Abstract (245 words)

Humans differ in their capability to judge the accuracy of their own choices via confidence

judgments. Signal detection theory has been used to quantify the extent to which confidence tracks

accuracy via M-ratio, often referred to as metacognitive efficiency. This measure, however, is static in

that it does not consider the dynamics of decision making. This could be problematic because humans

may shift their level of response caution to alter the tradeoff between speed and accuracy. Such shifts

could induce unaccounted-for sources of variation in the assessment of metacognition. Instead, evidence

accumulation frameworks consider decision making, including the computation of confidence, as a

dynamic process unfolding over time. We draw on evidence accumulation frameworks to examine the

influence of response caution on metacognition. Simulation results demonstrate that response caution has

an influence on M-ratio. We then tested and confirmed that this was also the case in human participants

who were explicitly instructed to either focus on speed or accuracy. We next demonstrated that this

association between M-ratio and response caution was also present in an experiment without any

reference towards speed. The latter finding was replicated in an independent dataset. In contrast, when

data were analyzed with a novel dynamic measure of metacognition, which we refer to as v-ratio, in all of

the three studies there was no effect of speed-accuracy tradeoff. These findings have important

implications for research on metacognition, such as the question about domain-generality, individual

differences in metacognition and its neural correlates.

Introduction

When asked to explicitly report how sure they are about their decisions, humans often claim high confidence for correct and low confidence for incorrect decisions. This capacity to evaluate the accuracy of decisions is often referred to as metacognitive accuracy. Although metacognitive accuracy about perceptual decisions is generally high [1], it varies significantly between participants [2] and between conditions [3]. Such differences in metacognitive accuracy have important real-life consequences, as they relate, for example, to political extremism [4] and psychiatric symptoms [5].

A debated question is how to quantify metacognitive accuracy. One prominent issue why one cannot simply calculate the correlation between confidence and accuracy [6] is that this confounds task accuracy with metacognitive accuracy; i.e. it is much easier to detect one's own mistakes in an easy task than in a hard task. Different solutions have been proposed in the literature, such as using coefficients from a logistic mixed-model [7], type 2 ROC curves [2], and meta-d' [8,9]. Rather than providing an in-depth discussion and comparison of these different measures, we here focus on one of these static approaches, namely the meta-d' framework, the state-of-the-art measure of metacognitive accuracy [10]. The meta-d' approach is embedded within signal detection theory, and quantifies the accuracy with which confidence ratings discriminate between correct and incorrect responses (*meta-d'*) while controlling for first-order task performance (d'). Because both measures are on the same scale, one can calculate the ratio between both, meta-d'/d', also called M-ratio, often referred to as metacognitive *efficiency*. When M-ratio is 1, all available first-order information is used in the (second-order) confidence judgment. When M-ratio is smaller than 1, metacognitive sensitivity is suboptimal, meaning that not all available information from the first-order response is used in the metacognitive judgment (Fleming & Lau, 2014). This measure has been used to address a variety of issues, such as whether metacognition is a domain-general capacity [3,11,12], the neural correlates of metacognition [13–16], how bilinguals differ from monolinguals [17], and how individual differences in metacognitive accuracy correlate with various constructs [4,5].

An important limitation is that the meta-d' framework (just like the other static approaches cited above), does not consider dynamic aspects of decision making. Put simply, this measure depends on end-of-trial confidence and accuracy, but not on the response process governing the choice and its resulting reaction time. It is well known, however, that choice accuracy depends on response caution; i.e. accuracy decreases when instructing participants to be fast rather than to be correct. The fact that static approaches of metacognition do not consider response caution is problematic because it confounds ability with caution: when focusing on speed rather than accuracy, one will produce many errors due to premature responding, and those errors are much easier to detect compared to errors resulting from low signal

quality [18]. Importantly, detecting "premature" errors does not imply "good metacognition" per se, but

instead simply depends on one's level of response caution.

