Abstract

Recent experiments and theories of human decision-making suggest positive and negative errors are processed and encoded differently by serotonin and dopamine, with serotonin possibly serving to oppose dopamine and protect against risky decisions. We introduce a temporal difference (TD) model of human decision-making to account for these features. Our model involves two opposing counsels, an optimistic learning system and a pessimistic learning system, whose predictions are integrated in time to control how potential decisions compete to be selected. Our model predicts that human decision-making can be decomposed along two dimensions: the degree to which the individual is sensitive to (1) risk and (2) uncertainty. In addition, we demonstrate that the model can learn about reward expectations and uncertainty, and provide information about reaction time despite not modeling these variables directly. Lastly, we simulate a recent experiment to show how updates of the two learning systems could relate to dopamine and serotonin transients, thereby providing a mathematical formalism to serotonin's hypothesized role as an opponent to dopamine. This new model should be useful for future experiments on human decision-making.

Author summary

Computational models have helped researchers understand how humans make decisions. Errors in model-derived predictions have long been known to relate to dopamine, but recent experiments support adding nuance to how prediction errors are modeled. In particular, prediction errors appear to be multidimensional and related to serotonin and dopamine in nonlinear ways. Accordingly, we introduce a simple model of decision-making to capture these features and explore the implications of such a model. This model should provide a conceptual framework for interpreting behavioral and neural data from decision-making experiments.

Introduction

Temporal difference (TD) learning has enjoyed tremendous support as a conceptual framework for understanding how people make decisions and what might be computed in the brain. TD learning is also supported by studies suggesting that prediction errors derived from a TD model are encoded in dopamine transients [1–5]. Recent theories and experiments, however, suggest that TD models can oversimplify human decision-making in meaningful ways [6–9]. In particular, models that are sensitive to risk or track multiple errors are better able to predict what decisions a person selects [10-17], yet the brain structures involved are not completely known. Similarly, a single-neurotransmitter based circuit, where positive concentrations match prediction-error, would struggle to encode large negative updates [17], and indeed, recent evidence suggests that serotonin may play a complementary role [6,7,18-22]. Our goal was to develop and analyze a 10 simple computational model that resolves and unites these observations. Our proposed model involves 11 opposing counsels, composed of an optimistic dopamine-like TD learner and a pessimistic serotonin-like TD 12 learner, who compete in time to determine decisions. 13

TD learning was designed to utilize simple mathematical updates to produce a system that learns how to make decisions [23]. Such models decompose decision-making into two processes: a learning process, which updates how one values a decision, and a decision process, which selects decisions according to how they are valued. These models, including the model of Rescorla and Wagner [24], can learn about reward expectations through updates that are linear in a single prediction error, but are not sensitive to risk or track multidimensional errors.

One reason to expect risk-sensitivity is there is asymmetry in how negative versus positive errors are ²⁰ updated. Dopamine transients, for example, have been found to respond more greatly to positive prediction ²¹

errors than negative prediction errors [25]. From a biological perspective, this is not surprising. Dopamine neurons have low baseline activity, which imposes a physical limit on how much their firing rates can decrease because firing rates are non-negative [26]. This limit suggests that dopamine neuron firing rates rates are non-negative prediction errors to the same degree as they can be increased to encode negative prediction errors to the same degree as they can be increased to encode positive prediction errors. If this is true, then the outsized influence of positive prediction errors would inflate the valuation of decisions — colloquially referred to as "wearing rose-colored glasses." 27

Computational models capture risk-sensitivity by weighing positive prediction errors differently than 28 negative prediction errors, usually accomplished with separate learning rates for positive and negative 29 prediction errors. These models are referred to as *risk-sensitive*, because they result in decision-making that 30 is sensitive to large gains (i.e. *risk-seeking*) or large losses (i.e. *risk-averse*). Taken to an extreme, 31 risk-seeking involves pursuing best possible outcomes, whereas risk-aversion involves avoiding worse possible 32 outcomes [27]. For comparison, traditional TD learning is considered *risk-neutral* because it focuses on 33 maximizing average (long-term discounted) rewards, so that all rewards, regardless of size, are weighted equally. Risk-sensitive models are frequently found to fit data better than risk-neutral models [15–17]. 35 Importantly, differences in risk-sensitivity, substantiated by a risk-sensitive learning model, is thought to underlie certain differences between individuals with and without psychiatric disorders [28, 29]. 37

The multidimensional aspect of TD-based human decision-making is supported by recent studies. One 38 theory is that serotonin also encodes prediction errors but acts as an opponent to dopamine [6,7]. In Moran 30 et al, for example, serotonin transients were found to respond to prediction errors in an opposite direction of 40 dopamine transients [7]. Their results were consistent with the hypothesis that serotonin protects against 41 losses during decision-making [7] or more broadly, plays a role in avoidance behavior [21, 30, 31]. Other 42 conceptual frameworks suggest individuals keep track of multiple prediction errors as a way to capture 43 reward uncertainty in addition to expected rewards [10–14]. Furthermore, a recent study even suggests 44 dopamine is capable of capturing a distribution of prediction errors, the computational benefit of which is 45 that the reward distribution can be learned rather than just its average and variance [9]. 46

In this paper, we introduce and analyze a new model of human decision-making, which we call the Opposing-Counsels model, which uses asymmetrical and multidimensional prediction errors. Based on a TD learning framework, the model decomposes decision-making into learning and decision processes. The learning process involves two opposing counsels, one optimistic and another pessimistic. The decision process integrates predictions from each system in time as decisions compete for selection. In what follows, we explore through simulation whether our model can capture ranges of risk-sensitive behavior from risk-averse to risk-seeking and can reflect reward mean and variance. Further, we use this model to make predictions

about reaction times and about uncertainty-sensitivity in terms of the degree to which reward uncertainty influences a person's consideration of multiple decisions. Lastly, we show how prediction errors in the Opposing-Counsels model might relate to dopamine and serotonin transients in the experiments of Kishida *et* al [8] and Moran *et al* [7]. Considering the simplicity of this model and its ability to synthesize several theories and experimental findings, this model should be useful as a framework for future human decision-making experiments, with potential to provide both predictive power and mechanistic insight.

