Abstract

Shigella spp. commonly causes gastroenteritis known as shigellosis, and severe cases require antibiotic treatments. However, the increased presence of antibiotics in the environment in recent years can lead to antibiotic resistance. Sub-lethal antibiotic concentrations can promote resistance, but its effect on sensitive bacteria prior to resistance development is unknown. In this study, the complete genome of *Shigella sonnei* UKMCC1015, a sensitive strain from Malaysia is presented. Subsequently, the transcriptomic response of this strain towards sub-MIC levels of norfloxacin, a commonly used fluoroquinolone is investigated. This study reveals that the expressions of the antimicrobial resistance genes and antibiotic targets (DNA gyrase and topoisomerase IV) are not affected. Interestingly, multiple ribosomal protein operons were downregulated while a small regulatory RNA (sRNA), GcvB was upregulated in response to constant exposure to sub-MIC norfloxacin.. To our knowledge, association between sub-lethal fluoroquinolone and expression of ribosomal protein operons as well as GcvB sRNA have never been reported. Collectively, these findings suggest that there are novel pathways possibly related to ppGpp levels that are involved in the adaptive response of *S. sonnei* towards fluoroquinolones.

Keywords

Shigella sonnei UKMCC1015, whole genome sequencing, comparative phylogenomics, transcriptome analysis, sub-MIC

Impact Statement

In this study, the genome of a sensitive *Shigella sonnei* UKMCC1015 and the transcriptomic analysis of its response towards sub-lethal norfloxacin is presented. This study brings new information towards the multitudes of responses *S. sonnei* can have against a low concentration of antibiotics, including the involvement of the stringent response and a small non-coding RNA called GcvB. This study also highlights the idea that the response of a sensitive strain towards antibiotics are different compared to a resistant strain. Future studies elucidating the exact pathways involving the stringent response and GcvB can lead to the discovery of potential targets as antibiotics or as anti-resistance agents.

Data Summary

The complete genome of *Shigella sonnei* UKMCC1015 and its plasmids has been deposited at GenBank under accession numbers CP060117, CP060118 and CP060119. RNA-seq data are accessible through BioSample accession number SAMN16871737.

Introduction

Shigella species is a common causal agent of global diarrhoea episodes, affecting mainly children younger than 5 years old (Baker & The 2018). Among the four species of *Shigella, Shigella dysenteriae* and *Shigella boydii* are infrequently isolated, while *Shigella flexneri* and *Shigella sonnei* are more commonly encountered in clinical settings. *S. flexneri* is commonly associated in resource-poor countries, while *S. sonnei* is associated with the disease in high-income countries. Due to the improving economic prosperity of many countries, *S. sonnei* has recently replaced *S. flexneri* as the dominant species to cause bacillary dysentery globally (Thompson, Duy & Baker 2015). The current population of *S. sonnei* descended from a common ancestor that led to distinct lineages and spread to other parts of the world, with strains in Asia that are mostly descendants of one lineage from Europe (Holt *et al.* 2012). This etiological shift of shigellosis cause to *S. sonnei* is also reported in Malaysia (Banga Singh *et al.* 2011; Koh *et al.* 2012). Most studies on *Shigella* in Malaysia focused on their antimicrobial susceptibility profiles and highlight the lack of research done on their genetics and phylogeny. Additionally, among all 36 *S. sonnei* complete genomes provided in the NCBI database (last accessed on 09/2020), there are no genomes of *S. sonnei* strains from Southeast Asia.

Due to the misuse and overuse of antibiotics, the increased concentration of antibiotics in the environment has exacerbated the antimicrobial resistance crisis (Gonzalez-Plaza *et al.* 2019). Among all antimicrobial-resistant bacteria, fluoroquinolone-resistant *Shigella spp.* are among the priority 3 (medium) category for new antibiotics research and development. Norfloxacin is one of the first fluoroquinolones synthesised. Although it is not the recommended drug of treatment for shigellosis,

its mechanism of action is similar to the recommended drug ciprofloxacin. All fluoroquinolones act by inhibiting DNA gyrase and topoisomerase IV by binding at the enzyme-DNA interface, blocking ligation of the DNA and leads to lethal chromosomal breaks (Alfred, Kerns & Osheroff 2014). By inhibiting bacterial DNA synthesis, it will ultimately cause bacterial cell death.

