Abstract

Pharmaceuticals find their way to the aquatic environment via wastewater treatment plants (WWTPs) and biodegradation plays an important role in mitigating environmental risks, however a mechanistic understanding of involved processes is limited. The aim of this study was to evaluate potential relationships between first-order biodegradation rate constants (ka) of nine pharmaceuticals and initial concentration of the selected compounds, and sampling season of the used activated sludge inocula. Four-day bottle experiments were performed with activated sludge from WWTP Groesbeek (The Netherlands) of two different seasons, summer and winter, spiked with two environmentally relevant concentrations (3 and 30 nM) of pharmaceuticals. Concentrations of the compounds were measured by LC-MS/MS, microbial community composition was assessed by 16S rRNA gene amplicon sequencing and ka values were calculated. The biodegradable pharmaceuticals, ranked from high to low biodegradation rates, were acetaminophen, metformin, metoprolol, terbutaline, and phenazone. Carbamazepine, diatrizoic acid, diclofenac and fluoxetine were not converted. Summer and winter inocula did not show significant differences in microbial community composition, but resulted in a slightly different ka for some pharmaceuticals. Likely microbial activity was responsible instead of community composition. In the same inoculum different ka values were measured, depending on initial concentration. In general, biodegradable compounds had a higher ka when the initial concentration was higher. This demonstrates that Michealis-Menten kinetics theory has shortcomings for some pharmaceuticals at low, environmentally relevant concentrations and that the pharmaceutical concentration should be taken into account when measuring the ka in order to reliably predict the fate of pharmaceuticals in the WWTP.

Keywords: kinetics; sorption; organic micropollutants; wastewater treatment plants; bacterial community; nitrification

1. Introduction

Tonnes of pharmaceuticals are prescribed annually, which partly find their way to the aquatic environment via sewage systems and wastewater treatment plants (WWTPs) (Fent et al. 2006). The concentration of these pharmaceuticals in the aquatic environment is generally low (ranging from nM to µM concentrations), and thus they are considered as organic micropollutants (OMPs). Even at such low concentrations, they can elicit large adverse
effects on aquatic life including long-term or short-term toxicity (e.g. Fent et al. 2006, Santos et al. 2010). In
WWTPs, the fate of a pharmaceutical is mostly influenced by microbial biodegradation (Verlicchi et al. 2012), a
process which is still difficult to capture accurately with modelling approaches. Statistical quantitative structure
activity relationship (QSAR) models can describe approximately 50% of the variability in biodegradation rate
constants (e.g. Nolte et al. 2020). This explains for a large part why some OMPs, including pharmaceuticals, are
better removed than others. However, the question remains why some WWTPs remove specific pharmaceuticals
better than others. Statistical meta-analyses either find a low explanatory value for the removal efficiency of a large
structurally diverse set of OMPs, including pharmaceuticals (17%; Douziech et al. 2018), or perform better but are
limited to specific groups of OMPs, including (R2adj ranged from 0.35-0.73; Wang et al. 2020). Due to the limited
knowledge on general principles influencing microbial conversion of pharmaceuticals, biodegradation is yet not
modelled mechanistically in fate models such as SimpleTreat, which is part of the European Union System for the
Evaluation of Substances (Franco et al. 2013, Struijs 2014).

Instead, biodegradation rate constants used in fate models are typically estimated with standard methods such as
OECD tests (OECD TG 301 series, TG 310, TG 302 series, TG 314B and TG 303A, in case of SimpleTreat). It has
to be noted that these tests are not designed for this purpose, but rate constants can nevertheless be derived from
percentage removal or biodegradability categories (Struijs 2014). When OECD test outcomes are used to predict the
fate in WWTPs, the environmental realism of the biodegradation rate constants is questionable as the test outcomes
apply to specific incubation conditions with a long time duration and the microbial community composition of the
inoculum varies (Goss et al. 2020, Kowalczyk et al. 2015, Li and McLachlan 2019, Rücker and Kümmner 2012). In
most OECD screening tests pharmaceutical concentrations of 10–400 mg of carbon per liter may be applied
(Kowalczyk et al. 2015), which is far above environmentally relevant concentrations (in the range of µg L⁻¹) and this
may affect biodegradation rate constants. Recent studies showed that first-order biodegradation rate constants depend
on initial concentration in activated sludge treatment plants (Nolte et al. 2020) and in biofilm reactors (Svendsen et
al. 2020). Biodegradation rate constants are often calculated as pseudo-first order constants (hereafter referred to as
kb, Schwarzenbach et al. 2005), assuming no saturation of enzymes occurs and the maximum velocity of the reaction
is not reached (for more information, see 2.4.1). In the calculation of kb, an effect of concentration is already taken
into account as the decrease in concentration over time depends on a rate constant and the concentration. Svendsen et
al. (2020) showed that for some pharmaceuticals, kb did not follow typical Michaelis-Menten kinetics at low,
environmentally relevant concentrations (1-10 µg L⁻¹) as kb is expected to stay constant and the removal rate
decreases over time as a result of the changing concentration. Instead, the kb of some pharmaceuticals such as
metoprolol increased with increasing initial concentration.