To account for dynamic influences on metacognition, we propose to instead quantify

metacognitive accuracy in a dynamic probabilistic framework [19,20]. Sequential sampling models explain

human decision making as a dynamic process of evidence accumulation [21–23]. Specifically, decisions are

conceptualized as resulting from the accumulation of noisy evidence towards one of two decision

boundaries. The first boundary that is reached, triggers its associated decision. The height of the decision

boundary controls the response caution with which a decision is taken [24,25]. When lowering the boundary,

decisions will be faster but less accurate; when increasing the boundary, decisions will be slower but

more accurate. The prototypical dynamic sampling model is the drift diffusion model (DDM). In this

model, confidence can be quantified as the probability of being correct, given evidence, decision time,

and the decision that was made [26–28]. The relation between these three variables is represented by the heat

map in Figure 1A. It captures the typical finding that trials with strong evidence are more likely to be

correct than trials with weak evidence; and that trials with short RTs are more likely to be correct than

trials with long RTs. As mentioned, the process of evidence accumulation terminates at the first boundary

crossing. Formally, at that time the probability that the choice was correct can be quantified as

$p(correct|e_t, t, X)$, where e_t is the level of evidence at time t, t is the timing of boundary crossing and X is

the choice made [26,28,29]. In typical experiments, however, confidence judgments are provided separately in

time (at time $t + s$, i.e., in a separate judgment after the choice), allowing evidence to further accumulate

after boundary crossing. As a consequence, confidence should then be quantified as $p(correct|e_{t+s}, t+s, X)$,

[19,20,30].

Within this formulation, good metacognitive accuracy can be considered as the ability to

distinguish corrects versus errors based on $p(correct|e_{t+s}, t+s, X)$. Critically, the difference in the quantity

$p(correct|e_{t+s}, t+s, X)$ for corrects versus errors, directly depends on the strength of post-decision

accumulation. Thus, we can use post-decision drift rate as a dynamic measure of metacognitive accuracy.

For comparison with the M-ratio framework, we quantified v-ratio as the ratio between post-decision drift

rate and drift rate. Figure 1B shows post-decision accumulation for three scenarios with varying levels of

v-ratio. As can be seen, if v-ratio is zero (left panel), additional evidence meanders adrift for both corrects

and errors, and the model does not detect its own errors, i.e., representing a case of poor metacognitive

accuracy. If however, v-ratio equals 1 (i.e., post-decision drift rate and drift rate are the same), additional

evidence confirms most of the correct choices (i.e., leading to high confidence) and disconfirms most of

the error choices (i.e., leading to low confidence), i.e., representing good metacognitive accuracy. We

thus propose that v-ratio can be used as a dynamic measure of metacognitive accuracy. In the following,

we will shed light on the role of variation in response caution on both M-ratio and v-ratio.

Figure 1. Quantifying metacognitive accuracy within an evidence accumulation framework. A.

Noisy sensory evidence accumulates over time, until the integrated evidence reaches one of two decision

boundaries (a or 0). After the decision boundary is reached, evidence continues to accumulate. The heat

map shows the probability of being correct conditional on time, evidence, and the choice made (the

choice corresponding to the upper boundary, in this example). Confidence is quantified as just this

probability. B. Histograms of model-predicted confidence for different levels of v-ratio (reflecting the

ratio between post-decision drift rate and drift rate). Higher levels of v-ratio are associated with better

dissociating corrects from errors. C. Simulations from this dynamic evidence accumulation model show

that M-ratio captures variation in v-ratio (r = .58; left panel), and critically, that M-ratio is also related

to the differences in decision boundary (r = -.52; middle panel). By design, decision boundary and v-ratio

are unrelated to each other (r ~ 0; right panel).

115   **Results**

Model simulations reveal a link between response caution and M-ratio

We simulated data from a drift diffusion model with additional post-decisional evidence

accumulation (see Figure 1A). Decision confidence was quantified as the probability of being correct

given evidence, time and choice [26,30,31]. We simulated data for 100 agents with 500 observations each; for

each agent, a different random value was selected for drift rate, non-decision time, decision boundary and

post-decision drift rate (see Methods). We then used these data to compute M-ratio. As explained before,

v-ratio was computed as the ratio between post-decision drift rate and drift rate. The results of our

simulation study showed that, first, there was a clear positive relation between M-ratio and v-ratio, $r(98)$

$= .58$, $p < .001$, reflecting that M-ratio captures individual variation in metacognition (Figure 1C, left

panel). However, we also observed a strongly negative relation between M-ratio and decision boundary,

$r(98) = -.52$, $p < .001$ (Figure 1C, central panel). This shows that M-ratio is highly dependent on the

speed-accuracy tradeoff that one adopts. This occurs because lowering the decision boundary increases

the probability of "fast errors" (i.e. due to noise), which are very likely to generate conflicting evidence in

the post-decisional period (i.e. to be detected as an error). Finally, by design there was no relation

between v-ratio and decision boundary, $r(98) = .006$, $p = .95$ (Figure 1C, right panel). The full correlation

matrix is shown in Table 1.

