°C (8 s), followed by extension at 72°C for 1 minute. Negative
768 control reactions were run using 1 μL milliQ water in place of DNA template. Amplicons
769 were analyzed by gel electrophoresis to verify size (~400 bp, including barcodes and
770 adaptor sequences) and purified using Diffinity RapidTip2 PCR purification tips (Diffinity
771 Genomics, West Chester, PA). Amplicons from different samples were pooled at
772 equimolar concentrations and sequenced using a paired-end Illumina MiSeq 500 cycle
773 kit (2 x 250 bp) with 5% PhiX to increase read diversity.

774
775 Metagenomes were generated from four water column samples: two from May (60 m
776 and 106 m) and two from September (60 m and 95 m). Libraries were prepared using
777 the Illumina Nextera XT DNA library preparation kit (Illumina Inc., San Diego, CA)
778 according to manufacturer's instruction and run on a Bioanalyzer 2100 instrument
779 (Agilent) using a high sensitivity DNA chip to determine library insert sizes. An
780 equimolar mixture of the libraries (final loading concentration of 12 pM) was sequenced
781 on an Illumina MiSeq instrument (School of Biological Sciences, Georgia Institute of
782 Technology), using a MiSeq reagent v2 kit for 600 cycles (2 x 300 bp paired end
783 protocol).

784
785 *Amplicon sequence data processing and analysis*

786
787 Demultiplexed amplicon sequences are available in the Patin FigShare account:
788 https://figshare.com/projects/Amberjack_Blue_Hole/85013. Raw sequences were run
789 through the DADA2 algorithm (72) in QIIME2 (73) to assess sequences at sequence
790 variant resolution, using the following command parameters: --p-trim-left-f 70 --p-trim-
791 left-r 70 --p-trunc-len-f 150 --p-trunc-len-r 150. Resulting SVs were assigned taxonomy
792 using the naïve Bayes classifier trained on the Silva 132 database (99% OTUs,
793 515F/805R sequence region).

794
795 The SV table with raw read counts of all water samples were exported from QIIME2 and
796 transformed in R using the variance stabilizing transformation (vst) in the DESeq2

797 package (74). Tables were not rarefied to preserve maximum available information.
798 Metadata including depth and SV taxonomy were imported and combined into a
799 Phyloseq object (75,76). Alpha and beta diversity analyses were run in DivNet (77) at
800 the SV level. Shannon and Simpson diversity results were extracted and plotted by
801 depth grouping using ggplot2 (78). Beta diversity was assessed using the resulting
802 Bray-Curtis distance matrix in a principal component analysis using the prcomp()
803 function in R and visualized in a PCA using ggplot2. The distance matrix was also used
804 to test for significant difference among samples by depth grouping and month using the
805 adonis() function in the R vegan package (79) with the following command:
806 adonis(formula = bc ~ Depth + Month, data = metadata, permutations = 999).

807

808 *Metagenomic sequence data processing and analysis*

809

810 Metagenome sequences are available in the Patin FigShare account:
811 https://figshare.com/projects/Amberjack_Blue_Hole/85013. Raw sequences from the
812 four metagenomes (May 60 m, May 106 m, September 60 m, September 95 m) were
813 trimmed and checked for quality and adapter contamination as described for the
814 amplicons above. Quality controlled reads were run through MicrobeCensus (80) to
815 generate genome equivalent (GE) values for each metagenome. To generate more
816 even coverage distribution across the metagenomes, quality controlled reads were
817 normalized using BBNorm, part of the open source BMap package
818 (<https://sourceforge.net/projects/bbmap/>).

819

820 Six assemblies were generated from the four water column metagenomes. Individual
821 assemblies of each sample were generated using metaSPAdes (v3.14.0) (81). Co-
822 assemblies for each depth pair (May 60 m with September 60 m, and May 106 m with
823 September 95 m) were also generated using MEGAHIT (v1.2.9) (82) using a minimum
824 contig length of 2500 bp. All assemblies were assessed for quality using metaQUAST
825 (83) and annotated using Prokka (84) and the KEGG database.