Studies had shown that low antibiotic concentrations may contribute to antimicrobial resistance. While antibiotic concentration that is higher than the minimum inhibitory concentration (MIC) leads to antimicrobial effects on susceptible cells, concentrations lower than the MIC (also known as sub-MIC) can instead act as a signal for diverse responses that ultimately induce tolerance (Bernier & Surette 2013). As antibiotic pollution leads to sub-MIC levels of antibiotics in the environment, this condition can not only enrich pre-existing resistant variants but also cause a selective pressure for the development of *de novo* resistance (Li *et al.* 2018). Thus, the effect of sub-MIC towards antibiotic tolerance in sensitive bacterial strains needs to be well understood to counteract the inevitable presence of resistant strains.

Although exposure to sub-MIC fluoroquinolone can promote resistance via mutations in the DNA gyrase gene (Ranjbar & Farahani 2019), it is not known what are the transcriptional responses of a sensitive bacterium to low levels fluoroquinolone prior to the development of resistance. This study first presents the complete genome of a *S. sonnei* strain UKMCC1015 from Malaysia, providing the first reference genome for *S. sonnei* from South East Asia. Next, RNA-seq was used to investigate how this fluoroquinolone-sensitive bacterium responds to sub-lethal levels of norfloxacin (a second generation fluoroquinolone). Interestingly, this study revealed some novel observations: 1) none of the gyrase or antibiotic resistance genes were differentially regulated and 2) multiple ribosomal protein operons and a small regulatory RNA, GcvB are differentially expressed, suggesting new unreported pathways are involved in the response of *S. sonnei* towards fluoroquinolone.

Methods and Materials

<u>Strain growth and culture conditions</u>

Shigella sonnei UKMCC1015 strain is a clinical isolate purchased from the University Kebangsaan Malaysia Culture Collection (UKMCC). The strain was cultured in Mueller-Hinton broth (Oxoid, UK) and incubated at 37°C with shaking at 200 rpm overnight. Total genomic DNA was extracted from the mid-log culture using Wizard® Genomic DNA Purification Kit from Promega according to the manufacturer's protocol.

<u>Genome sequencing, assembly and annotation</u>

To obtain a closed genome, we used a hybrid approach employing long-read Nanopore and short-read Illumina MiSeq sequencing. Briefly, for long-read sequencing DNA libraries were prepared using the Ligation Sequencing Kit (SQK-LSK109) according to the manufacturer's protocol and sequenced on a MinION FLOW-MIN106 flowcell and MinION MK1B sequencing device (Oxford Nanopore Technologies). Base calling was conducted with Guppy v3.2.10 on MinKnow 3.6.17 using a fast base calling configuration. For the genome assembly, multiple long-read assemblers were used: Flye v2.6 (Kolmogorov *et al.* 2019), Raven v1.1.10 (https://github.com/lbcb-sci/raven) and Miniasm-Minipolish v0.3 (https://github.com/rrwick/Minipolish). Then, Trycycler (https://github.com/rrwick/Trycycler) was used to obtain the consensus long-read assemblies from different long-read assemblers. The long reads were also used for error correction using Medaka v1.0.3 (https://github.com/nanoporetech/medaka). For Illumina sequencing, DNA libraries were prepared using Nextera XT library preparation kit and sequenced using a 2 X 250 bp paired-end configuration. The Illumina reads were trimmed and used for error correction using Pilon v1.23 (Walker *et al.* 2014). The closed genome was annotated using PGAP (Tatusova *et al.* 2016).

<u>Core genes phylogenetic analysis among all *shigella* spp.</u>

To establish the phylogenetic relatedness of UKMCC1015 strain within all *Shigella*, a total of 122 *Shigella* complete genomes from NCBI, including UKMCC1015, with one *Escherichia coli* K-12 substrain MG 1655 were obtained (Figure 2). The complete genomes of *Shigella* species obtained consist of 19 *S. boydii,* 23 *S. dysenteriae,* 42 *S. flexneri* and 37 *S. sonnei* including UKMCC1015 (Supplementary Table S2). The core genome sequences were determined using Roary v3.13.0 (Page *et al.* 2015), which were then used for multiple sequence alignment using PRANK (Löytynoja 2014). The phylogenetic tree was inferred using RAxML (Stamatakis 2014) with 100 bootstrap replicates and visualized using FigTree v1.4.3 (http://tree.bio.ed.ac.uk/software/figtree). The tree was rooted using *E. coli* K12 strain.