Modeling

We introduce a model of human decision-making that relies on two opposing learning systems. Figure 1 61 provides a high-level view of the proposed model in a simple example in which an individual makes decisions 62 between two choices. Here the individual learns to value their decision by weighing prior outcomes observed 63 upon selecting each choice, denoted by R_t , in two different systems. The first learning system weighs better outcomes more heavily than worse outcomes, which effectively leads to a more optimistic valuation of 65 outcomes, denoted by Q^+ . The second learning system does the opposite: weighs worse outcomes more 66 heavily than better outcomes, leading to a more pessimistic valuation of outcomes, denoted by Q^{-} . We 67 remark that both values, Q^+ and Q^- , are assumed to be updated according to prediction errors δ_t^+ and δ_t^- , 68 following common risk-sensitive temporal difference (TD) learning frameworks described below. 69

An individual who relied solely on the first learning system to make decisions would be considered 70 risk-seeking due to the outsized influence of better outcomes. Similarly, an individual who relied solely on the 71 second system to guide decisions would be considered *risk-averse* due to the outsized influence of worse 72 outcomes. Our model, however, supposes both of these opposing learning systems contribute to 73 decision-making in the following way. For each choice, the risk-seeking learning system sends a go signal to 74 the individual to signify that this choice is viable, with larger Q^+ values corresponding to earlier signals. 75 Afterwards, the risk-sensitive learning system sends a *no-qo* signal to the individual to signify that this 76 choice is no longer viable, with small Q^- associated with later signals. For simplicity, the individual is 77 assumed to select the respective choice at any time between these two signals, provided no other choice has 78 been selected or choice exploration has been pursued. Hence, both go and no-go signals determines how 79 likely each choice is selected. For example, choices whose go signal is initiated after a no-go signal of another 80 choice will never be selected except for exploration. Put differently, any choice when valued optimistically is 81 still worse than another choice valued pessimistically will not be selected except for exploration. We now 82 proceed to formalize this conceptual framework. 83

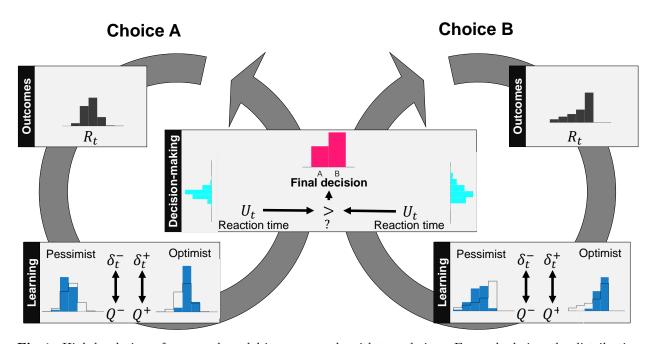

Fig 1. High-level view of proposed model in an example with two choices. For each choice, the distribution of rewards R_t (gray histograms) is learned by opposing counsels through the updates δ_t^+ and δ_t^- . One system is optimistic, upweighting large rewards, and another is pessimistic, downweighting large rewards (blue histograms). As a result, each choice is associated with multiple values Q^- and Q^+ . To determine which choice is selected, a random variable U_t is drawn for each choice uniformly from (Q^-, Q^+) (teal histograms). The largest U_t determines which choice is selected and when the decision is made.

Setting

84

Our model will describe psychological experiments that have the following decision-making scenario. The scenario starts at the initial state S_0 on which the participant bases their action A_0 , which brings in a numerical reward R_1 . Consequently, the participant finds itself in the next state S_1 and selects another action A_1 , which brings in a numerical reward R_2 and state S_2 . This process then repeats until the participant makes T decisions, yielding a sequence of observations collected for each participant of the form: s_1

$$S_0, A_0, R_1, S_1, A_1, R_2, S_2, \dots, R_{T-1}, S_{T-1}, A_{T-1}, R_T$$

Above, observations fall into three types on a given trial t: the *state* that the participant visits, denoted by S_t , the *action* that the participant takes when visiting state S_t , denoted by A_t , and the subsequent *reward*, R_{t+1} , that a participant receives upon visiting state S_t and taking action A_t . For simplicity, let us assume that both the space of possible states S and the space of possible actions A are discrete. Further, assume the experiment defines subsequent rewards and states as a function of the current state and action according to a

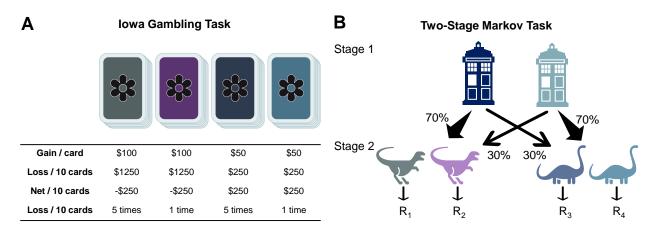

Fig 2. Popular tasks for evaluating decision-making: (A) Iowa Gambling and (B) Two-Stage Markov tasks. Both tasks can be formulated as Markov decision processes.

Markov transition probability

$$p(s', r|s, a) : \mathcal{S} \times \mathcal{R} \times \mathcal{S} \times \mathcal{A} \to [0, 1]$$

An experiment described above constitutes a (discrete-time, discrete-state) Markov Decision Process (MDP).

Several popular experiments can be described by the setting above. The Iowa Gambling Task (IGT), for example, asks participants to repeatedly chose between four decks labelled A to D. After each choice, they gain and/or lose monetary rewards (Fig 2). Hundreds of studies have used the IGT to evaluate human decision-making [32]. Initial findings found healthy controls would learn to select "good" decks (Decks C and D), so-called because, on average, they yielded a net gain [33]. By contrast, individuals with a damaged prefrontal cortex would continue to select "bad" decks (Decks A and B) despite yielding net losses on average. Selecting bad decks is considered a marker of impaired decision-making.

The above formulation can be recovered for the IGT with $A_t \in \{A, B, C, D\}$ capturing the selected desks, $S_t \in \{1\}$ capturing a trivial case with only one state, and R_t capturing the summed gain and loss per trial. In particular, we will simulate R_t as independent draws from a distribution that depends on the selected deck and matches characteristics in Fig 2A on average. For example, R_t is drawn uniformly from $\{\$50,\$0\}$ when Deck C is selected. We point out that the IGT is a specific case of a multi-armed bandit, which is a common framework to evaluate human decision-making and can also be described by the above setting.