826

827 For the latter, open reading frames were generated using Prodigal (85) and clustered
828 using MeShClust (86) at 90% nucleotide identity. The longest sequence from each
829 cluster was extracted using a custom Python script and these representative sequences
830 were run against the KEGG ortholog profile HMM models (KOfams) using KofamScan
831 with the 'prokaryote' database (87). The parameter '-f mapper' was applied to provide
832 only the most confident annotations (those assigned an individual KO). Orthologies
833 were matched to their corresponding functions using a parsed version of the
834 'ko00001.keg' database text file (<https://github.com/edgraham/GhostKoalaParser>),
835 which provides a three-tiered hierarchical categorization of each gene, referred to here
836 as 'Group', 'Subgroup1', and 'Subgroup2'. Sequence coverage of each gene was

837 generated by mapping metagenomic short reads against each one using Magic-BLAST
838 (88). The Magic-BLAST output was filtered to include only the best hit for each read and
839 the read counts were normalized by GE value of the corresponding metagenome.

840
841 The normalized counts were used to run hierarchical clustering analyses in Python
842 using the Seaborn 'clustermap' function. KofamScan outputs were grouped by the three
843 hierarchical categories to generate heat maps at different levels of categorization. At the
844 highest categorical level ('Group') the categories 'Human Diseases,' 'Organismal
845 Systems,' 'Cellular community – eukaryotes,' and 'Brite Hierarchies' were removed
846 before performing the cluster analysis. The first three groups are not relevant to
847 microbial gene functions and the fourth provides a different hierarchical categorization
848 scheme for the same annotations and was thus redundant. All cluster analyses were
849 run using ward linkage and Euclidean distance methods.

850
851 Open reading frames generated from the SPAdes individual assemblies were run
852 through the Hidden Markov Model search tool described in (89) and available at
853 https://github.com/ShadeLab/PAPER_Dunivin_meta_arsenic/tree/master/HMM_search
854 to query for genes involved in arsenic metabolism. HMM outputs were run through the
855 data_preparation.R script (also available in the GitHub repository) to generate plots
856 showing the quality distributions of hits to the *aioA* and *arrA* genes. The amino acid
857 sequence of a potential sequence for the *arrA* gene extracted from BH30 (alignment
858 fraction 89%, bitscore 237) was also queried against the *arrA* BLAST database from the
859 same toolkit.

860
861 *Metagenome-assembled genomes*

862
863 Genomic bins were generated from all individual assemblies as well as co-assemblies.
864 For each co-assembly, short reads from both metagenomes were submitted to MaxBin
865 to leverage contig co-variation patterns across samples. All bins were assessed for
866 quality using CheckM (90) and anvi'o (v6.1) (91). Bins with a quality score greater 40
867 were retained for dereplication, with quality score calculated as completion – 5 x
868 contamination (CheckM values). Dereplication was performed with dRep (92) with an
869 ANI cutoff of 95% for secondary clustering and a 20% minimum pairwise overlap
870 between genomes. For bins belonging to the same secondary cluster (ie, likely
871 representing the same microbial population), the highest-quality was chosen as a
872 representative. In cases where the qualities of two MAGs were within 1%, the
873 completeness and redundancy values from anvi'o were applied to determine the higher
874 quality bin. Further analyses were performed on these representative bins.

875

876 All dereplicated high-quality MAGs were assessed for taxonomy with *anvi'o* and the
877 Genome Taxonomy Database toolkit (GTDB-Tk) (93,94). Each MAG was checked for
878 the presence of rRNA genes using the *anvi'o* HMM models and one MAG from the 60M
879 assembly was found to contain a eukaryotic 18S rRNA gene with an 80% match to a
880 copepod sequence (*Calanus* sp.). This contig was removed from the co-assembly of
881 origin and the process of binning, quality assessment, and de-replication was repeated.

882
883 All MAGs were queried for the presence of 16S rRNA gene amplicons by using the SVs
884 as a query for a BLASTn analysis against the two co-assembly contigs. MAG contigs
885 containing 100% identity matches across the entire SV length were identified, and the
886 SV SILVA-based taxonomy was compared with the whole genome taxonomy
887 assignment from GTDB.