The concentration of pharmaceutical compounds in the influent of WWTPs can vary between seasons as a result of
different consumption patterns by the population and a different amount of rainfall (Caucci et al. 2016, Di
Marcantonia et al. 2020). Furthermore, WWTP operational parameters (i.e. solid retention time and hydraulic
retention time) and other environmental conditions such as temperature have seasonal variability (Awolusi et al.
2018, Limpiyakorn et al. 2005). As a consequence of these changes, different microbial community compositions
have been found in same WWTPs at different seasons. For example, ammonia oxidizing bacteria (AOB) were often
found more abundant during summer than during winter and this was correlated to higher nitrification rates and
et al. 2012). Previous experiments have observed a positive correlation between the kb of specific pharmaceuticals
and ammonium removal or nitrification rate (Fernandez-Fontaina et al. 2012, Helbling et al. 2012). Furthermore,
higher abundance of specific microbial taxa has been correlated to a higher kb and removal efficiency of some
pharmaceuticals in AS (Helbling et al. 2015, Kim et al. 2017).

The aim of this study was to determine the influence of initial pharmaceutical concentration and sampling season of
AS inocula on the kb of pharmaceutical compounds. To our knowledge, this is the first time that the effect of
pharmaceutical concentration on kb is experimentally studied in activated sludge by means of a batch test. We
selected nine pharmaceuticals based on high prescription rates in Europe (Fent et al. 2006) and/or with a high priority
to monitor due to adverse environmental effects (i.e. pharmaceuticals on EU and Dutch watch lists): acetaminophen,
metformin, diclofenac, metoprolol, terbutaline, diatrizoic acid, fluoxetine, and carbamazepine. Four-day batch assays
were performed with AS inocula of the same WWTP taken at different seasons (summer and winter). Biodegradation
rate constants and solids water partition coefficients (kb and kd, respectively) were generated at two environmentally
relevant concentrations (3 and 30 nM). Summer and winter samples were analyzed on nitrification activity and
microbial community. We hypothesized that i) a higher spiked concentration in the range of 3 to 30 nM result in a
higher kb; ii) inocula taken at different seasons in the same WWTP have different characteristics (i.e. microbial
community, nitrification activity and pharmaceutical concentration) that will affect the biodegradation rate constants of pharmaceuticals, with higher rate constants during summer.

2. Materials and methods

2.1. Chemical selection and experimental setup

We conducted biodegradation assays with nine pharmaceuticals (Table 1) twice: in June 2019 (summer) and December 2019 (winter). The log $K_{ow}$ was obtained from Drugbank (Wishart et al. 2006), while information on the solid form of the pharmaceuticals was provided by the supplier (SI 1).

Table 1. Information on the pharmaceuticals selected in the experiment and the solid form that was used to obtain the dissolved spiking mixture. Log $K_{ow}$ is the octanol water partition coefficient.

The removal of pharmaceuticals was tested for a duration of 96 h, which is sufficient to observe short term activity due to the high microbial activity of undiluted activated sludge samples (e.g. Helbling et al. 2010). As the AS samples were undiluted and microorganisms were not washed in order to obtain environmental realism of the test, no lag phase was anticipated on. We tested three treatments in summer and winter AS inocula (Figure 1):

1) “AS” treatment: where we evaluated pharmaceutical biodegradation at low concentrations in AS. In the summer experiment we measured the removal of background concentrations and in the winter experiment we spiked 3nM of each pharmaceutical.

2) “AS30” treatment: where we evaluated pharmaceutical biodegradation a high concentration in AS. To do that, we spiked with 30 nM of each pharmaceutical in both summer and winter experiments.
3) “iAS30” treatment: where we assessed the abiotic removal of pharmaceuticals in AS (i.e. sorption). For that we doubled autoclaved AS and spiked 30 nM of each pharmaceutical.

**Figure 1.** Treatments used in the summer and winter experiments: AS was either non-spiked, only including the background concentration of pharmaceuticals (Summer experiment), or spiked with 3 nM pharmaceuticals (Winter experiment); AS30 is the AS treatment that was spiked with 30 nM of pharmaceuticals; and iAS30 is the inactivated sludge treatment that was spiked with 30 nM of pharmaceuticals.