Experiment 1: Explicit speed-accuracy instructions affect static but not dynamic measures

of confidence

Next, we tested these model predictions in an experiment with human participants. We recruited

36 human participants who performed a task that has been widely used in the study of evidence

accumulation models: discrimination of the net motion direction in dynamic random dot displays [21].

Participants were asked to decide whether a subset of dots was moving coherently towards the left or the

right side of the screen (See Figure 2A). The percentage of dots that coherently moved towards the left or

right side of the screen (controlling decision difficulty) was held constant throughout the experiment at

20%. After their choice, and a blank screen, participants indicated their level of confidence using a

continuous slider. Critically, in each block, participants either received the instruction to focus on

accuracy ("try to decide as accurate as possible"), or to focus on speed ("try to decide as fast as

possible"). Consistent with the instructions, participants were faster in the speed condition than in the

accuracy condition, $M_{speed} = 727$ms versus $M_{accuracy} = 1014$ms, $t(35) = 4.47$, $p < .001$, and numerically

more accurate in the accuracy condition than in the speed condition, $M_{accurate} = 75.6\%$ vs $M_{speed} = 73.8\%$,

$t(35) = 1.63$, $p = .111$. Participants were also more confident in the accuracy condition than in the speed

condition, $M_{accuracy} = 70$ versus $M_{speed} = 67$, $t(35) = 3.57$, $p = .001$ (See Figure 2D).

Figure 2. The influence of speed-accuracy instructions on metacognitive accuracy

*(**Experiment 1**). **A.** Sequence of events in the experimental task. Participants decided whether the*

majority of dots were moving left or right, by pressing "E" or "T" with their left hand. After a short

blank, they then indicated their level of confidence on a continuous scale. Depending on the block,

*instructions during the ITI were either to focus on accuracy or to focus on speed. **B.** Fitted parameters of*

a drift diffusion model with additional post-decision accumulation. Fitted decision boundaries were lower

in the speed vs accuracy condition, whereas drift rates did not differ. Critically, M-ratio was higher in the

*speed vs accuracy condition whereas v-ratio did not differ between both instruction conditions. **C.***

Distribution of reaction times and confidence for empirical data (bars) and model fits (lines), separately

*for corrects (green) and errors (red). **D**. Participants were faster, less accurate and less confident when*

instructed to focus on speed rather than on accuracy. Note: grey lines show individual data points; black

lines show averages; green dots show model fits; error bars reflect SEM; ***p<.001, **p<.01, *p<.05.

To shed further light on the underlying cognitive processes, we fitted these data using the

evidence accumulation model described in Figure 1A. The basic architecture of our model was a DDM, in

which noisy perceptual evidence accumulates over time until a decision boundary is reached. Afterwards,

evidence continued to accumulate for a specified amount of time [19]. In addition to drift rate, decision

boundary and non-decision time, our model featured a free parameter controlling the strength of the post-

decision evidence accumulation (v-ratio, reflecting the ratio between post-decision drift rate and drift rate)

and two further parameters controlling the mapping from $p(correct)$ onto the confidence scale (see

Methods). Generally, our model fitted the data well, as it captured the distributional properties of both

reaction times and decision confidence (see Figure 2C). As a first sanity check, we confirmed that

decision boundaries were indeed different between the two instruction conditions, $M_{speed} = 1.40$ versus

$M_{accuracy} = 1.77$, $t(35) = 4.60$, $p < .001$, suggesting that participants changed their decision boundaries as

instructed. Also non-decision time tended to be a bit shorter in the speed condition compared to the

accuracy condition, $M_{speed} = 309$ms versus $M_{accuracy} = 390$ms, $t(35) = 3.19$, $p = .003$. Drift rates did not

differ between both instruction conditions, $p = .368$. There was a small but significant difference between

the two instruction conditions in the two additional parameters controlling the idiosyncratic mapping

between $p(correct)$ and the confidence scale, reflecting that in the accuracy condition confidence

judgments were slightly higher, $t(35) = 2.506$, $p = .017$, and less variable, $t(35) = 2.206$, $p = .034$,

compared to the speed condition.