Growth curve under different antibiotic concentrations

The MIC of *S. sonnei* UKMCC1015 was determined to be 0.08125 µg/ml using broth dilution method. To determine the antibiotic concentration used for transcriptome analysis, the growth curve of *S. sonnei* UKMCC1015 was determined using 0xMIC, 0.1xMIC (0.008µg/ml), 0.25xMIC (0.02 µg/ml) and 0.5xMIC (0.04 µg/ml) of norfloxacin (TCI, Japan). Briefly, the overnight bacterial culture was aliquoted to 50ml of broth containing the different antibiotic concentrations. The OD at 600nm was obtained every 15 minutes for 5.5 hours. The growth curve was performed in triplicates. As 0.1xMIC was shown to have the least growth defect on the bacteria, further analysis was performed using 0.1xMIC

Total RNA extraction

RNA isolation of the samples was performed in duplicates. S. sonnei UKMCC1015 were grown overnight at 37°C with shaking at 200 rpm. Four 250ml conical flasks containing MH broth were inoculated with the overnight culture to an initial optical density of 0.05 at 600nm. 0.1xMIC of norfloxacin were added to two of the experimental cultures. The culture was then incubated 37°C with shaking at 200 rpm until it reached mid-log phase (OD 600nm of 0.5). As a control, another set of duplicates was done without exposure towards norfloxacin. The bacterial cell pellets obtained were frozen before RNA extraction. Total RNA extraction was done using Trizol™ reagent (Invitrogen, US) according to the manufacturer's instructions. Briefly, the frozen bacterial cells were defrosted in ice at room temperature, and the cells were collected by centrifuging at 4°C, 4000 rpm for 10 minutes. The obtained pellet was resuspended with Trizol and incubated at room temperature for 5 minutes for complete dissociation of nucleoprotein complexes. After adding chloroform and incubating at room temperature for 5 minutes, the mixture was centrifuged at 13000 rpm at 4°C for 15 minutes. The colourless aqueous phase was obtained and an equal amount of isopropanol was added. The mixture was incubated in ice for 10 minutes, then centrifuged at 13000rpm for 10 minutes. To wash the RNA from the salt residue, 75% ethanol was added to the pellet. After centrifuging at 13000 rpm at 4°C for 5 minutes, the supernatant was completely removed. The pellet was air-dried for around 10 minutes and resuspended in sterile Milli-Q water.

cDNA library preparation and sequencing

rRNA depletion was performed using the MICROB*Express* Bacterial mRNA Enrichment kit (Thermo Fisher Scientific, Massachusetts, USA) following the manufacturer's protocol, followed by cDNA library preparation using the NEBNext Ultra RNA Library Prep Kit for Illumina (New England Biolabs, Massachusetts, USA). DNA library quality control was done by measuring concentration using Qubit 2.0 fluorometer (Invitrogen, California, USA) and assessing the size distribution using TapeStation 2200 (Agilent Technologies,California, USA). All libraries were pooled equimolar and 15pM was loaded into the MiSeq cartridge. Sequencing was performed on the MiSeq system using a 150 bp run configuration.

Bioinformatics analyses

The *Shigella sonneii* UKMCC genome (GenBank assembly accession: GCA_014217935.1) was used as the reference genome to map the RNA sequencing data. Genome annotation was obtained from the NCBI PGAP annotation. To find additional ncRNA genes in the genome, *Shigella sonneii* Ss046 ncRNA sequences from the BSRD database (Li et al., 2013) were used to BLAST against *Shigella sonnei* genome; BLAST hits were then appended into the annotation. To properly merge the two annotation sources if annotations of the two sources overlap, PGAP annotation takes precedence over BLAST BSRD hits.

Illumina adapter sequences and low quality bases were trimmed off using Trimmomatic v0.39 using parameters ILLUMINACLIP:adapters.fa:2:30:10:1:true, SLIDINGWINDOW:5:20, LEADING:20, TRAILING:20 (Bolger et al., 2014). The trimmed, quality-filtered reads were mapped to the reference genome using Bowtie2 v2.3.5 and samtools v1.9 (Langmead and Salzberg, 2012; Li et al., 2009). The counting of the alignments on annotated genes was done using htseq-count v0.11.2 using parameters mode = union, order = pos and minaqual = 0 (Anders et al., 2015). Features included into htseq counting were CDS, rRNA, ncRNA, tRNA, antisense RNA and riboswitch. Differential abundance analyses and visualizations were conducted on Degust web platform (Powell, 2017) using the edgeR quasi-likelihood method. The clusters of orthologous groups (COGs) of the genes were determined using eggNOG (evolutionary genealogy of genes: Non-supervised Orthologous Groups) web-based server (Huerta-Cepas *et al.* 2018).