The biotransformation experiments were carried out in 120 mL glass bottles. AS samples were taken from WWTP Groesbeek (Gelderland, The Netherlands), identified as a national hotspot of OMPs (Vissers et al. 2017). This WWTP has a maximum hydraulic capacity of 900 m³/h and it treats mostly domestic water (estimated 90%). The WWTP contains an aeration tanks with a sludge age of 12 days. Five liters of activated sludge were sampled in Winter and Summer time less than 72 hours before the start of the experiment. The sample was immediately transported to the laboratory where it was stored at 4 °C till the start of the experiment (t = 0). Individual stock solutions were prepared in methanol for each pharmaceutical at a concentration of 3 mM. Afterwards, a mixture of the nine pharmaceuticals was prepared in methanol too (final concentration of each pharmaceutical: 0.3 mM). To minimize the potential effects of the methanol solvent, the spike mixture of pharmaceuticals (to a final bottle concentration of 3 or 30 nM) was added to each bottle prior to addition of sampled AS. Methanol was allowed to evaporate in a fume hood with gentle air circulation for approximately 30 minutes and subsequently 90 mL of AS or iAS were added to the bottles. Additionally, 50 mM HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) was added in order to prevent acidification and maintain a pH around 7. Prior incubations showed a drop in pH below 6 leading to inhibition of nitrification (Ruiz et al. 2003) with possible consequences for biodegradation rates. The bottles were manually mixed to allow for complete dissolution of pharmaceuticals and the first samples were taken (t = 0) and centrifuged to separate the sludge from the aqueous phase. Hereafter, samples were taken after 4, 8, 24, 48 and 96 h. Bottles were closed with cotton plugs to allow aeration and prevent contamination from the environment. The bottles were incubated at 15 °C and shaken at 200 RPM to ensure continuous mixing and aeration, so that a constant dissolved oxygen concentration of approximately 1 mg L⁻¹ was maintained. All biotransformation assays were run in triplicates. Bottles were incubated in the dark in order to reflect WWTP conditions and to exclude photodegradation or growth of photoautotrophs. Double autoclaved inactivated sludge bottles (treatment iAS30) were prepared before the start of the experiment (and spiking) by autoclaving bottles at 121 °C and 103 kPa for 20 min and repeating this procedure after 24 h as previously described (Helbling et al. 2010).

2.2. Wastewater analyses of the batch incubation

Temperature and pH were monitored every 24h with a Metrohm Applikon pH meter (Schiedam, the Netherlands). In the beginning and at the end of the experiment (t = 0 and 96h), the dissolved organic and inorganic carbon concentrations (DOC and DIC, respectively) were measured, as well as total suspended solids. Water samples for DIC analyses were filtered with glass-fiber filters (Ø 0.45 µm), stored at 4 °C and measured within 24 h after sampling using infrared gas analyses (IRGA, ABB Advance Optima, Frankfurt, Germany; as in van Bergen et al. 2020). Samples for dissolved organic carbon (DOC) were filtered (Ø 0.45 µm) and analyzed using a Shimadzu TOC-
2.4.2 Sorption analyses

For some pharmaceuticals, only part of the curve was used for model fitting and prior to analyses, the reaction volumes were adjusted to the 96 well plate: 10 µL of sample and 200 µL of OPA reagent. Nitrite was measured colorimetrically at 540 nm using the Griess assay. Afterwards, an incubation with vanadium chloride at 60°C reduced all nitrate to nitrite and the sample was measured again at 540 nm (García-Robledo et al., 2014).

2.4.2 Biodegradation analyses

Biodegradation rate constants are often assumed to follow Michaelis-Menten kinetics (Schwarzenbach et al. 2005), where the reaction rate is a result of enzyme binding, product formation and dissociation of the enzyme-substrate complex (Michaelis and Menten 1913), therefore depending on substrate concentration (Equation 1).

\[
V = \frac{V_{\text{max}} \cdot [S]}{[S] + K_m}
\]  
(Equation 1)

Where \( V \) is the reaction rate (mol L\(^{-1} \) h\(^{-1} \)), \( V_{\text{max}} \) is the maximum reaction rate (mol L\(^{-1} \) h\(^{-1} \)), \([S]\) is the substrate concentration (mol L\(^{-1} \)) and \( K_m \) is the substrate concentration where \( V \) is half of \( V_{\text{max}} \) (mol L\(^{-1} \)). As pharmaceutical concentrations in the wastewater are very low, it can be assumed that the substrate concentration is far below \( K_m \) and the reaction rate is linearly proportional to the substrate concentration. Hence, biodegradation rate constants can be calculated via pseudo-first order biodegradation kinetics (Schwarzenbach et al. 2005):

\[
C_t = C_0 \cdot e^{-k_b t} 
\]  
(Equation 2)

Where \( C_t \) is the concentration at time \( t \) (nM), \( C_0 \) is the concentration at time 0 (nM) and \( k_b \) is the biodegradation rate constant (h\(^{-1} \)). Theoretically, the \( k_b \) (which includes the effect of substrate concentration at each time point) should be constant when the substrate concentration is below \( K_m \).