We next focused on metacognitive accuracy in both conditions (see Figure 2B). In line with the

model simulations, our data showed that M-ratio was significantly affected by the speed-accuracy tradeoff

instructions, $M_{speed} = 0.84$ versus $M_{accuracy} = 0.66$, $t(35) = 2.26$, $p = .030$. Moreover, apart from these

between-condition differences we also observed significant correlations between M-ratio and decision

boundary both in the accuracy condition, $r(34) = -.36$, $p = .030$, and in the speed condition, $r(34) = -.53$, p

$< .001$.Consistent with the notion that metacognitive accuracy should not be affected by differences in

decision boundary, v-ratio did not differ between both instruction conditions, $p = .938$.

Experiment 2: Spontaneous differences in response caution relate to static but not dynamic

measures of metacognitive accuracy

Although Experiment 1 provides direct evidence that changes in decision boundary affect M-
ratio, it remains unclear to what extent this is also an issue in experiments without speed stress. Notably,
in many metacognition experiments, participants do not receive the instruction to respond as fast as
possible. Nevertheless, it remains possible that participants implicitly decide on a certain level of response
caution. For example, a participant who is eager to finish the experiment quickly might adopt a lower
decision boundary compared to a participant who is determined to perform the experiment as accurate as
possible, thus leading to a natural across-subject variation in decision boundaries. To examine this
possibility, in Experiment 2 we analyzed data from an experiment in which participants (N = 63) did not
receive any specific instructions concerning speed or accuracy. Participants decided which of two boxes
contained more dots, and afterwards indicated their level of confidence on a continuous scale (see Figure
3A). The same evidence accumulation model as before was used to fit these data, and again this model
captured both reaction times and decision confidence distributions (Figure 3B). Consistent with our
model simulations, model fits showed a positive correlation between M-ratio and v-ratio, $r(61) = .21$, $p = $
.092, although this correlation was not statistically significant (Figure 3C). However, we again observed
that M-ratio correlated negatively with the fitted decision boundary, $r(61) = -.34$, $p = .006$, whereas v-
ratio did not, $r(61) = -.19$, $p = .129$.

Figure 3. The influence of spontaneous variations in speed-accuracy tradeoff on metacognitive
*accuracy. **A.** Sequence of events in Experiment 2. On each trial participants decided which of the two*
circles contained more dots. Afterwards, they indicated their level of confidence on a continuous scale.
*Note that participants did not receive any instructions concerning speed or accuracy. **B.** Distribution of*
*reaction times and confidence for Experiment 2, using the same conventions as in Figure 2. **C.** The data*
of Experiment 2 showed a non-significant positive relation between M-ratio and v-ratio (r=.21).
Critically, only M-ratio correlated negatively with decision boundary (r=-.34) whereas this relation was
*not significant for v-ratio (r= -.19). **D.** Sequence of events in Experiment 3. On each trial, participants*
decided in which temporal interval (first or second) one of the Gabor patches had a higher contrast. After
*this choice, participants indicated confidence on a continuous scale. **E.** Distribution of reaction times and*
*confidence for Experiment 3, using the same conventions as in Figure 2. **F.** The data of Experiment 3*

showed a significant positive relation between M-ratio and v-ratio (r=.38) and a significant negative

correlation between M-ratio and decision boundary (r=-.18) but not between v-ratio and decision

boundary (r= -.04).

Experiment 3: Replication in an independent dataset

To assess the robustness of our findings, in Experiment 3 we aimed to replicate our analysis in an

independent dataset with high experimental power. To achieve this, we searched the confidence database

[32] for studies with high power (N > 100) in which a 2CRT task was performed with separate confidence

ratings given on a continuous scale. Moreover, because our fitting procedure was not designed for

multiple levels of difficulty, we focused on studies with a single difficulty level. We identified one study

that satisfied all these constraint (Figure 3D; Prieto, Reyes & Silva, *under review*). Their task was highly

similar to the one reported above, but their high experimental power (N=204) assured a very sensitive

analysis of our claims. Consistent with the previous analysis, model fits on this independent dataset

showed a positive and statistically significant correlation between M-ratio and v-ratio, $r(202) = .38$, $p <$

.001, suggesting that both variables capture shared variance reflecting metacognitive accuracy (see Figure

3F). We again observed that M-ratio correlated negatively with the fitted decision boundary, $r(202) = -$

$.18$, $p = .009$, whereas no relation with decision bound was found for v-ratio, $r(202) = .04$, $p = .535$.