Results

Genome analysis reveals AMR genes, prophages and genome islands

Using hybrid assembly, a closed chromosome and two plasmids were obtained for *S. sonnei* strain UKMCC1015 (Figure 1, constructed using BRIG (Alikhan *et al.* 2011)). The chromosome has a size of 4,926,332 bp, while the two plasmids (termed UKMCC1015_2 and UKMCC1015_3) have a size of 7,231 and 2,101 bp, respectively, with an average GC content of 51.03%. Annotation with PGAP predicted a total of 4808 coding sequences (CDS), 103 tRNA, 22 rRNA and 11 ncRNA in the UKMCC1015 genome. The UKMCC1015 strain has two plasmids: UKMCC1015_2 (7k bp) and UKMCC1015_3 (2k bp). We performed sequence comparison using *sourmash* (Pierce *et al.* 2019) against the PLSDB database (Galata *et al.* 2018). UKMCC105_2 has the highest similarity (34%) with NZ_CP027259.1 *E. coli* strain EC11 plasmid unnamed4. UKMCC1015_3 has the highest similarity (98.6%) with CM009398.1 *S. sonnei* strain 4351 plasmid p_C.

UKMCC1015 has 45 annotated AMR genes that are involved in the resistance of fluoroquinolone, macrolides, tetracycline and many others (Figure 1a. Full list in Supplementary Table 1). Interestingly, there were no AMR genes detected on the two plasmids, even though numerous resistance genes are often of plasmid origins, such as plasmid-mediated quinolone resistance (PMQR) genes namely *qnr,* or extended spectrum beta-lactamase (ESBLs) (Ranjbar & Farahani 2019). Other than that, phage profiling by PHASTER (Arndt *et al.* 2016) showed 17 prophage regions, including 10 intact regions (Figure 1a). These regions showed homology towards enterobacteria phages including SflV, phiP27, DE3 and Gifsy-2, and they carry multiple transposase and integrase genes. Insertion elements (IS) are associated with genome degradation as they cause loss of gene function by disrupting coding sequences, or genome rearrangement. *Shigella* genomes often contain a high number of IS which leads to formation of pseudogenes (inactivated genes) (Feng, Chen & Liu 2011). There are a total of 404 insertion sequences in UKMCC1015 detected using ISEScan (Xie & Tang 2017) from numerous IS families such as IS1, IS3, and IS4. This genome also contained 662 pseudogenes, most of which are frameshifted, incomplete or contain an internal stop, or multiple problems in one gene. Almost all pseudogenes in *Shigella* spp. are directly caused by IS, demonstrating that IS can have a significant effect on the Shigella genome.

Figure 1: **A. Closed chromosome of *Shigella sonnei* UKMCC1015.** UKMCC1015_1 (chromosome), from inner ring outwards: GC skew, Genome Islands (Grey, obtained from IslandViewer, predicted with at least 2 prediction methods), Prophage regions (Blue, underlined, obtained from Phaster), AMR genes (Black, obtained from Abricate using databases CARD). B.

To establish the phylogenetic relatedness of UKMCC1015 strain within all *Shigella*, a total of 122 *Shigella* complete genomes from NCBI, including UKMCC1015, with one *Escherichia coli* K-12 substrain MG 1655 were obtained (Figure 2). Compared to other species, *S. sonnei* has a monophyletic clade, indicating their clonal nature, and this is supported by other phylogenetic studies of *Shigella* (Pupo, Lan & Reeves 2000; Sahl *et al.* 2015). Other species of *Shigella,* however, did not have monophyletic genomic distribution. From the phylogenetic analysis, while *S. sonnei* are in the same clade except for one species *S. sonnei* SE6-1, other *Shigella* species are not monophyletically distributed. This is supported by other phylogenetic studies of *Shigella* (Pupo, Lan & Reeves 2000; Sahl *et al.* 2015). All *Shigella* spp. and enteroinvasive *E. coli* are derived from *E. coli* several times independently and formed a single pathovar (Yang *et al.* 2005). Traditionally, to differentiate *Shigella* from *E. coli* as well as to identify their species, biochemistry and serotyping was used to differentiate the pathogenic *Shigella* from the previously known to be non-pathogenic *E. coli* (Chattaway *et al.* 2017). However, the recurring problem with differentiating *Shigella* from *E. coli* demonstrated that they are closely related to the extent that they should be classified as the same species (Pettengill, Pettengill & Binet 2016). Additionally, species designation among *Shigella* which is done through biochemistry and serotyping does not support the clustering using phylogeny, as can be seen from the mixing of species in a cluster (Figure 3). Thus, the phylogenetic analysis demonstrates that *S. sonnei* is monophyletic according to core genes comparison, unlike other *Shigella* species.