2.4.2.1 Theory

Biodegradation rate constants are determined according to standard methods (APHA et al. 2017). Ammonium, nitrite and nitrate assays were performed with technical duplicates in 96-well microtiter plates. Ammonium was measured at 420 nm on a 96-well fluorescence spectrophotometer after reaction with OPA reagent (0.54% (w/v) ortho-phthaldialdehyde, 0.05% (v/v) β-mercaptan and 10% (v/v) ethanol in 400 mM potassium phosphate buffer (pH 7.3)) as previously described (In’t Zandt et al. 2018). The reaction volumes were adjusted to the 96 well plate: 10 µL of sample and 200 µL of OPA reagent. Nitrite was measured colorimetrically at 540 nm using the Griess assay. Afterwards, an incubation with vanadium chloride at 60°C reduced all nitrate to nitrite and the sample was measured again at 540 nm (García-Robledo et al., 2014).
To check whether gradual abiotic removal processes (hydrolyses, sorption) occurred in the inactivated sludge treatment, similar first order models were applied for that treatment. When we found a significant rate constant, we subtracted this from the \( k_b \) of the activated sludge treatment in order to obtain the biodegradation rate constants, thereby excluding chemical processes. Additionally, the solids water partition coefficient (\( K_d \)) for each chemical based on the inactivated sludge treatment were calculated, assuming instantaneous sorption, according to equation 3 (as in Helbling et al. 2012):

\[
K_d = \frac{C_{\text{aq}}}{C_{\text{ss}} - C_{\text{aq}}} - 1
\]

where \( K_d \) is the solids partitioning coefficient (\( K_d \), L g\(^{-1} \)); where TSS is the total suspended solids concentration in the sample (g L\(^{-1} \)). The value for \( C_{\text{ss}} \) was directly measured in the aqueous phase for each sample from the glass bottles (t=0; nM). Assuming instantaneous sorption, \( K_d \) can be related to the known spike concentration (\( C_{0,\text{spike}} \), nM) and \( C_{0,\text{aq}} \). All average values are given with their SD (±1SD).

### 2.5. Molecular analyses

#### 2.5.1. Sampling and DNA isolation

Samples were taken from the inoculum before the experiments (in technical triplicates) and from the bottles at the end of the experiments. Sampling consisted of pipetting 2 mL of activated sludge suspension after thorough mixing. Afterwards, samples were centrifuged for 4 min at 20,000 x g: supernatants were transferred to another tube for chemical analysis and pellets were stored at −20°C until further analysis. DNA was extracted and purified using the DNeasy PowerSoil kit (QIAGEN Benelux) following the manufacturer’s instructions. DNA concentrations were determined using the Qubit dsDNA HS Assay kit and a Qubit fluorometer, both from Thermo Fischer Scientific (Waltham, MA USA).

#### 2.5.2. Bacterial 16S rRNA gene sequencing and analysis

DNA samples were submitted to Macrogen (Seoul, South Korea) for amplicon sequencing of the bacterial 16S rRNA gene hypervariable V3 and V4 region. Sequencing was performed on an Illumina Miseq. The primers used for amplification were Bac341F (5′- CCTACGGGNGGCWGCAG-3′) and Bac785R (5′- GACTACHVGGGTATCTAATCC-3′) (Klindworth et al. 2013). Subsequent analysis of the sequencing output files was performed with R version 3.4.1 (R Core Team 2020). Pre-processing of the sequencing data was done using the DADA2 pipeline (Callahan et al. 2016). Taxonomic assignment of the reads was done up to the species level when possible using the Silva non-redundant database version 128 (Yilmaz et al. 2014). Count data were normalized to relative abundances. Data visualization and analysis were performed using phyloseq and ggplot packages (McMurdie and Holmes 2013, Wickham and Wickham 2007). All sequencing data were submitted to the GenBank database under the BioProject ID PRJNA641582 (https://www.ncbi.nlm.nih.gov/bioproject/641582) [available upon acceptance of manuscript; reviewer link: https://dataview.ncbi.nlm.nih.gov/object/PRJNA641582?reviewer=spgi2sb233j9252q74937qeejk].