Discussion

Metacognitive accuracy is a quickly emerging field in recent years. Crucial to its study is a
method to objectively quantify the extent to which participants are able to detect their own mistakes,
regardless of decision strategy. We here report that a commonly used *static* measure of metacognitive
accuracy (M-ratio) highly depends on the decision boundary – reflecting decision strategy – that is set for
decision making. This was the case in simulation results, in an experiment explicitly manipulating the
tradeoff between speed and accuracy, and in two datasets in which participants received no instructions
concerning speed or accuracy. We propose an alternative, *dynamic,* measure of metacognitive accuracy
(v-ratio) that does not depend on decision boundary.

Caution is warranted with static measures of metacognition
The most important consequence of the current findings is that researchers should be cautious
when interpreting static measures of metacognitive accuracy, such as M-ratio. In the following, we will
discuss several examples where our finding might have important implications. In the last decade there
has been quite some work investigating to what extent the metacognitive evaluation of choices is a
domain-general process or not. These studies often require participants to perform different kinds of tasks,
and then examine correlations in accuracy and in metacognitive accuracy between these tasks [3,11–14,33]. For
example, Mazancieux and colleagues [11] asked participants to perform an episodic memory task, a
semantic memory task, a visual perception task and a working memory task. In each task, participants
rated their level of confidence after a decision. The results showed that whereas correlations between
accuracy on these different tasks were limited, there was substantial covariance in metacognitive accuracy
across these domains. Because in this study participants received no time limit to respond, it remains
unclear whether this finding can be interpreted as evidence for a domain-general metacognitive monitor,
or instead a domain-general response caution which caused these measures to correlate. Another popular
area of investigation has been to unravel the neural signatures supporting metacognitive accuracy [13,14,34–
36]. For example, McCurdy et al. observed that both visual and memory metacognitive accuracy correlated
with precuneus volume, potentially pointing towards a role of precuneus in both types of metacognition.
It remains unclear, however, to what extent differences in response caution might be responsible for this
association. Although differences in response caution are usually found to be related to pre-SMA and
anterior cingulate [24,25], there is some suggestive evidence linking precuneus to response caution [37].
Therefore, it is important that future studies on neural correlates of metacognition rule out the possibility
that their findings are caused by response caution. Finally, our study has important consequences for
investigations into differences in metacognitive accuracy between specific, e.g. clinical, groups. For
example, Folke and colleagues [17] reported that M-ratio was reduced in a group of bilinguals compared to

a matched group of monolinguals. Interestingly, they also observed that on average bilinguals had shorter

reaction times than monolinguals, but this effect was unrelated to the group difference in M-ratio.

Because these authors did not formally model their data using evidence accumulation models, however, it

remains unclear whether this RT difference results from a difference in boundary, and if so to what extent

this explains the difference in M-ratio between both groups that was observed. In a similar vein,

individual differences in M-ratio have been linked to psychiatric symptom dimensions, and more

specifically to a symptom dimension related to depression and anxiety [5]. At the same time, it is also

known that individual differences in response caution are related to a personality trait known as *need for*

closure [38]. Given that need for closure is, in turn, related to anxiety and depression [39], it remains a

possibility that M-ratio is only indirectly related to these psychiatric symptoms via response caution.

The potential of dynamic measures of metacognition

In order to control for potential influences of response caution on measures of metacognitive

accuracy, one approach could be to estimate the decision boundary and examine whether the relation

between metacognitive accuracy and the variable of interest remains when controlling for decision

boundary (e.g., using mediation analysis). However, a more direct approach would be to estimate

metacognitive accuracy in a dynamic framework, thus taking into account differences in response caution.

In the current work, we proposed v-ratio (reflecting the ratio between post-decision drift rate and drift

rate) as such a dynamic measure of metacognitive accuracy (following the observation that post-decision

drift rate indexes how accurate confidence judgments are[19,20]). In both simulations and empirical data, we

observed a positive relation between v-ratio and M-ratio, suggesting they capture shared variance.