Figure 2: Phylogeny of complete *Shigella* genomes with an *E. coli* representative strain. Genomes of all complete *Shigella* (*S. boydii,* SB, black without symbol, *S. dysenteriae,* SD, cyan circle, *S. flexneri,* SF, blue triangle, *S. sonnei,* SS, orange star) genomes including UKMCC1015 (black arrow) and *E. coli* K12 MG1655 (maroon square) were used.

Transcriptome analysis

Growth curve of *S. sonnei* UKMCC1015 under different concentrations of norfloxacin indicated that 0.1xMIC norfloxacin causes the least growth defect (Figure 3a). Thus the transcriptome analysis was performed using 0.1xMIC. The total RNA of *S. sonnei* UKMCC1015 grown on normal broth (control) and under 0.1xMIC norfloxacin (experimental) was extracted, sequenced and analysed. The total read counts of all the genes were used in Degust (Powell 2017) to determine the differentially expressed genes (DEGs) (Figure 3). Relative to the control, there are a total of 151 DEGs in the experimental group. 52 genes show >2-fold upregulation, while 99 genes show >2-fold downregulation (Figure 3b. Full list of DEGs in Supplementary Table 3). Among these 151 genes, 4 are ncRNAs and 9 are pseudogenes. Thus, the remaining 138 genes were categorized using the COG database to further elucidate their role in *S. sonnei* response towards 0.1xMIC norfloxacin (Figure 3c). The top five categories are J (translation, ribosomal structure and biogenesis) with 54 genes, K (transcription) with 14 genes, S (function unknown) with 14 genes, C (energy production and conversion) with 11 genes, and F (nucleotide transport and metabolism) with 9 genes.

Figure 3: A. Growth curve of *S. sonnei* UKMCC1015 under 0xMIC, 0.1xMIC, 0.25xMIC and 0.5xMIC of norfloxacin. **B.** Volcano plot of transcriptome analysis. **C.** COG categorization of the 136 genes annotated by the non-supervised Orthologous Group (eggNOG).

Figure 4: A. Heatmap of DEGs of the four top categories - Category J (translation, ribosomal structure and biogenesis), Category K (transcription), Category C (energy production and conversion), and Category F (nucleotide transport and metabolism). **B.** Heatmap of AMR genes and norfloxacin

targets. **C.** Ribosomal proteins operons of *S. sonnei* UKMCC1015. Green indicates genes that are differentially expressed, grey indicates genes that are not differentially expressed.

Ribosomal protein genes are downregulated in response to sub-lethal norfloxacin

56 DEGs are in the COG category J (translation, ribosomal structure and biogenesis). Two genes, *iraP* and *raiA* are upregulated, while the rest of the genes are downregulated. The downregulated genes encode for ribosomal proteins (r-proteins), which are commonly expressed in operons. Among all the DEGs, 42 genes are expressed in 8 operons, suggesting that any regulation towards these genes are done through the promoters of these 8 operons. To further investigate these operons and their gene order, the locus of these r-proteins genes are identified (Figure 4c) and compared to *Escherichia coli* K12 (Supplementary Figure S1). Except for rpsP operon, the r-proteins operons of both this strain and *E. coli* K12 have the same orientation and the gene positions, indicating their similarity. The downregulation of r-proteins may be a result of a common regulator, and one potential regulator is the alarmone nucleotides, guanosine tetraphosphate and guanosine pentaphosphate, collectively referred to as (p)ppGpp (ppGpp from here on). ppGpp is involved in the stringent response, which is triggered during amino acid or fatty acid starvation, or other environmental stress such as osmotic shock, heat shock and oxygen variation (Pacios *et al.* 2020). Some roles of ppGpp include growth rate control by inhibiting production of ribosomal RNA, and regulation of general metabolism through expression of genes in amino acid biosynthesis, and nucleotide biosynthesis and uptake (Hauryliuk *et al.* 2015). The elevated ppGpp levels leads to this molecule binding to DksA to downregulate the transcription of multiple r-proteins operons. In the stringent response, this downregulation would conserve energy during nutrient starvation. Hence, these results suggest that *S. sonnei* increases the levels of intracellular ppGpp as a response towards low levels of norfloxacin.