### 2.5.3. Quantitative PCR

The relative \(cq\) numbers of \(amoA\) gene/16S rRNA gene copy numbers in inocula and samples from experiment bottles spiked with 30 nM or no pharmaceuticals were obtained using quantitative PCR. The above primers were used for 16S rRNA gene amplification. For bacterial \(amoA\) gene amplification, the following primers were used: (5′-GGGGTTTCTACTGGTGGT-3′) and (5′-CCCCCTCGSAAAAGCCTTCTTC-3′) (Rotthauwe et al. 1997). A detailed qPCR protocol can be found in the supplementary material (SI3).

### 3. Results

#### 3.1. WWTP and incubation conditions

Table 2 gives an overview of the characteristics of AS inocula used for the summer and winter experiments. WWTP conditions such as oxygen concentration, DOC and TSS were largely similar in summer and winter at the time of sampling. The water temperature at the WWTP was higher during summer, as well as the DIC concentration, while the concentration of \(NH_4^+\) was higher during winter. During both experiments, samples were incubated at 15 °C,
with an oxygen concentration of approximately 1 mg L\(^{-1}\) and a constant pH of 7 to prevent ionization changes. During both experiments, TSS slightly increased (3.6-4.1 g ds L\(^{-1}\)). In general, the background concentration of pharmaceuticals in the AS was similar (Table 3), with exception of the concentration of metformin, which was almost four times higher in winter (40 nM).

3.2. Nitrification activity

As previously mentioned, the ammonium concentration in the winter inoculum was higher than in summer. All ammonium was completely consumed in active bottles (AS and AS30) in both experiments during the first day (Figure S2). Nitrification activity in summer and winter experiments was quantified via nitrate production since ammonium was probably also consumed by heterotrophic bacteria for biomass production. Nitrite was always below the detection limit (2.5 µM) in active bottles. In the summer experiment, the production of 140 µM nitrate was observed in the first two days. In the winter experiment, an increase of 274 µM nitrate was measured mostly during the last three days of the experiment. Bottles with autoclaved biomass did not produce any nitrate (all data shown in Supplementary Figure S3). The nitrification rate was 17 µmoles nitrate day\(^{-1}\) g TSS\(^{-1}\) in the summer experiment and 28 µmoles nitrate day\(^{-1}\) g TSS\(^{-1}\) in the winter experiment.

3.3 Solid water partition coefficients (K\(_d\))

Solid water partition coefficients were calculated based on instantaneous sorption. We found the highest K\(_d\) for fluoxetine (0.6 ± 0.1 L g\(^{-1}\)), followed by carbamazepine (0.03 ± 0.06 L g\(^{-1}\)), diclofenac (0.02 ± 0.02 L g\(^{-1}\)) and metoprolol (0.01±0.2 L g\(^{-1}\)). Results of the autoclaved inactivated sludge treatment showed that most pharmaceutical concentrations did not decrease in this treatment. Therefore, gradual sorption over time was limited and no chemical processes such as hydrolysis were observed. Only a small but significant decrease of diclofenac was observed in the inactivated sludge treatment, likely due to gradual sorption (0.004 ± 0.001 h\(^{-1}\), p < 0.01).

3.4 Biodegradation rate constants

Table 3 shows background concentrations of pharmaceuticals at the start of the summer and winter experiment and the biodegradation rate constants. No lag phase was observed before biodegradation of pharmaceuticals occurred. Acetaminophen and metformin had a high biodegradability in both experiments. Within 48 hours the concentration of metformin was below the limit of detection (LOD), while for acetaminophen the concentration started to increase again (Figure S4). At the start of the summer experiment (t = 0 h, < 20 minutes after addition of pharmaceuticals), the concentration of acetaminophen was much lower than expected and it was even below LOD in the winter experiment indicating a rapid turnover or uptake by the cells. Biodegradation of acetaminophen was only observed in the treatments with the highest concentration (AS30), while biodegradation of metformin was observed in the low and high concentration treatments (spiked with 3 and 30 nM). The k\(_b\) of metformin increased at higher concentrations of pharmaceuticals in both experiments. Metoprolol and terbutaline were biodegraded in both experiments at lower rates than acetaminophen and metformin. In the summer experiment, the k\(_b\) of metformin increased at higher concentrations of pharmaceuticals, while at the winter experiment biodegradation was only observed in the high concentration (spiked with 30 nM). Terbutaline was only biodegradable when activated sludge was spiked with a high concentration of pharmaceuticals (30 nM). No biodegradation of fluoxetine was observed. Similarly, phenazone was not biodegraded nor adsorbed during the winter experiment. In the summer experiment, we observed a low biodegradation rate for phenazone (0.002 ± 5E-5 h\(^{-1}\)) when activated sludge was spiked with 30
Diclofenac was not biodegraded in both experiments and when activated sludge was spiked with a low concentration of pharmaceuticals (3 nM), we even observed an increase in the diclofenac concentration.