888
889 All MAGs were functionally annotated using both Prokka and KofamScan as described
890 above, without the read mapping step. The following genes were verified by running
891 amino acid sequences against the NCBI-nr database using blastp: *pmoA-amoA*
892 (K10944; KEGG), *pmoB-amoB* (K10955; KEGG), *pmoC-amoC* (K10956; KEGG),
893 K23573 (DSPP, dentin sialophosphoprotein; KEGG), *pmoA* (Prokka), *pmoB* (Prokka),
894 *aiob* (Prokka), *arsC2* (Prokka), *arsM* (Prokka). To confirm the annotations of arsenic
895 respiration and resistance genes, and to query other genes involved in arsenic
896 metabolism, including the arsenate reductase gene *arrA*, all MAGs were run through the
897 Hidden Markov Model search tool described in (89) and available at
898 https://github.com/ShadeLab/PAPER_Dunivin_meta_arsenic/tree/master/HMM_search.

899
900 *Manual MAG refinement and generation*

901
902 Six MAGs contained more than one 16S rRNA gene SV. In cases where the SVs within
903 a MAG were distantly related to each other, any contigs containing a copy that was
904 divergent from the genome-wide GTDB-TK taxonomic assessment were removed from
905 the bin. Quality assessments were repeated on the edited MAG using CheckM and
906 *anvi'o*, and if the quality score (as defined above) was over 5 points lower than the
907 original MAG, the edited MAG was discarded. This happened in only one case (BH22);
908 all other MAGs were kept in their edited form.

909
910 One of these edited MAGs was BH28, classified by GTDB as Patescibacteria but
911 containing an SV classified as *Magnetospiraceae* (Alphaproteobacteria,
912 Rhodospirillales) by SILVA. Conversely, BH24, which was classified by GTDB as
913 Rhodospirillales, contained no 16S rRNA genes. The contig containing the
914 *Magnetospiraceae* SV was removed from the Patescibacteria bin and added to BH24
915 based on its tetranucleotide clustering proximity to other contigs in that bin (as seen in

916 the anvi'o interactive interface) and the matching taxonomy between the MAG and the
917 SV.

918
919 The dominant *Nitrosopumilus* amplicon SV was not present in any of the MAGs
920 generated from the 60 M samples. However, it was found on an unbinned contig in the
921 60M co-assembly. The anvi'o interactive interface was used to manually generate a bin
922 containing this sequence, along with a 23S rRNA sequence with 99% identity to
923 *Nitrosopumilus catalina*, and other contigs of similar tetranucleotide frequency, GC
924 content, and coverage (BH19). This MAG was assessed for quality using CheckM and
925 anvi'o.

926
927 All MAGs were run through GTDB using the 'classify_wf' (for taxonomic classification)
928 and 'ani_rep' (for closest relative by ANI) commands in GTDB-Tk (93), and through
929 Prokka (84) and KofamScan (87) for functional annotation. Closest relatives were
930 determined using a minimum 65% alignment fraction; if no reference genome exceeded
931 this minimum there was no result.

932
933 All MAG sequences are available in the Patin FigShare account:
934 https://figshare.com/projects/Amberjack_Blue_Hole/85013.

935
936 *Phylogenomic analyses*

937
938 Phylogenomic trees were generated for the MAGs BH19 (*Nitrosopumilus*), BH20
939 (SUP05 clade, *Thioglobaceae*), and BH21 (Woese archaeota). In each case, genomes
940 with the same or similar taxonomy as the MAG were downloaded from the NCBI
941 Assembly database and run through anvi'o for quality assessment using anvi-estimate-
942 genome-completeness. High-quality MAGs (quality score > 40 as defined above) were
943 retained (Table S4) and single-copy genes were extracted using the anvi'o script anvi-
944 get-sequences-for-hmm-hits. The two archaeal MAGs (BH19 and BH21) were run
945 against the 'Archaea_76' HMM database and the bacterial MAG (BH20) was run
946 against the 'Bacteria_71' HMM database. Genes occurring in most or all MAGs were
947 concatenated and aligned (see Table S4 for taxon-specific minimum gene occurrences).
948 The alignment was run through RAxML (95) with optimization of substitution rates and a
949 GAMMA model of rate heterogeneity ("PROTGAMMA" substitution model) with 999
950 bootstraps for a maximum likelihood phylogeny. The resulting .tre files were uploaded to
951 the interactive Tree of Life website (96) (itol.embl.de) and labeled with their strain or
952 sample of origin.