Another example is the two-stage Markov task [34], in which a participant repeatedly selects images over ¹⁰⁴ two stages. Participants are presented one of three pairs of images at a given stage. At the first stage, all ¹⁰⁵ participants are shown the first pair of images and have the option to choose either the left or right image. ¹⁰⁶ After choosing an image, participants are shown the second or third pair of images, with the pair selected ¹⁰⁷ randomly according to probabilities that depends on their first stage selection. Participants then select an ¹⁰⁸ image on the second stage and receive monetary rewards. This task is used in experiments to determine the 109 degree to which individuals are learning about the common (p = 0.7) versus rare (p = 0.3) transition 110 associated with each action in stage 1. To mark this type of learning, the authors point to the probability of 111 staying on the same first-stage decision depending on the type of transition (common vs. rare) and whether 112 or not the person was rewarded on the second stage. In particular, if a person was learning about the 113 transitions and was rewarded, then they were expected to see a drop in the stay probability when a common 114 versus rare transition occurred. If if a person was learning about the transitions and was not rewarded, then 115 they were expected to see a jump in the stay probability when a common versus rare transition occurred. 116

In terms of the above formulation, this task gives rise to actions $A_t \in \{\text{left}, \text{right}\}$ representing selected images, states $S_t \in \{1, 2, 3\}$ capturing presented image pairs, and rewards R_t capturing rewards after image selection with rewards after the first stage set to zero. Despite the multi-stage aspect of this task, here tcounts the total number of actions so that t = 0 refers to the first time that a participant takes an action in the first stage and t = 1 refers to the first time that a participant takes an action in the second stage.

Temporal difference (TD) learning

In the setting described above, human decision-making is often modeled using TD learning. One 123 widely-known algorithm for TD learning is called SARSA, so-named for its explicit use of the sequence of 124 observations $\{S_0, A_0, R_1, S_1, A_1, \ldots\}$. This algorithm supposes that the agent, i.e., the participant in a 125 psychological experiment, tries to learn the "value" of their actions as a function of a given state in terms of 126 future rewards. This notion gives rise to a state-action value function Q(s, a) mapping states $s \in S$ and 127 actions $a \in A$ to a real number that reflects the value of this state-action pair. A SARSA learner updates 128 this state-action function according to their experiences: 129

$$Q(S_t, A_t) \leftarrow Q(S_t, A_t) + \alpha \Big[R_{t+1} + \gamma Q(S_{t+1}, A_{t+1}) - Q(S_t, A_t) \Big].$$
(1)

Here, the learner has just taken action A_t in state S_t , receiving the immediate reward R_{t+1} and transitioning to a new state S_{t+1} , where upon they take action A_{t+1} . A learning rate α accounts for the extent to which the new information, i.e. their reward and the new state-action value, overrides old information about their state-action value function. For instance, one can see that if $\alpha = 0$, there is no overriding - the estimate stays the same. The discount parameter γ weighs the impact of future rewards. A discount parameter $\gamma = 0$ would mean the learner does not care about the future at all, while $\gamma = 1$ would mean the learner cares about the sum total of future rewards (which may even cause the algorithm to diverge).

Risk-sensitive TD learning

A variant of the SARSA learner allows a learner to be particularly sensitive to smaller, or more negative, rewards, i.e. *risky* situations. In particular, a risk-sensitive SARSA learner weighs the prediction error, which is given by

$$\delta_t = R_{t+1} + \gamma Q(S_{t+1}, A_{t+1}) - Q(S_t, A_t),$$

differently depending on whether the prediction error is positive or negative. This yields the following update: 138

$$Q(S_t, A_t) \leftarrow Q(S_t, A_t) + \alpha \left[(1+k) \mathbb{1}_{\delta_t > 0} + (1-k) \mathbb{1}_{\delta_t < 0} \right] \delta_t.$$

The parameter k controls the degree to which the learner is risk sensitive. If k = 0, then the learner weighs positive and negative prediction errors equally, in which the updates are the same as before and we say the learner is *risk-neutral*. If k < 0, then negative prediction errors are weighed more than positive prediction errors. In this case, smaller rewards have a stronger influence relative than larger rewards on the state-action value function Q, resulting in a learner who is considered *risk-averse*. Similarly if k > 0, the reverse is true: larger rewards have a stronger influence relative to smaller rewards, and the learner is considered *risk-seeking*.

A learning model with opposing counsels

With the introduction of risk-sensitive TD learning, we can consider a range of learning behaviors from ¹⁴⁶ risk-sensitive to risk-seeking, all modulated by parameter k and reflected in the state-action value function Q. ¹⁴⁷ Researchers are often focused on how pessimism or risk-sensitivity, substantiated by k, might vary between ¹⁴⁸ individuals. In our model, however, we investigate how risk-sensitivity might vary within individuals. ¹⁴⁹ Specifically, we consider two learning systems, one pessimistic (risk-adverse) and one optimistic (risk-seeking). ¹⁵⁰

Our model captures two opposing systems by keeping track of two state-action value functions, Q^+ and Q^- , and updated each function according to: 152

$$Q^{+}(S_{t}, A_{t}) \leftarrow Q^{+}(S_{t}, A_{t}) + \alpha \left[(1+k^{+}) \mathbb{1}_{\delta_{t}^{+} > 0} + (1-k^{+}) \mathbb{1}_{\delta_{t}^{+} < 0} \right] \delta_{t}^{+}$$

$$Q^{-}(S_{t}, A_{t}) \leftarrow Q^{-}(S_{t}, A_{t}) + \alpha \left[(1-k^{-}) \mathbb{1}_{\delta_{t}^{-} > 0} + (1+k^{-}) \mathbb{1}_{\delta_{t}^{-} < 0} \right] \delta_{t}^{-}$$
(2)

with prediction errors given by

$$\delta_t^+ = R_{t+1} + \gamma Q^+(S_{t+1}, A_{t+1}) - Q^+(S_t, A_t)$$

$$\delta_t^- = R_{t+1} + \gamma Q^-(S_{t+1}, A_{t+1}) - Q^-(S_t, A_t).$$

For simplicity, we initialize Q^+ and Q^- to zero. Parameters k^+ , k^- are assumed to lie in [0, 1]. Large k^+ 153 controls the degree to which the learner is risk-seeking and k^- controls the degree to which the learner is 154 risk-sensitive. It is important to point out that we are not the first to consider multiple risk-sensitive TD 155 learning systems. This idea was recently put forth in [9], where multiple risk-sensitive TD learning systems 156 were thought to be encoded in multiple dopamine neurons. 157

A decision-making model with opposing counsels

Now that we have a model of learning, namely Q^+ and Q^- , it is sensible to consider how the agents makes ¹⁵⁹ decisions based on what they have just learned. This means that the individual has to make the decision of ¹⁶⁰ choosing from the available actions, having obtained pessimistic and optimistic estimates for action-value ¹⁶¹ pairs. ¹⁶²

A naive approach is what is called the greedy method, meaning that the action with the highest value is 163 chosen. This approach, however, does not account for actions with multiple values (e.g., optimistic and 164 pessimistic values) nor does it allow the individual to do any exploration, during which they might discover a 165 more optimal strategy. A way to incorporate exploration into decision-making is to act greedy $1 - \varepsilon$ of the 166 time and for ε of the time, the individual explores non-greedy action with equal probabilities. This method 167 referred to as ε -greedy and is used by our model. 168

To integrate multi-valued actions into a ε -greedy method, our model supposes that a random variable $U_t(a)$ is selected for each action a uniformly from the interval 170

$$\left[Q^{-}(S_t,a),Q^{+}(S_t,a)\right],$$

whenever an individual has to make a decision in state S_t . Then whenever the individual acts greedily, they select the action A_t that maximizes $U_t(a)$. These decision rules along with learning models comprise Opposing-Counsels model, which is summarized in Algorithm 1.