The gene *iraP* encodes for anti-adapter protein IraP that increases the stability of the signal stress factor RpoS (σS) and inhibits its proteolysis (Bougdour *et al.* 2008). In particular, *iraP* promoter is positively regulated by ppGpp, leading to the rapid accumulation of the stress factor. Along with other genes regulated by ppGpp, the anti-adapter protein IraP can affect the σS response. The gene *raiA* encodes for ribosome-associated inhibitor A, which role is to interfere with translation by blocking the dissociation of 70S ribosome (Agafonov & Spirin 2004). The upregulation of this inhibitor will cause a disruption in translation, thereby downregulating translation. In general, genes in this category are regulated to ultimately reduce translation.

Downregulation of cold shock proteins and transcription factors

Among the 14 DEGs in the category K (transcription), four genes involved in transcription termination and antitermination are downregulated (*cspA, cspC, nusA* and *nusG)*. The two cold-shock domain family proteins (Csps) genes, *cspA* and *cspC* can function as RNA chapenrones to maintain the single-stranded state of target RNA, allowing efficient transcription and translation (Keto-Timonen *et al.* 2016). CspA is inducible by cold, while CspC is constitutively expressed during growth at 37C (Phadtare & Inouye 2001). Both CspA and CspC, were shown to be transcription antiterminators, and their overexpressions are capable of inducing transcription of genes downstream of multiple transcription terminators (Bae *et al.* 2000). Other than the Csps, two transcription termination/antitermination proteins expressions, *nusA* and *nusG* are downregulated. These two transcription factors can affect the speed of RNA chain elongation and termination, and they are both involved in Rho-dependent termination (Burns *et al.* 1998). NusA both promotes intrinsic transcription termination (Gusarov & Nudler 2001; Mondal *et al.* 2016) and antitermination factor in the presence of P7 (Esyunina *et al.* 2015; You *et al.* 2019). Additionally, NusA is demonstrated to be crucial in stress-induced mutagenesis (Cohen & Walker 2010), and it is involved in the cellular response to DNA damage through coupling nucleotide excision repair (NER) and translesion synthesis (TLS) processes to transcription (Cohen *et al.* 2010). Similarly, NusG is essential for transcription termination and antitermination, both enhancing the RNA polymerase processivity (Burova *et al.* 1995) and regulating the Rho-dependent termination (Pasman & von Hippel 2000). The effects of the downregulation of these two transcription factors remains unclear in terms of *S. sonnei* response towards norfloxacin, and needs further investigation.

Downregulation of genes involved in energy production and nucleotide metabolism

All the DEGs in category C (energy production and conversion) and F (nucleotide transport and metabolism) are downregulated except for *dmlA* and *ygcN* from category C. *dmlA* encodes for the d-malate dehydrogenase which allows for aerobic growth on d-malate as the sole carbon source (Stern & Hegre 1966). *ygcN* encodes for the probable electron transfer flavoprotein-quinone oxidoreductase YgcN. It is thus indicated that 0.1xMIC norfloxacin exposure had led the bacteria to downregulate energy production and nucleotide metabolism. This is interesting because ppGpp is shown to positively regulate energy production/conversion (Yang *et al.* 2020). Additionally, ppGpp plays a role in maintaining normal cellular energy homeostasis (Roghanian *et al.* 2019). However, it is unclear whether it is the downregulation of energy production leading to a decrease in ATP production that ultimately leads to the stringent response, or if ppGpp is the one responsible to repress energy production. Other than that, nucleotide transport and metabolism are repressed. All nine DEGs are involved in the synthesis of nucleotides. Nucleotide metabolism has also been shown to be affected by

ppGpp (Traxler *et al.* 2008; Liam *et al.* 2018). It is possible that the stringent response has downregulated nucleotide synthesis in order to conserve energy.

<u>Common AMR genes and norfloxacin targets (gyrase and topoisomerase IV) are not differentially expressed during 0.1xMIC exposure</u>

In the *S. sonnei* UKMCC1015 genome, CARD has annotated 45 AMR genes, and 19 of these genes confer resistance to fluoroquinolones by antibiotic efflux. However, none of these genes are differentially expressed during 0.1xMIC norfloxacin exposure. Several studies on fluoroquinolone-resistant *Shigella* indicate that the overexpression of genes encoding efflux pumps contributes to their resistance towards fluoroquinolones (Kim *et al.* 2008; Yang *et al.* 2008; Taneja *et al.* 2015). This suggests that the initial transcriptional response of a fluoroquinolone-sensitive bacteria is different from resistant ones. Instead of overexpressing the efflux pumps available, the sensitive strain perhaps uses other pathways as a response towards 0.1xMIC norfloxacin.