Critically, v-ratio was not correlated with decision boundary, suggesting it is not affected by differences

in response caution. Thus, our dynamic measure of metacognition holds promise as a novel approach to

quantify metacognitive accuracy while taking into account the dynamics of decision making.

In our approach we allowed the drift rate and the post-decision drift rate to dissociate. This

proposal is in line with the view of metacognition as a second-order process whereby dissociations

between confidence and accuracy might arise because of noise or bias at each level [40–42]. However, when

formulating post-decision drift rate as a continuation of evidence accumulation, it remains underspecified

which evidence the post-decision accumulation process is exactly based on. It has been suggested that

participants can accumulate evidence that was still in the processing pipeline (e.g. in a sensory buffer)

even after a choice was made [30,43]. However, it is not very likely that this is the only explanation,

particularly in tasks without much speed stress. One other likely possibility, is that during the post-

decision process, participants resample the stimulus from short-term memory [44]. Because memory is

subject to decay, dissociations between the post-decision drift rate and the drift rate can arise. Other

sources of discrepancy might be contradictory information quickly dissipating from memory [45] which

should lower metacognitive accuracy, or better assessment of encoding strength with more time [46] which

should increase metacognitive accuracy.

To sum up, we provided evidence from simulations and empirical data that a common static

measure of metacognition, M-ratio, is confounded with response caution. We proposed an alternative

measure of metacognition based on a dynamic framework, v-ratio, which is insensitive to variations in

caution, and may thus be suitable to study how metacognitive accuracy varies across subjects and

conditions.

 Methods

          Computational model

     Simulations

          Data were simulated for 100 observers with 500 trials each. For each simulated observer, we

     randomly selected a value for the drift rate (uniform distribution between 0 and 2.5), for the decision

     boundary (uniform distribution between .5 and 3), for the non-decision time (uniform distribution

     between .2 and .6) and for the v-ratio (uniform distribution between 0 and 1.5; see below for details). To

     estimate meta-*d'*, data is needed for both of the possible stimuli (i.e., to estimate bias); therefore, for half

     of the trials we multiplied the drift rate by -1. Finally, we fixed the values for starting point ($z = .5$),

     within-trial noise ($\sigma = 1$) and post-decision processing time (1s).

     Fitting procedure

          We coded an extension of the drift diffusion model (DDM) that simultaneously fitted choices,

     reaction times and decision confidence. The standard DDM is a popular variant of sequential sampling

     models of two-choice tasks. We used a random walk approximation, coded in the rcpp R package to

     increase speed [47], in which we assumed that noisy sensory evidence started at *z*a*; 0 and a are the lower

     and upper boundaries, respectively, and *z* quantifies bias in the starting point ($z = .5$ means no bias). At

     each time interval τ a displacement Δ in the integrated evidence occurred according to the formula shown

     in equation (1):

$$\Delta = v * \tau + \sigma * \sqrt{\tau} * \mathcal{N}(0,1) \tag{1}$$

          Evidence accumulation strength is controlled by *v*, representing the drift rate, and within-trial

     variability, σ, was fixed to 1. The random walk process continued until the accumulated evidence crossed

     either 0 or *a*. After boundary crossing, the evidence continued to accumulate for a duration depending on

     the participant-specific median confidence reaction time. Importantly, consistent with the signal detection

     theoretical notion that primary and secondary evidence can dissociate, we allowed for dissociations

     between the drift rate governing the choice and the post-decision drift rate. For compatibility with the M-

     ratio framework, we quantified metacognitive accuracy as the ratio between post-decision drift rate and

     drift rate, as shown in equation (2):

$$v\text{-}ratio = \frac{post-decision\ drift\ rate}{drift\ rate} \tag{2}$$

          As a consequence, when v-ratio = 1, this implies that post-decision drift and drift are the same.

     When v-ratio = .5, the magnitude of the post-decision drift rate is half the magnitude of the drift rate. To

calculate decision confidence, we first quantified for each trial the probability of being correct given

evidence, time, and choice. The heat map representing $p(correct|e, t, X)$ is shown in Figure 1A, and was

constructed by means of 300.000 random walks without absorbing bounds, with drift rates sampled from

a uniform distribution between zero and ten. This assured sufficient data points across the relevant part of

the heat map. Subsequently, the average accuracy was calculated for each (response time, evidence,

choice) combination, based on all trials that had a data point for that (response time, evidence, choice)

combination. Smoothing was achieved by aggregating over evidence windows of .01 and τ windows of 3.