Algorithm 1: Opposing-Counsels

Data: Learning rate α , risk parameters k^+ , k^- , discount factor γ , and exploration parameter ε . Initialize $Q^{\pm}(s, a)$ for all $(s, a) \in \mathcal{S} \times \mathcal{A}$ Initialize STake action A from S using ε -greedy from the values $U(a) \sim \operatorname{Unif}\left[Q^{-}(S, a), Q^{+}(S, a)\right]$ while not terminated do Take action A, observe R, S'For each permissible action a' in state S', sample $U(a') \sim \text{Unif}[Q^{-}(S', a'), Q^{+}(S', a')]$ Choose A' using ε -greedy from the values U(a')% Compute prediction errors $\delta^{\pm} \leftarrow R + \gamma Q^{\pm}(S', A') - Q^{\pm}(S, A)$ % Update state-action value functions $Q^{\pm}(S,A) \leftarrow Q^{\pm}(S,A) + \alpha \left[(1 \pm k^{\pm}) \mathbb{1}_{\delta^{\pm} > 0} + (1 \mp k^{\pm}) \mathbb{1}_{\delta^{\pm} < 0} \right] \delta^{\pm}$ % move to new state-action pair $A \leftarrow A'$ $S \leftarrow S'$ end

Simulation experiments

We used simulation to investigate individual behavior in several experiments were they to learn and make decision according to our decision-making model. In particular, we wanted to identify possible vulnerabilities in behavior that arise from a shift in the balance between the internal optimist and pessimist, instantiated by changes in parameters k^+ and k^- . For simplicity, parameters are fixed:

$$(\alpha, \epsilon, \gamma, k^+, k^-) = (0.5, 0.3, 0, 0.9, 0.9),$$

unless otherwise specified. A detailed description of the simulations can be found in the S1 Text and at: https://github.com/eza0107/Opposite-Systems-for-Decision-Making

Learning the shape of rewards

Let us first focus on learning behavior by considering the simple case of trivial state and action spaces: $S = \{1\}$ and action $\mathcal{A} = \{1\}$. In this case, learning in the Opposing-Counsels model is determined completely by the distribution of rewards R_t . We considered what an individual would learn given four different Pearson distributions of R_t , with varying mean μ , standard deviation σ , and skew, while kurtosis was fixed at 2.5. For reference, we also consider the classic Q described at Eq. (1).

Figure 3 illustrates what an individual with balanced risk-sensitivity parameters, $(k^+, k^-) = (0.9, 0.9)$, ¹⁸³

174

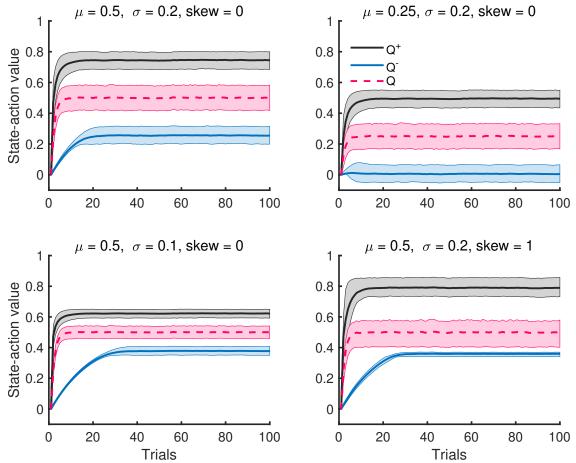

Fig 3. Comparison of mean and interquartile range of state-action value functions over 4000 simulations. The state-action values Q^+ and Q^- reflect changes in the mean μ , standard deviation σ , and skew of the reward distribution. Notably, asymptotes of these values shift by 0.25 when μ decreases by 0.25, and their gap decreases by 1/2 when σ decreases by a factor of 1/2.

learns over 100 trials. Solid dark lines denote state-action value function averaged over simulations and 184 shaded regions represent associated interquartile ranges (IQRs) for each function. One can immediate notice 185 several things. By design, the optimistic value function Q^+ is on average larger than the neutral value 186 function Q, which is larger than the average pessimistic value function Q^{-} . In addition, the distribution of 187 each value function appears to converge and can capture shifts in mean rewards μ and scaling of the 188 standard deviation σ . Specifically, the long-term relationship between Q^+, Q^- and Q is preserved when μ is 189 shifted from 0.5 to 0.25, whereby all value functions shift down by about 0.25. Further, the gap between Q^+ 190 and Q^- is halved when σ is halved from 0.2 to 0.1; each IQR is also halved. Meanwhile, Q^+ and Q^- are 191 roughly symmetric around the Q when the reward distribution is symmetric (i.e. zero skew), so that the 192 average of Q^+ and Q^- is approximately Q. However, moving skew from 0 to 1 is reflected in both the gap 193 between Q^+ and Q, which lengthens, and the gap between Q^- and Q, which shortens. 194

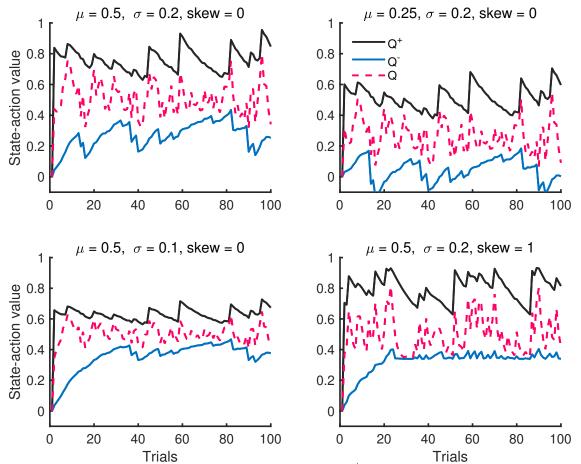

Fig 4. A single simulation run of state-action value functions Q^{\pm} and Q. The state-action values preserve the ordering $Q^- < Q < Q^+$ through the entire run.