**Table 3.** Pharmaceutical background concentrations, k_b constants (h^{-1}, in case of activated sludge treatments) of summer and winter experiments per treatment. AS is the activated sludge treatment without spiking (summer) or spiked with 3 nM pharmaceuticals (winter) and AS30 is the activated sludge treatment spiked with 30 nM pharmaceuticals. All data points and models used to estimate k_b can be found in Figure S4 and details on the statistical analyses can be found in Table S3.

</table>

*a* indicates p ≤ 0.05, ** indicates p ≤ 0.01 and *** indicates p ≤ 0.001

ns indicates the slope of the concentration over time graph was not significant (Fig. S4)

na indicates that this was not tested

^a In Summer, the spiked concentration was 0 nM, while at Winter, the spiked concentration was 3 nM

^b due to fast biodegradation k_b was based on three timepoints (t = 0, 4 and 8 h), therefore results are insignificant although a trend was observed

^c The limit of detection (LOD) of the pharmaceuticals in our method are reported in Table S1

ns means that the rate constant k_b by the fitted model (equation 1) was not significant (p > 0.05)
3.5 Relationship of $k_b$ with concentration and sludge seasonality

In general, pharmaceuticals with a higher background concentration showed a higher $k_b$ value ($n=5$ pharmaceuticals; difference between pharmaceuticals; Figure 2). Of these compounds, metformin and metoprolol show an increase in $k_b$ with concentration (difference within pharmaceuticals). Small effects of seasonality on $k_b$ were observed. In the winter time, the $k_b$ of acetaminophen was higher than in summer. In winter time, the $k_b$ of metformin was higher on average than in summer time, although standard deviation error bars overlap, the 95% CI did not, indicating a significant difference. Metoprolol and terbutaline had only a slightly higher $k_b$ in summer than in winter time (note that Figure 2 shows the log y-axis). Phenazone was slightly biodegraded in summer, but not in winter time.

Metformin and metoprolol showed a different exponential decrease over time depending on initial concentration in the experiment as a result of spiking and season (Table 3; Figure S4).

![Graph](image.png)

Figure 2. The pseudo-first order biodegradation rate constants $k_b$ (log h$^{-1}$) plotted against initial pharmaceutical concentration (nM) at $t = 0$ of the experiment. All average values are plotted with their SD, but sometimes the SD is too small to see. Colors represent different pharmaceuticals, while circles indicate summer values and triangles indicate winter values.

3.6 Microbial community analysis

Microbial community analysis based on bacterial 16S rRNA gene sequencing was first performed on summer and winter inocula. Alpha diversity indices (Chao1, Simpson, Shannon) were not significantly different between summer and winter inocula ($p$-value>0.05). PERMANOVA testing was used to calculate the significance of compositional differences between the groups. No significant difference was found between inocula ($p$-value > 0.05 at different taxonomic levels). The bacterial community composition is visualized in a relative abundance bar plot at the lowest taxonomic level (Figure 3). Overall, the data show that the microbial communities of summer and winter inocula closely resemble each other. Zooming into the low differences between inocula (based on PERMANOVA calculated eigenvalues), the phyla contributing the most to variation were Bacteroidetes, Firmicutes, and Actinobacteria. All of them were significantly different between both sampling times except for Bacteroidetes. At family level, the main contributors were Burkholderiaceae, Saprospiraceae, Cellvibrionaceae, Haliangiaceae, and Rhodanobacteraceae.

Previous studies suggested a putative role of several microorganisms in acetaminophen degradation in AS (Akay and Tezel 2020, Chopra and Kumar 2020, De Gusseme et al. 2011, Palma et al. 2018, Park and Oh 2020a, b, Park and Seungdae 2020, Żur et al. 2018). Among them, the genera Dokdonella, Flavobacterium, Acinetobacter, and Enterococcus showed a significant ($p$-value < 0.05) relative abundance increase in winter correlating to a higher
biodegradation rate constant of acetaminophen in our experiments (Figure S6 and Figure 2). Microbial community analysis was also performed on biomass at the end of each experiment. The microbial community composition of the inocula and the biomass after 96 h of incubation were still very similar (PERMANOVA p-value > 0.05). There were also no significant microbial community changes between experiment bottles with different pharmaceutical concentrations (PERMANOVA p-value > 0.05). Differences in bacterial amoA gene abundance between inocula and at the end of the bottle incubations were quantified by qPCR and compared as relative cq values using the bacterial 16S rRNA gene cq as internal standard. A small but significant decrease (4%) in the relative cq number of amoA/16SrRNA was observed in the winter inoculum (Figure S7). This result aligns with the higher ammonium concentration found in Groesbeek WWTP due to decreased nitrification during winter. As a result of the higher ammonium concentration present at the beginning of the winter experiment, the nitrification rates in the bottles were higher than during the summer experiment.