Next, to take into account idiosyncratic mappings of $p(correct|e, t, X)$ onto the confidence scale used in

the experiment, we added two extra free parameters that controlled the mean (M) and the width (SD) of

confidence estimates, as shown in equation (3):

$$confidence = \frac{p(correct|e_{t+s}, t + s, X) + M}{SD} \qquad (3)$$

Although empirical confidence distributions appeared approximately normally distributed, there

was an over-representation of confidence values at the boundaries (1 and 100 in Experiment 1; 1 and 6 in

Experiments 2 and 3) and in the middle of the scale (50 in Experiment 1, 3.5 in Experiment 2). Most

likely, this resulted from the use of verbal labels placed at exactly these values. To account for frequency

peaks at the endpoints of the scale, we relabeled predicted confidence values that exceeded the endpoints

of the scale as the corresponding endpoint (e.g., in Experiment 1 a predicted confidence value of 120 was

relabeled as 100), which naturally accounted for the frequency peaks at the endpoints. To account for

peaks in the center of the scale, we assumed that confidence ratings around the center were pulled towards

the center value. Specifically, we relabeled *P*% of trials around the midpoint as the midpoint (e.g., in

Experiment 1, *P* = 10% implies that 10% of the data closest to 50 were (re)labeled as 50). Note that *P* was

not a free parameter, but instead its value was taken to be the participant-specific proportion based on the

empirical data. Note that the main conclusions reported in this manuscript concerning the relation

between M-ratio, decision boundary and post-decision drift rate, remain the same in a reduced model

without *P*, and also in a reduced model without *P*, *M* and *SD*. Because these reduced models did not

capture confidence distributions very well though, we here report only the findings of the full model.

To estimate these 6 parameters (*v, a, Ter, v-ratio, M, and SD*) based on choices, reaction times

and decision confidence, we implemented quantile optimization. Specifically, we computed the

proportion of trials in quantiles .1, .3, .5, .7, and .9, for both reaction times and confidence; separately for

corrects and errors (maintaining the probability mass of corrects and errors, respectively). We then used

differential evolution optimization, as implemented in the DEoptim R package [48], to estimate these 6

parameters by minimizing the chi square error function shown in equation (4):

$$x^2 = \sum \frac{(oRT_i - pRT_i)^2}{pRT_i} + \sum \frac{(oCJ_i - pCJ_i)^2}{pCJ_i}$$

(4)

371   with oRT$_i$ and pRT$_i$ corresponding to the proportion of observed/predicted responses in quantile i,

372   separately calculated for corrects and errors both reaction times, and oCJ$_i$ and pCJ$_i$ reflecting their

373   counterparts for confidence judgments. We set τ to 1e-2. Model fitting was done separately for each

374   participant. Note that in Experiment 3 there was no clear peak in the middle of the scale so P was fixed to

375   0 in that experiment.

Parameter recovery

To assure that our model was able to recover the parameters, we here report parameter recovery.

In order to assess parameter recovery with a sensible set of parameter combinations, we used the fitted

parameters of Experiment 1 (N = 36), simulated data from these parameters with a varying number of

trials, and then tested whether our model could recover these initial parameters. As a sanity check, we

first simulated a large number of trials (25000 trials per participant), which as expected provided excellent

recovery for all six parameters, rs > .97. We then repeated this process with only 200 trials per

participants, which was the trial count in Experiment 2 (note that Experiment 1 and 3 both had higher trial

counts). Recovery for v-ratio was still very good, r = .85, whereas it remained excellent for all other

parameters, rs > .98.

Experiment 1

Participants

Forty healthy participants (18 males) took part in Experiment 1 in return for course credit (mean

age = 19.82, between 18 and 30). All reported normal or corrected-to-normal vision. Two participants

were excluded because they required more than 10 practice blocks in one of the training blocks (see

below) and two participants were excluded because their accuracy, averaged per block and then compared

against chance level using a one-sample t-test, was not significantly above chance level. The final sample

thus comprised thirty-six participants. All participants provided their informed consent and all procedures

adhered to the general ethical protocol of the ethics committee of the Faculty of Psychology and

Educational Sciences of Ghent University.