Remarkably, the relationship $Q^+ > Q > Q^-$ is also present within a single simulation run (Figure 4). Intuitively, this makes sense because they capture the behaviors of risk-seeking, risk-neutral and risk-sensitive agents, respectively and it turns out that this ordering can be preserved provided k^{\pm} are neither too small or large. See S1 Text for the proof of this result. Furthermore, the last subplot also illustrates that introducing a positive skew to the reward distribution R_t , also causes the distribution of Q^{\pm} and Q to also have positive skew.

Value functions Q^+ and Q^- are not only modulated with the reward distribution, but also risk-sensitivity 201 parameters. Increasing k^+ moves Q^+ in a positive direction away from the risk-neutral value function Q, 202 whereas increasing k^- moves Q^- in a negative direction away from the risk-neutral value function Q. With 203 k^+ pulling Q^+ in one direction and k^- pulling Q^- in the opposite direction, the midpoint of Q^+ and Q^- is 204 largely influenced by the gap in k^- and k^+ (Figure 5A). Meanwhile, the gap between Q^+ and Q^- is largely 205 influenced by the midpoint of k^+ and k^- . 206

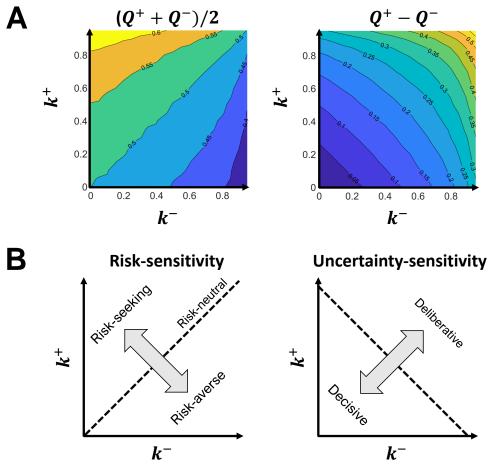

Fig 5. Impact of risk-sensitivity parameters k^+ and k^- on **A**) the midpoint and gap between Q^+ and Q^- averaged over 4000 simulations, and **B**) how an individual makes decisions. In particular, the model decomposes decision-making behavior along two axes, a risk-sensitivity and an uncertainty-sensitivity, which are rotated 45° degrees from the k^{\pm} axes. In the simulation, $\mu = 0.5$, $\sigma = 0.2$, and skew = 0.

Since decisions are selected according to the interval between Q^+ and Q^- , the gap in k^- and k^+ 207 determines the degree to which an individual selects action with high payoffs vs. small losses, i.e. their 208 risk-sensitivity. The midpoint of k^- and k^+ determines the degree to which reward uncertainty influences 209 whether or not an individual deliberates between actions, i.e. their uncertainty-sensitivity (Figure 5B). This 210 deliberation allows a learner to consider multiple decisions, as one does during exploration but for different 211 reasons. Conceptually, multiple decisions are considered in the model, because different decisions may be 212 optimal depending on different ways they are valued (e.g., optimistically vs. pessimistically), which is 213 encoded in the Q^- to Q^+ interval. By contrast, exploration is used to account for sampling error in how 214 decisions are valued, so that decisions can be considered that might be incorrectly valued. 215

In summary, risk-sensitivity parameters k^{\pm} can capture a range of behavior from being too risky to not risky enough and from too decisive to too deliberative. We demonstrate these decision-making behaviors in 217 the next two examples.

Capturing a penchant for gambling

To demonstrate how risk-sensitivity parameters drive decision-making behavior in our model, let us consider ²²⁰ the IGT, which we introduced earlier. Selecting bad decks was put forth as a marker of impaired ²²¹ decision-making, or more specifically, an insensitivity to future consequences. This interpretation, however, ²²² presumes that the participant's objective is indeed to make decisions that maximize expected rewards as ²²³ opposed to making decisions that seeks large gains or avoids large losses. Risk-seeking behavior (i.e. a ²²⁴ penchant for gambling), in particular, may encourage individuals to pursue bad decks, since they yield the ²²⁵ largest one-time gains. ²²⁶

To that point, balanced $(k^+, k^-) = (0.9, 0.9)$ risk-sensitivity parameters, reflecting risk-neutral behavior, 227 results in a preference for Deck A, i.e. one of the good decks that leads to average net gains (Fig 6A). By 228 contrast, imbalanced $(k^+, k^-) = (0.9, 0.1)$ risk-sensitivity parameters, reflecting risk-seeking behavior, results 229 in a preference for Deck B, i.e. one of the bad decks that leads to average net losses. In each case, pessimistic 230 state-action values Q^- are larger for good decks (C and D), correctly signifying that these decks are the more 231 risk-averse choices (Fig 6B). Meanwhile, optimistic state-action values Q^+ are larger for bad decks (A and B), 232 correctly signifying that these decks are the more risk-seeking choices. Imbalanced risk-sensitivity parameters, 233 however, dramatically underplays the risk of Deck B compared to balanced risk-sensitive parameters. 234 Consequently, the chance of large gains encoded in Q^+ is suitably enticing to encourage a Deck B preference. 235 That is, Deck B preference, which is actually a well-known phenomenon of healthy participants [32], can be 236 interpreted as a penchant for gambling rather than an insensitivity to future consequences. 237

As was done in [35], we can also partition the parameter space $\{(k^+, k^-) | 0 \le k^+, k^- \le 1\}$ by preference for good and bad decks (Fig 6C). This figure tells us that in the "blue" region of the parameter space, bad decks A + B are selected at greater frequency than good decks C + D. In the context of risk-seeking vs risk-averse terminology, our choice of $k^+ >> k^-$ means that our learner, despite the fact that B incurs incomparably large loss, keeps sticking to it because Q^+ is driving the choice. In another words, our agent is unable to learn the good decks in the IGT, thus mimicking the behaviors of the participants with prefrontal cortex damage as demonstrated in [36].

218

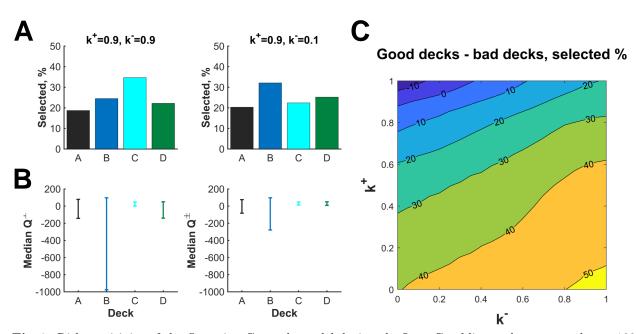

Fig 6. Risk-sensitivity of the Opposing-Counsels model during the Iowa Gambling task aggregated over 100 trials and 20,000 simulations. A) The "risky" Deck B becomes the most popular choice rather than Deck C, when parameter k^- is decreased from 0.9 to 0.1. B) Deck B becomes more favorable because of a dramatic increase to the pessimistic value function Q^- . C) Bad decks A and B are chosen at higher rates moving along the risk-sensitivity axis (i.e. the $k^+ = 1 - k^-$ line).