953
954 *Cell staining and microscopy*

955

956 Duplicate samples from the following depths were processed for microscopy: 30 m, 50
957 m, 70 m, 80 m, and 95 m. Samples preserved in PBS-buffered formaldehyde (1.55 mL
958 total) were combined with 2.0 mL milliQ water and filtered onto 0.2 μm GTBP filters
959 (Millipore) using vacuum filtration. Filters were dried for approximately 20 minutes and
960 incubated in the dark on ice with 50 μL DAPI (0.2 $\mu\text{g}/\text{mL}$). Filters were then rinsed in
961 milliQ water and 100% ethanol, dried for approximately 10 minutes, and placed on a
962 microscope slide with one drop of Citifluor (Electron Microscopy Sciences). Slides were
963 visualized with a Zeiss Axio Observer D1 confocal epifluorescence microscope using a
964 DAPI filter (Zeiss filter set 49). Between twenty and twenty-five photographs were taken
965 in a grid pattern from each slide and counted in ImageJ (97) using a custom script. The
966 average value of cell counts from all photos for each sample was plotted in Microsoft
967 Excel.

968

969 **Figure legends**

970

971 Figure 1. The blue hole water column in September 2019 was highly stratified. (A)
972 Compared to the overlying water, salinity was slightly higher and pH was slightly lower
973 inside the hole (i.e. below 30 m). A coincident dip in salinity and rise in pH was present
974 at 75 m. (B) Dissolved oxygen concentrations varied widely, with both a primary and
975 secondary oxycline. At 80 m, the onset of anoxia immediately below the secondary
976 oxycline coincided with a spike in turbidity. (C) Dissolved inorganic carbon (DIC)
977 increased slightly from 20 to 50 m but more intensely between 70 and 90 m, from
978 approximately 2.2 to 2.5 mM. A sharp increase in NO_x ($\text{NO}_2^- + \text{NO}_3^-$) between 40 and 50
979 m was followed by a return to near 0 between 60 and 90 m. Phosphate (PO_4^{3-}) and
980 ammonium (NH_4^+) remained below 1 μM before increasing to 5-6 μM between 70 m and
981 80 m, respectively. (D) Dissolved ferrous iron (Fe(II)_d), and total dissolved iron (Fe_d)
982 increased with the transition to anoxia. Sulfur species are presented as follows: $\text{S}_2\text{O}_3^{2-}$
983 (thiosulfate, S in the +II oxidation state) peaked between 80 and 90 m. S(0) represents
984 combined dissolved and colloidal elemental sulfur; however, the dissolved fraction may
985 also include a small amount of polysulfide species (i.e. $\text{S}_x(-\text{II})$). Finally, $\Sigma\text{S}(-\text{II})$
986 represents primarily hydrogen sulfide (HS^-) but could also be minorly redundant with
987 S(0). All iron and sulfur species increased sharply by 70-85 m, with S(0) representing
988 the largest component of the reduced sulfur pool.

989

990 Figure 2. Microbial communities represented three water column depth groupings:
991 shallow (0-32 m), middle (40-70 m), and deep (80-95 m). (A) Principal components
992 analysis shows communities were highly similar within each depth grouping regardless
993 of sampling date. (B) Community composition of representative samples from each of
994 the three depth groupings show both middle and deep water column layers feature high
995 levels (~40% frequency) of a single taxon, the ammonia-oxidizing *Nitrosopumilus* sp. in

996 the middle water column and the Woesearchaeota in the deepest layers. Samples
997 shown here are from September 2019 at 30 m, 40 m, and 85 m.

998

999 Figure 3. The relative abundances of the most commonly observed taxa are similar
1000 between May (A, B) and September (C, D). Notably, *Nitrosopumilus* sp. and
1001 Woesearchaeota dominated the middle and deep water column, respectively. The
1002 sulfur-oxidizing SUP05 clade increased continuously with depth in May but decreased in
1003 frequency below 70 m in September, while *Arcobacter* sp. spiked sharply at 80 m in
1004 September. Sampled depths are represented by points on each line.