Figure 3. Phylum relative abundance of summer and winter inocula. No significant difference in microbial composition was observed between both inocula (PERMANOVA p-value > 0.05).

4. Discussion

In this study we evaluated the effect of initial pharmaceutical concentration and AS seasonality on the biodegradation rate constants ($k_b$) of nine highly prescribed pharmaceutical compounds. Acetaminophen and metformin had the highest $k_b$ followed by metoprolol, terbutaline and phenazone. Diclofenac, carbamazepine, fluoxetine, and diatrizoic acid were not biodegraded at all. The $k_b$ values of biodegradable pharmaceuticals were higher at the highest initial concentration, thereby confirming our hypothesis (i). More specifically, for pharmaceuticals metformin and metoprolol, a higher initial concentration increased their $k_b$ (Table 3; Figure 2), even though in the calculation of $k_b$ the concentration at each point in time is already taken into account (see 2.4.1). For the other biodegradable compounds, the lowest concentration did not result in any biodegradation, which might indicate a mass transfer constrain as previously demonstrated with the well-known pesticide atrazine (Kundu et al. 2019). In general, biodegradable compounds with a higher background concentration in the AS had the highest $k_b$ (Table 3). We observed small differences between the $k_b$ obtained with summer and winter AS inocula. The $k_b$ of acetaminophen and metformin were higher in the winter experiment, while the $k_b$ of terbutaline, metoprolol, and phenazone were slightly lower. The background concentration of the pharmaceuticals was mostly similar in winter and summer, only metformin had a three times higher concentration in winter, explaining the higher $k_b$ in winter. Nitrification rates were significantly higher in the winter experiment as a result of the higher ammonium concentration present at the beginning of the experiment. This could not be clearly linked to a difference in $k_b$ of specific pharmaceuticals, as acetaminophen was likely not degraded by co-metabolism and differences for metformin were low. No significant differences in microbial community composition were observed between the summer and winter inocula (Figure 3; PERMANOVA p-value > 0.05), opposed to our hypothesis (ii) and not between the start and the end of the experiment. Only the relative abundance of putative acetaminophen degraders (Dokdonella,
Microbial communities. Other pharmaceuticals such as carbamazepine and diclofenac showed a higher kb with our amplicon dataset, indicating that metformin degradation is not limited to with metformin degradation (Poursat et al. 2019a). However, the 16S rRNA gene of isolated from activated sludge (Figure S6) (Akay and Tezel 2020, Chopra and Kumar 2020, Palma et al. 2018, De Gusseme et al. 2011). Furthermore, the relative abundance of putative acetaminophen degraders WWTPs (Helbling et al. 2012). In our assays, we observed small kb differences when the inocula came from the process, especially in case for antibiotics.

which are notably higher than the concentrations tested in this study and likely caused inhibition of microbial concentrations higher than environmentally relevant (25-300 µg L-1). Svendsen et al. (2020) furthermore found a increase in kb at environmentally relevant concentrations. It is likely that Michealis-Menten theory is not always sufficient to describe biodegradation at low, environmentally relevant concentrations. Based on Michaelis-Menten kinetics, kb should be constant at low concentrations, when the substrate concentration is far below km (substrate concentration at half the maximum reaction rate, also see theory 2.4.1). We assume this is the case for environmentally relevant concentrations (in the nM range). A possible explanation for this is that Michealis-Menten theory is only developed for one substrate and one enzyme and the enzyme concentration is not considered to increase over time. However, in activated sludge multiple enzymes could be responsible for the biodegrading the same substrate and enzyme concentrations can increase due to microbial growth (Bilal et al. 2019, Tawfik and S 2010). At higher concentrations (above environmentally relevant in the µM range) inhibition processes might start to play a role. For instance, Svendsen et al. (2020) found that the kb of citalopram and metoprolol was decreasing at concentrations higher than environmentally relevant (25-300 µg L-1). Svendsen et al. (2020) furthermore found a decrease in kb with increasing concentration for the ibuprofen, sotalol, atenolol, trimethoprim and diclofenac in the concentration range 0.3-300 µg L-1. Wei et al. (2019) also found that the kb of four pharmaceuticals (metronidazole, bezafibrate, ibuprofen and sulfamethoxazole) was negatively influenced by concentrations ranging from 0.1 to 3 µM, which are notably higher than the concentrations tested in this study and likely caused inhibition of microbial processes, especially in case for antibiotics.