The ambiguity of deliberation

To demonstrate how parameters k^{\pm} drives uncertainty-sensitivity in the Opposing-Counsels model, let us consider the 2-stage Markov task, mentioned earlier. Recall this task uses the gap in stay probabilities to determine the degree to which individuals are learning about the common (p = 0.7) versus rare (p = 0.3)transition associated with each action in stage 1. As with the IGT, this interpretation supposes that individuals seeks to maximize excepted (discounted) rewards, rather than balance their internal optimist and pessimist. To account for the multi-stage aspect of this task, we use a discount factor γ to 0.9 which allows information to pass between task stages.

The bar graphs in Figure 7 represents the probability of sticking to the current choice categorized by whether it resulted in reward or not and whether the transition was common or rare. The contour plots on the right side of the figure tells us the difference between the probabilities of staying when the transition was common or rare, given rewarded or unrewarded.

For instance, whether the current decision was rewarded or not, the agent tends to become very deliberative if we let $k^+, k^- \rightarrow 1$. This case captures the behavior of someone who is both risk-seeking and risk-averse at the same time. Balancing these polar opposite behaviors is perhaps difficult, thus resulting in 259

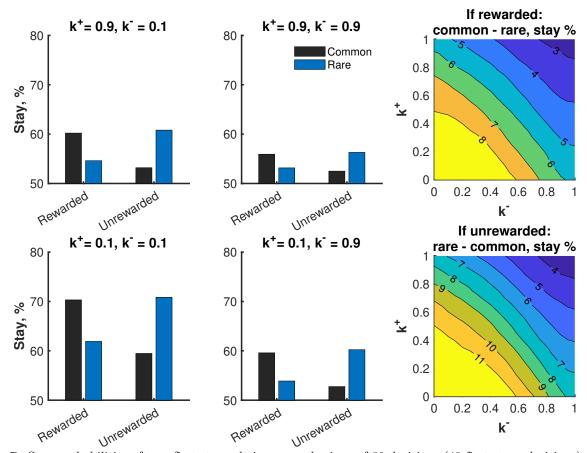

Fig 7. Stay probabilities after a first stage choice over a horizon of 80 decisions (40 first-stage decisions) and 20,000 simulations. The gap between stay probabilities for common vs. rarer transitions increases along the uncertainty-sensitivity axis (i.e. $k^+ = k^-$ axis) as the learner increases their deliberation about multiple choices.

stagnated actions. One can see that in this case all 4 probabilities are roughly the same, meaning the individual does not discriminate between characteristics of the task.

On the other hand, our model stipulates that the choice of $(k^+, k^-) = (0.1, 0.1)$ should give an agent who is rather risk-neutral and behaves rather optimally with respect to expected rewards, because $k^+ = k^- = 0$ will give the regular SARSA learner. One can see that the agent is more likely to stay when the current choice was rewarded. Furthermore, the agent is most likely to stay when the transition was common which led to a reward and least likely to stay when the transition was common which did not lead to a reward. 266

Regardless of the choice of (k^+, k^-) , our model does not change the degree to which individuals are learning about common versus rare transitions. Yet, if we would only look at the gap in stay probabilities, we would conclude the smaller values of (k^+, k^-) are associated with better ability to learn these transitions. Further, a person's tendency to explore decisions will also have a lower gap in stay probabilities. In other words, it is difficult to disambiguate a change in how deliberative a person is with their decisions from their 270

260

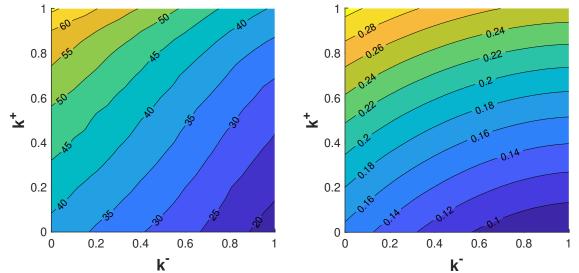

Fig 8. Mean $\max_a U_t(a)$ in the Iowa Gambling Task (left) and two-stage Markov task (right). Larger values of $\max_a U_t(a)$ are hypothesized to correspond to faster reaction times.

ability to learn transitions or their tendency to explore.

Predicting reaction time

One prediction of the Opposing-Counsels model is that the translation of Q^+ and Q^- into decisions plays out in time. The value Q^+ determines when (in time) a decision is considered, so that decisions with larger Q^+ are considered earlier, and the value Q^- determines when a decision is no longer considered, so that decisions with smaller Q^- are considered for longer. Mathematically, we capture this idea by letting the decisions *a* compete for the largest random uniform draw $U_t(a)$ from $(Q^-(S_t, a), Q^+(S_t, a))$. We propose that there is some non-increasing function that maps the max draw to time and that may depend on the person and the task. Larger max_a $U_t(a)$ leads to faster decisions; smaller to slower decisions. 270

In light of this prediction, we simulated $\max_a U_t(a)$ for both the IGT and two-stage Markov task (Figure 8). In both tasks, larger $\max_a U_t(a)$ are found for large k^+ and small k^- , i.e. when the overall behavior is more risk-seeking. Hence, our model predicts that risk-seeking decisions are quick and risk-averse decisions are slow.

Neural encoding of updates

As we mentioned, the rough intuition behind the reinforcement learning update we chose for the state-value functions Q^+ and Q^- is that they capture the behaviors of risk-seeking and risk-averse learners, respectively. Going even further, we investigate the possibility that dopamine transients encode the update ΔQ^+ 286 287 288

272

associated with the risk-seeking system and serotonin transients encode the negative of the update ΔQ^- 289 associated with the risk-averse system. In view of this claim, we present one last study, which measured 290 dopamine and serotonin during a decision-making task [7]. 291

In this study, participants were asked to make investing decisions on a virtual stock market. In total, participants made 20 investment decisions for 6 markets for a total of 120 decisions. Each participant was allocated \$100 at the start of each market and could allocate bets between 0% to 100% in increments of 10%. The participant would gain or lose money depending on their bet. Given a bet A_t on trial t and market value p_{t+1} after betting, percent monetary gain (or loss) on trial t was

$$\left(\frac{p_{t+1}-p_t}{p_t}\right)A_t.$$

To model this experiment, we use the simplifying assumption that bets are low or high: $A_t = \{25\%, 75\%\}$, and suppose rewards are

$$R_t := \left(\frac{p_{t+1} - p_t}{p_t}\right) \left(A_t - 50\right).$$

Actions are centered to 50% to account for the hypothesized role of counterfactual in this experiment [8]. 292 Hence, R_t is the percent monetary gain relative to the *counterfactual* gain were a neutral 50% bet made. 293 Following [7], trials are split according to a reward prediction error (RPE): the percent monetary gain 294 centered to its past mean and inversely scaled by its past standard deviation. 295

Let us consider the scenario where a decision made on trial t resulted in a negative RPE, which means that a lower monetary gain relative to past expected gains (Left panel in Figure 9). Without accounting for counterfactuals, a risk-neutral system would experience a negative update independent of bet level. Risk-seeking update ΔQ^+ , however, depends on bet level during a negative RPE: large for a low bet (25%) compared to a high bet (75%). The reverse is true for the negative of the risk-averse update ΔQ^- : it is large for a high bet (75%) compared to a low bet (25%).