There are 5 DEGs that are commonly regarded as SOS genes (Simmons *et al.* 2008). The genes that are upregulated are *dinB, sulA, recN* and LexA family transcriptional regulator. *nrdB* and *purF* which are LexA-independent genes are downregulated. Norfloxacin and other fluoroquinolones commonly induce the SOS response through production of DNA double-stranded breakage (DSBs) by blocking DNA gyrase and affecting the DNA replication (Pohlhaus & Kreuzer 2005; Qin *et al.* 2015). However, there is little evidence that supports the suggestion that SOS response is induced as only these 5 genes are differentially regulated. No late SOS genes such as *umuCD* were differentially regulated. *umuCD* encodes for error-prone DNA polymerase V, and they are induced only when the damage is extensive (Maslowska *et al.* 2019). Under 0.1xMIC norfloxacin, the damage done by the antibiotic is not sufficient to induce the SOS response.

There are also no changes in the expression of *gyrA, gyrB, parC* and *parE* (Figure 4B)*.* These genes encode for DNA gyrase and topoisomerase IV, which are the targets of norfloxacin. This is interesting because commonly the regulation of antibiotic target genes are often differentially regulated in response to antibiotic exposure. Machuca *et al.* (2017) reported that low-level quinolone-resistant *E. coli* downregulates the genes of DNA gyrase subunits. In contrast, exposure towards norfloxacin induced the expression of *gyrA* and *gyrB* in *Acinetobacter baumannii* (Heo *et al.* 2014). Similarly, *E. coli* overexpresses *gyrA* as a response towards DNA gyrase inhibitors such as norfloxacin and aminocoumarin (Neumann & Quinones 1997; Anderle *et al.* 2008). Even though the main fluoroquinolone resistance mechanism is linked to chromosomal mutations of *gyrA* and *parC* (Fabrega *et al.* 2009) and not their regulation, it is possible that the upregulation of the drug target is an attempt to oversaturate the antibiotics. This increases the levels of DNA gyrase not bound to the drug, thus reducing the amount of double-stranded DNA breaks that the antibiotics can cause. In our

case, the normal expression of these target genes suggest that the bacteria has other methods of responding to the effects of norfloxacin.

<u>The increase in the levels of a small regulatory RNA GcvB suggest possible role in antibiotic response</u>

S. sonnei UKMCC1015 differentially expressed a small regulatory RNA GcvB. GcvB is upregulated during exposure to 0.1xMIC norfloxacin, which is interesting because there has not been any correlation between this small regulatory RNA with norfloxacin or fluoroquinolone response. In fact, there is only one study linking GcvB to D-cycloserine, an antibiotic that inhibits cell wall biosynthesis. GcvB in *E. coli* negatively regulates *cycA,* a gene that encodes for a permease that can transport D-cycloserine, thus providing resistance (Pulvermacher *et al.* 2009). However, GcvB can promote mutagenic break repair (MBR) via the general σS stress response by indirectly promoting membrane integrity and suppressing the competing σE membrane stress response (Barreto *et al.* 2016). As norfloxacin causes DSBs, GcvB may be upregulated in response to norfloxacin to fix the damages through MBR. The mutations caused by these repair systems might lead to the chromosome-mediated quinolone resistance, including the mutations in the *gyrA* genes and *parC* genes (Fabrega *et al.* 2009). Thus, the upregulation of GcvB to indirectly promote mutagenesis may be one of the methods used by the sensitive *S. sonnei* to develop resistance.

The targets of GcvB such as *oppA* and *dppA* are not differentially regulated in *S. sonnei* during 0.1xMIC exposure. GcvB, like any other small non-coding RNAs (sRNAs) regulate multiple mRNAs at the post-transcriptional level. For example, GcvB regulates *phoPQ* by binding to the translation initiation region (TIR) of the *phoPQ* mRNA, thereby blocking ribosome binding and translation initiation (Coornaert *et al.* 2013). The mRNA will thus be degraded over time. However, it has been shown that oppA and dppA are not involved in σS stress response, while GcvB does not regulate *rpoS* at the transcriptional level (Jin *et al.* 2009). This may explain why these two genes are not differentially expressed in response to sub-lethal norfloxacin.

Discussion

In this study, the effects of sub-lethal norfloxacin towards the gene expression of the fluoroquinolone-sensitive *S. sonnei* were demonstrated. In response to 0.1xMIC of norfloxacin, *S. sonnei* differentially expressed 148 genes. The results show that the exposure towards sub-MIC of norfloxacin causes *S. sonnei* to: 1) downregulate the ribosomal proteins expression, indirectly indicating that the bacteria increases the production of ppGpp; 2) upregulate a small regulatory RNA GcvB; and 3) trigger the SOS response. More surprisingly, even though this strain has AMR genes in its genome, they are not differentially expressed. Additionally, the targets of the norfloxacin, DNA

gyrase and topoisomerase IV are also not differentially expressed. In general, *S. sonnei* downregulates translation, transcription, energy production and nucleotide production in order to cope with the sub-lethal norfloxacin, possibly through a never-before reported pathway that includes increasing ppGpp and GcvB levels in the cell.