In a previous experiment, pharmaceutical biotransformation kinetics differed when inocula were taken from different WWTPs (Helbling et al. 2012). In our assays, we observed small kb differences when the inocula came from the same WWTP at different seasons, summer and winter. Acetaminophen and metformin biodegradation rate constants were higher in the winter experiment, wherein nitrification rate was higher as well (Figures S2; S3). However, acetaminophen degradation has been associated to heterotrophic bacteria rather than ammonia oxidizing organisms (De Gusseme et al. 2011). Furthermore, the relative abundance of putative acetaminophen degraders (Flavobacterium, Dokdonella, Acinetobacter, and Enterococcus) was significantly higher in the winter inoculum (Figure S6) (Akay and Tezel 2020, Chopra and Kumar 2020, Palma et al. 2018, Zur et al. 2018). A bacterium isolated from activated sludge (Aminobacter sp. affiliated with Phyllobacteriaceae) has been previously correlated with metformin degradation (Poursat et al. 2019a). However, the 16S rRNA gene of Aminobacter was absent from our amplicon dataset, indicating that metformin degradation is not limited to Aminobacter in activated sludge microbial communities. Other pharmaceuticals such as carbamazepine and diclofenac showed a higher kb with
increasing ammonium concentrations in previous 6-day batch experiments inoculated with nitrifying AS (Tran et al. 2009). Likewise, fluoxetine biodegradation has been previously linked to nitrifying activities in a bioreactor of HRT=3.6 days (Fernandez-Fontaina et al. 2012). However, in our assays these three pharmaceuticals did not biotransform at all. Terbutaline, metoprolol, and phenazone biodegradation rates were slightly higher during the summer experiment, wherein nitrification rates were lower. Interestingly, metoprolol biodegradation was inhibited by nitrification in a previous experiment with biomass from constructed wetlands (He et al. 2018). Although there were no significant differences in total microbial community composition between both inocula (Figure 3), there might have been differences in activity of microorganisms able to degrade these pharmaceuticals. Previous studies have reported different microbial composition between seasons (Ju et al. 2014, Liu et al. 2019), but other researchers including us did not observe that (Isazadeh et al. 2016). This shows that microbial seasonal changes might be dependent on each WWTP. In order to identify which exact microorganisms are responsible for all these pharmaceuticals biodegradation under WWTP conditions, further experiments are needed.

5. Conclusion

We can conclude that our test shows environmental realism, as the microbial community did not change during the experiment and can therefore be translated to WWTP conditions. Although we found changes in $k_b$ of pharmaceuticals, this could not be largely explained by microbial community composition. Likely microbial activity was responsible instead. Seasonality had mostly a minor effect on $k_b$ – except for acetaminophen, which was explained by a higher relative abundance of putative acetaminophen degraders. Our test also shows that even similar biodegradation assays with the same inoculum may lead to a different $k_b$, depending on pharmaceutical concentration and that Michaelis-Menten theory is not always sufficient to describe kinetics at very low, environmentally relevant concentrations. Therefore, the pharmaceutical concentration should be taken into account when predicting/measuring the $k_b$ in order to reliably predict the fate of pharmaceuticals in the WWTP. The concentration dependency of $k_b$ may even be used to model the $k_b$ more accurately without knowing exact mechanisms. Methods such as transcriptomics may help to model biodegradation more accurately as it gives information on microbial activity.

6. Declaration of competing interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

7. Acknowledgements

The authors thank Stefanie Berger for support with the practical work, Pieter Blom for helping with the ammonium and nitrate analyses and Rob Anzion and Maurice van Dael for the LC-MS/MS analyses. The authors also thank Leon Lamers, for making the infrared gas analyses machine available to us, and Sebastian Krosse for help with the TOC analyses. This work was supported by the NWO-domain TTW [grant number 15759], the Netherlands, and the SIAM Gravitation grant funded by NWO [grant number 024.002.002].

8. Author contributions

JH, RvZ, AR, MJ and CW initiated the project; JH, RvZ, AR, MJ, CW, TN, TB and ARM contributed to the conceptual framework. TB and ARM conducted the experiments and data analyses. MG and PS developed the LC-MS/MS method. TB and ARM did the majority of manuscript writing and all authors contributed to improved versions of the manuscript.