These characteristics of ΔQ^+ and $-\Delta Q^-$ during negative RPE mirror, respectively, dopamine and serotonin transients in [7]. The authors hypothesized that the large dopamine transient for a low bet encourages the *rewarding* decision of betting low, whereas the large serotonin transient for a high bet protects the individual from the *risky* decision of betting high. Betting low is only rewarding when compared to the counterfactual loss of betting a higher amount and losing. This hypothesis is consistent with the role in the Opposing-Counselsmodel of a positive ΔQ^+ to encourage a rewarding decision and a negative ΔQ^- to

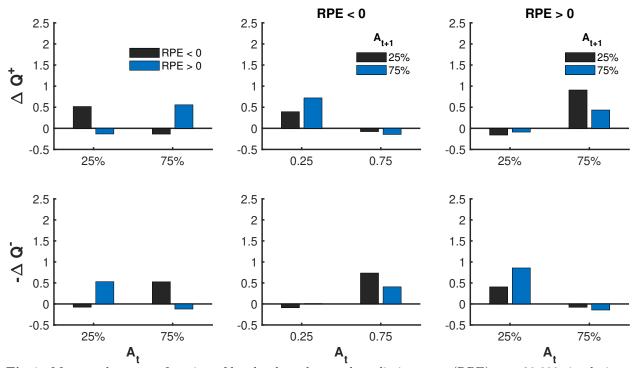

Fig 9. Mean updates as a function of bet levels and reward prediction error (RPE) over 20,000 simulations. Mirroring dopamine transients in [8], large mean ΔQ^+ reinforces either a large bet for positive RPE or a small bet when negative RPE. Mirroring serotonin transients in [7], large mean $-\Delta Q^-$ reinforces either a large bet for negative RPE or a small bet for positive RPE. In addition, mean updates can predict the upcoming bet and are asymmetrical, respecting potential asymmetry in the degree to which dopamine and serotonin transients can increase vs. decrease.

protect oneself from risky decisions.

When RPE is positive, which is when the agent has a lower monetary gain relative to past expected gains, 309 the direction of the updates flip. The update ΔQ^+ is now large for a high bet (75%) compared to a low bet 310 (25%), and the negative of ΔQ^- is large for a low bet (25%) compared to a high bet (75%). Again, these 311 characteristics mirror dopamine and seroton transients in [7, 8]. In this case, it was hypothesized that the 312 relatively large dopamine transient for a high bet encourages the rewarding decision of betting high, whereas 313 the relatively large seroton transient for a low bet protects the individual from the risky decision of betting 314 low. As before, betting low is only considered risky when compared to the counterfactual loss of what they 315 could have gained if they bet higher. 316

As an aside, we point out that average updates ΔQ^+ and $-\Delta Q^-$ are generally more positive than they are negative. This asymmetry respects the fact that dopamine and serotonin transients have a biophysical constraint whereby positive transients are easily induced but negative transients are not.

Following [7], we consider how updates ΔQ^+ and $-\Delta Q^-$ influence how a person subsequently bets (Middle and right panels in Figure 9). Trials are split further based on the subsequent decision made on the

next trial. The negative of update ΔQ^- is largest when switching from a high to low bet during negative RPE and from a low to high bet during positive RPE. These trends mirror serotonin transients in [7], where a relatively large serotonin transient preceded a lowering of a bet when RPE was negative and preceded a raising or holding of a bet when RPE was positive. These findings provided further support that serotonin transients protect an individual from actual and counterfactual losses.

Meanwhile, the update ΔQ^+ is largest when switching from a low to high bet during negative RPE and from a high to low bet during positive RPE. Since dopamine transients were not investigated as a function of subsequent bets in [7], we have the following model prediction without experimental validation: a relatively large dopamine transient preceding a raising of a bet when RPE was negative and preceding a lowering a bet when RPE was positive.

Discussion

We presented a computational model of human decision-making called the Opposing-Counsels model. The model conceptualizes decision-making with two opposing counsels, an optimist and a pessimist, which are modulated by parameters k^+ and k^- , respectively. We posit that information is integrated from each system over time while decisions compete. The optimist activates decisions ("go"); the pessimist inhibits decisions ("no-go"). We show how our model can illuminate behavior observed in experiments using the Iowa gambling, two-stage Markov, or the stock market tasks.

A key prediction of the Opposing-Counsels model is that the updates in the optimistic and pessimistic 339 learning systems are directly encoded in dopamine and serotonin transients. This finding arose from efforts 340 to reproduce observations during the stock market task in Moran et al [7] and Kishida et al [8]. While 341 computational models such as TD learning have provided a useful framework to interpret experiments 342 involving dopamine [37], serotonin has been more difficult to pin down [19]. If serotonin can be understood 343 as updates to a pessimistic learning system, then we would expect serotonin, like dopamine, to influence 344 decision-making in important ways. It would oppose dopamine, protect a person from risky behavior, inhibit 345 certain decisions, and change the value (and timing) of decisions. These functions agree with several leading 346 theories [6, 7, 18-22]; yet, the mathematical form we propose for serotonin is new. 347

We are not the first to try to interpret observations of serotonin and dopamine through the lens of a ³⁴⁸ computational model [6, 18, 30, 38]. Daw *et al*, for instance, describe how prediction error in a TD learning ³⁴⁹ system could be transformed into tonic and phasic parts of dopamine and serotonin signals [6]. Alternatively, ³⁵⁰ Montague *et al* argue that two prediction errors, derived from reward-predicting and aversive-predicting TD ³⁵¹

learning systems, could be transformed into serotonin and dopamine transients [18]. While these models map prediction errors to dopamine and serotonin, the more useful task might be mapping dopamine and serotonin to learning. In other words, trying to understand what certain dopamine and serotonin transients could mean to how a person learns and makes decisions. Our model provides a surprisingly simple answer: dopamine and serotonin transients are exactly the updates to two learning systems.