Stimuli and apparatus

The data for Experiment 1 were collected in an online study, due to COVID-19. Participants were

allowed to take part in the experiment only when they made us of an external mouse. Choices were

provided with the keyboard, and decision confidence was indicated with the mouse. Stimuli in

Experiment 1 consisted of 50 randomly moving white dots (radius: 2 pixels) drawn in a circular aperture

on a black background centered on the fixation point. Dots disappeared and reappeared every 5 frames.

The speed of dot movement (number of pixel lengths the dot will move in each frame) was a function of

the screen resolution (screen width in pixels / 650).

Task procedure

Each trial started with the presentation of a fixation cross for 1000 ms. Above and below this

fixation cross specific instructions were provided concerning the required strategy. In accuracy blocks the

instruction was to respond as accurately as possible; in speed blocks the instruction was to respond as fast

as possible. The order of this block-wise manipulation was counterbalanced across participants. Next,

randomly moving dots were shown on the screen until a response was made or the response deadline was

reached (max 5000 ms). On each trial, 20% of the dots coherently moved towards the left or the right side

of the screen, with an equal number of leftward and rightward movement trials in each block. Participants

were instructed to decide whether the majority of dots was moving towards the left or the right side of the

screen, by pressing "E" or "T", respectively, with their left hand. After their response, a blank screen was

shown for 500 ms, followed by the presentation of a continuous confidence scale. Below the scale the

labels "Sure error", "guess", and "sure correct" were shown, arranged outer left, centrally and outer right,

respectively. After clicking the confidence scale, participants had to click a centrally presented

"Continue" button (below the confidence scale) that ensured that the position of the mouse was central

and the same on each trial.

The main part of Experiment 1 consisted of 10 blocks of 60 trials, half of which were from the

accuracy instruction condition and half from the speed instruction condition. The experiment started with

24 practice trials during which participants only discriminated random dot motion at 50% coherence, no

confidence judgments were asked. This block was repeated until participants achieved 85% accuracy

(mean = 2 blocks). Next, participants completed again 24 practice trials with the only difference that now

the coherence was decreased to 20% (mean = 1.05 blocks). When participants achieved 60% accuracy,

they then performed a final training block of 24 trials during which they practiced both dot discrimination

and indicated their level of confidence (mean = 1.05 blocks).

Experiment 2

Full experimental details are described in Drescher et al. [49]. On each trial participants were

presented with two white circles (5.1° diameter) on a black background, horizontally next to each other

with a distance of 17.8° between the midpoints. Fixation crosses were shown for 1s in each circle,

followed by dots clouds in each circle for 700ms. The dots had a diameter of 0.4°. Dot positions in the

boxes, as well as the position of the box containing more dots were randomly selected on each trial.

Participants indicated which circle contained more dots by pressing "S" or "L" on a keyboard. Then, the

question "correct or false?" appeared on the screen, with a continuous confidence rating bar, with the

labels "Sure false", "No idea", and "Sure correct". Participants moved a cursor with the same keys as

before, and confirmed their confidence judgment with the enter key. No time limit was imposed for both

primary choice and confidence rating. Subjects received several practice trials (10 without confidence

rating, 14 with confidence rating), before they completed eight experimental blocks of 25 trials.

Experiment 3

Data from this experiment were taken from the confidence database [50], a collection of openly

available studies on decision confidence. In this experiment, Prieto, Reyes and Silva (unpublished paper),

used the same task as described in Fleming and colleagues [2]. Each participant (N=204 woman, aged 18-

35) completed 50 practice trials, followed by 5 blocks of 200 trials.

Data and code availability

All data and analysis code have been deposited online and can be freely accessed (insert link

upon publication).

Acknowledgments

The authors like to thank Peter R Murphy, Bharath Chandra Talluri, and Annika Boldt for

insightful discussions and Pierre Le Denmat, Robin Vloeberghs and Alan Voodla for comments on an

earlier draft. This research was supported by an FWO [PEGASUS]² Marie Skłodowska-Curie fellowship

(12T9717N, to K.D.) and a starting grant from the KU Leuven (STG/20/006, to K.D.). L.V. was

supported by the FWO (11H5619N)