1005

1006 Figure 4. Phylogenomic analysis of the Woesearchaeotal MAG and ninety publicly
1007 available MAGs from a range of biomes show the AJ population is mostly closely
1008 related to Woesearchaeota from other marine water columns.

1009

1010 Figure 5. Relative abundances of genes involved in sulfur (A) and nitrogen (B)
1011 metabolism in each metagenome (May 60 m, May 106 m, September 60 m, September
1012 95 m) show some dissimilatory genes, such as *dsrAB* and *napAB*, are enriched in the
1013 deep water layer.

1014

1015 **Table Legends**

1016

1017 Table 1. All de-replicated, high-quality metagenome-assembled genomes (MAGs) from
1018 the 60 m and deep co-assemblies, as well as one MAG from the September 95 m
1019 individual assembly. Taxonomy assessed at the whole-genome level and nearest
1020 relative (GTDB) are provided. If applicable, taxonomy according to the associated 16S
1021 rRNA gene (SILVA) is provided with additional higher-order classification in
1022 parentheses. Amplicon frequencies for corresponding SVs are provided for each
1023 sample. One MAG contained two SVs (*, see Table S3) and here the frequencies for
1024 the first SV are provided.

1025

1026 Table 2. Taxonomy and functional annotations identified in each MAG. The biochemical
1027 process associated with each gene is provided by headers in bold.

1028

1029 Table S1. Amberjack Hole water column sample metadata and amplicon sequencing
1030 results. Processed reads are those that were quality-filtered, trimmed, and run through
1031 DADA2.

1032

1033 Table S2. Metagenome assembly data including sample source, pre- and post-quality
1034 filtered reads, and assembly statistics for both single and co-assemblies.

1035

1036 Table S3. Metagenome-assembled genomes (MAGs) and their associated samples,
1037 quality metrics, and assigned taxonomy.

1038
1039 Table S4. Metagenome-assembled genomes (MAGs) assessed in the phylogenomic
1040 trees (Fig. 4, Fig. S4, Fig. S5) including the Amberjack MAG of interest and the source
1041 of all other MAGs included in the phylogeny.

1042

1043 **Conflicts of interest**

1044

1045 The authors declare no conflict of interest.

1046

1047 **Funding**

1048

1049 This work was funded by the National Oceanic and Atmospheric Administration Office of
1050 Exploration and Research (grant #NA18OAR0110291).

1051

1052 **Acknowledgments**

1053

1054 We thank the captains of the *R/V William R. Mote* and *R/V Eugenie Clark* for their
1055 support and professionalism, and staff at Mote Marine Lab for their work in sample
1056 collection and processing. We are grateful to Dr. Navid Constantinou for his help
1057 modeling the wind speeds required for turnover of the water column.

Tree scale: 0.1

A. Sulfur metabolism

B. Nitrogen metabolism

hydB: sulfur reductase
thsC: thiosulfate reductase
ttrB: tetrathionate reductase

amoABC: ammonia monooxygenase

cysC: adenylylsulfate kinase
soxCD sulfane dehydrogenase
msmA: methanesulfonate monooxygenase
dmdABCD: dimethylsulfoniopropionate demethylation
metB: cystathione gamma-synthase
tmoC: toluene monooxygenase system
unknown function

hcp: hydroxylamine reductase
nosZ: nitrous oxide reductase
nrfA: nitrite reductase
GDH2: glutamate dehydrogenase
nirS: nitrite reductase
nrfH: cytochrome c nitrite reductase

nmaA: oligoribonuclease and PAP phosphatase
phsA/psrA: thiosulfate reductase

napAB: nitrate reductase
norC: nitric oxide reductase

aprA: adenylylsulfate reductase
sat: sulfide adenylyltransferase
sqr: sulfide:quinone oxidoreductase

glnA: glutamine synthetase
narK: nitrite/nitrate transporter
narH: nitrate reductase
narJ/narV: nitrate reductase
gltD: glutamate synthase

dsrAB: dissimilatory sulfite reductase