Critically, these learning systems can capture ranges of decision-making behavior. These learning systems ³⁵⁷ (and hence, dopamine and serotonin) may oppose each other, but they are not perfect antipodes. Hence, the ³⁵⁸ systems are not redundant and obey a principle about efficient coding of information [18]. For instance, we ³⁵⁹ show that the two learning systems in the Opposing-Counsels model can implicitly reflect at least two ³⁶⁰ properties of rewards: reward expectations and reward uncertainty. Several other mathematical models of ³⁶¹ learning and decision-making suggest individuals track reward uncertainty, but do so explicitly [10–14]. ³⁶²

In addition, the Opposing-Counsels model reveals how risk-sensitivity and uncertainty-sensitivity 363 represent two orthogonal dimensions of decision-making and how extreme values in either direction could 364 pose unique impairments in decision-making. Sensitivity to risk and uncertainty are well documented in the 365 psychological, economics, and reinforcement learning literature. For instance, risk-seeking (risk-aversion) can 366 be beneficial when large rewards (small losses) are required to escape (avoid) bad scenarios. Platt provides 367 several examples of animals behaving in a risk-sensitive way, e.g., birds switching from risk-aversion to 368 risk-seeking as a function of the temperature [39]. Miscalibrated risk-sensitivity is thought to cause 369 significant problems for people and underlie a number of psychiatric conditions such as addiction or 370 depression [28,29]. Mathematically, risk-sensitivity is captured either explicitly through functions that reflect 371 risk-sensitive objectives [40, 41] or implicitly through differential weighting of positive and negative prediction 372 errors [15–17], such as we do here. We recommend the paper by Mihatsch et al [27] for a nice theoretical 373 treatment of risk-sensitivity. 374

Meanwhile, uncertainty-sensitivity represents the degree to which uncertainty in the reward distribution, 375 and in their knowledge of this distribution, influences their decisions. Like risk-sensitivity, miscalibrated 376 uncertainty-sensitivity is thought to underlie psychiatric conditions such as anxiety [42-45]. Huang *et al*, for 377 example, describe this miscalibration in anxiety as a "failure to differentiate signal from noise" leading to a 378 "sub-optimal" decision strategy [43]. Conceptually, our model provides a different interpretation. Rather than 379 being a failure or sub-optimal behavior, extreme uncertainty-sensitivity embodies a strategy that attempts to 380 satisfy competing objectives, some of which are risk-averse and others which are risk-seeking. In experiments, 381 this conflicted strategy will look similar to an exploration-exploitation trade-off, making it difficult to 382 distinguish between the two. 383

Interestingly, any attempt to modify solely the optimistic and pessimistic learning system (or dopamine 384 and serotonin transients) will affect both risk sensitivity and uncertainty-sensitivity. The reason is that 385 risk-sensitivity and uncertainty-sensitivity axes are rotated 45 degrees from the axes of the parameters k^+ and 386 k^- modulating the two learning systems. For instance, increasing k^- in an attempt to reduce risk-seeking 387 would have the unintended consequence of increasing the sensitivity to uncertainty. Under our interpretation, 388 this would correspond to interventions on serotonin transients to reduce risk-seeking having the potential 389 side-effect of a loss of decisiveness. Similarly, reducing k^+ , or intervening on dopamine transients, to reduce 390 risk-seeking would decrease sensitivity to uncertainty. A similar tradeoff occurs when trying to decrease 391 risk-aversion or sensitivity to uncertainty through manipulations of just k^+ or just k^- . Notably, many 392 current pharmacological interventions (e.g., Lithium) act on both dopamine and serotonin neurons. 393

Another key prediction of our model is that values placed on decisions by the two learning system (i.e. 394 Q^{\pm}) determine the time to make a decision. Thus, the distribution of reaction time may provide additional 395 data beyond choice selection for which to inform or falsify our model. This connection to reaction time might 396 also help to make sense of the impact of serotonin and dopamine on how quickly decisions are made (e.g., 397 impulsively) [19,26,46]. Considering that reaction time is not part of the standard TD learning model, an 398 ability to capture reaction time may be a welcome addition. For comparison, models for reaction time are 300 often built with stochastic differential equations to reflect a process of evidence accumulation (c.f., [47] for an 400 overview). 401

There are several limitations of this work to consider. We hope it is clear that the modeling of learning in 402 the updates of Q^+ and Q^- is largely modular from the modeling that maps these values to actions and 403 reaction times. There are numerous ways that pairs of Q^+ and Q^- values can be mapped to a choice of 404 actions and a time delay in making that choice. In addition, our model was built upon a SARSA algorithm, 405 but Q-learning may prove to be equally suitable. It should also be clear that our model is over-simplified. 406 One notable absence, for example, is that our model did not track average outcomes or map these outcomes 407 or other parts of our model to tonic dopamine and serotonin, unlike the model of Daw *et al* [6]. Relatedly, we 408 directly incorporated counterfactuals into our rewards to reproduce findings from the stock market task [7, 8], 409 but perhaps a separate process, such as tonic serotonin or dopamine, should be included to track 410 counterfactuals. Another limitation of our model is that it relies on only two prediction errors. However, a 411 recent study suggests dopamine is capable of capturing a distribution of prediction errors [9], which has the 412 advantage of being able to learn about the distribution of rewards. 413

Lastly, one of the key properties of our model, the ordering $Q_t^+ > Q_t^-$ assumes that the parameter α is 414 the same for Q^+ and Q^- . If parameter α were not equal, then the relationship between Q^+ and Q^- could 415 reverse. The possible effects of $Q^+ < Q^-$ largely fall outside the specifics of the Opposing-Counsels model, but it is conceivable such a situation could result in no-go signals arriving before go signals, leading to a decision process unwilling to even consider an option. A situation when no options were even worth consideration may be similar to anhedonia.

In conclusion, this work establishes a new model of human decision-making to help illuminate, clarify, and 420 extend current experiments and theories. Such a model could be utilized to quantify normative and 421 pathological ranges of risk-sensitivity and uncertainty-sensitivity. Overall, this work moves us closer to a 422 precise and mechanistic understanding of how humans make decisions. 423

Supporting information

 S1 Text. Additional support. This supplement is divided into two sections. The first section,
 425

 Stochastic dominance, derives a key property of the Opposing-Counsels mode. The second section, Python
 426

 Implementation, describes code for simulating the experiments. Code can also be found at
 427

 https://github.com/eza0107/0pposite-Systems-for-Decision-Making.