Currently, there is no link between ppGpp and GcvB nor with norfloxacin. But there are studies showing that ppGpp can lead to antibiotic tolerance and formation of persister cells, thus contributing to antibiotic resistance (Das & Bhadra 2020). Additionally, ppGpp can inhibit the gene expression of DNA gyrase (*gyrA*) and topoisomerase IV (*parC*), which are targets of norfloxacin (Fernandez-Coll *et al.* 2020). DNA replication is inhibited by ppGpp to help the bacteria stabilize the genome DNA during starvation as well as conserving energy (Fernandez-Coll *et al.* 2020; Yang *et al.* 2020). Yang *et al.* 2020 also showed that ppGpp can suppress SOS system, which is contradictory to another paper stating that the stalling of transcription elongation complexes and the arrest of DNA replication forks by ppGpp can expose the single-stranded DNA and thus induce the SOS response (Srivatsan & Wang 2008).

In this study, both stringent response and SOS response are activated by 0.1xMIC norfloxacin as seen from the downregulation of the r-proteins genes and the upregulation of SOS genes. Comparing the number of genes involved in each of these two systems, the response of the fluoroquinolone-sensitive *S. sonnei* towards norfloxacin at sub-MIC seems to lean towards the stringent response. The bacteria enters a semi-dormant state with the repression of the pertinent genes by ppGpp, with the end result of decreased ribosomal proteins and production, and the decrease in 70S ribosome due to the upregulation of *iraP* by ppGpp. By decreasing the DNA replication, the bacteria decreases the effect of norfloxacin on the DNA gyrase and topoisomerase IV. This is also supported by how *gyrA* and *parC,* the targets of norfloxacin are not being upregulated. Instead of increasing the amount of targets and DNA replication to overwhelm the concentration of antibiotics like others (Heo *et al.* 2014), this fluoroquinolone-sensitive *S. sonnei* decreases its activities and becomes semi-dormant.

Exposure to sub-lethal antibiotics are known to be able to induce tolerance and even resistance in sensitive bacteria (Gullberg *et al.* 2011; Chow, Waldron & Gillings 2015; Wistrand-Yuen *et al.* 2018). This is also seen in our study where exposure to 0.1xMIC and 0.5xMIC of norfloxacin for 250 generations can lead to an increased number of cells able to grow at certain concentrations of antibiotics. Studies on the genome of bacteria that were grown under sub-lethal concentration of antibiotics for more than 100 generations showed that the weaker selective pressure can induce and select for small resistance mutations. This suggests that the low concentration of antibiotics can induce mutations in the genome through the process of inducing ppGpp and GcvB. And therefore the bacteria develops the small resistance mutations that ultimately are selected by the presence of antibiotics in the environment.

In conclusion, 0.1xMIC of norfloxacin triggers SOS response as well as the stringent response in fluoroquinolone-sensitive *S. sonnei* UKMCC1015 as seen through the upregulation of *lexA* and downregulation of r-proteins genes expression. This is the first study to link norfloxacin with the downregulation of r-proteins genes through a possible increase in the cellular ppGpp levels. This is also the first study to observe the increase of the small regulatory RNA GcvB during norfloxacin exposure. The exposure towards sub-MIC of norfloxacin causes the downregulation of transcription, translation, energy production, and nucleotide metabolism in the fluoroquinolone-sensitive *S. sonnei*.

Table S2: List of strains used in phylogenetic tree, including 19 *Shigella boydii,* 24 *Shigella dysenteriae,* 43 *Shigella flexneri,* 36 *Shigella sonnei,* and *Escherichia coli* K-12 substrain MG 1655

Table S3: Total list of genes and non-coding RNAs annotated in the transcriptomic study. Bold indicates the differentially expressed genes (DEGs) in *Shigella sonnei* UKMCC1015 in response to 0.1xMIC of norfloxacin.

Figure S1: Comparison of ribosomal protein operons between *E. coli* K12 (left) and *S. sonnei* UKMCC1015 (right). Other than operon 8 where the orientation of the operon in *S. sonnei* is the opposite of *E. coli* K12, the other 7 operons are similar to each other.
