Zeros in scRNA-seq data: good or bad? How to embrace or tackle zeros in scRNA-seq data analysis?

Ruochen Jiang [1], Tianyi Sun [1], Dongyuan Song [2], and Jingyi Jessica Li [1,3,4,*]

Abstract

Single-cell RNA sequencing (scRNA-seq) technologies have revolutionized biomedical sciences by enabling genome-wide profiling of gene expression levels at an unprecedented single-cell resolution. A distinct characteristic of scRNA-seq data is the vast proportion of zeros unseen in bulk RNA-seq data. Researchers view these zeros differently: some regard zeros as biological signals representing no or low gene expression, while others regard zeros as false signals or missing data to be corrected. As a result, the scRNA-seq field faces much controversy regarding how to handle zeros in data analysis. In this paper, we first discuss the origins of biological and non-biological zeros in scRNA-seq data. Second, we clarify the definitions of several commonly-used but ambiguous terms, including "dropouts," "excess zeros," and "zero inflation." Third, we evaluate the impacts of non-biological zeros on cell clustering and differential gene expression analysis. Fourth, we summarize the advantages, disadvantages, and suitable users of three input data types: original counts, imputed counts, and binarized counts. Finally, we discuss the open questions regarding non-biological zeros, the need for benchmarking, and the importance of transparent analysis.

Introduction

The rapid development of single-cell technologies has brought unprecedented opportunities to quantify transcriptome heterogeneity among individual cells and transcriptome dynamics along cell developmental trajectories [1–4]. Several single-cell RNA sequencing (scRNA-seq) protocols have been developed. Two major types of protocols are (1) tag-based, unique molecular identifier (UMI) protocols such as Drop-seq [5] and 10x Genomics Chromium [6, 7] and (2) full-length, non-UMI protocols such as Smart-seq2 [8] and Fluidigm C1 [9]. Data generated by different protocols exhibit disparate accuracy and noise levels in quantifying gene expression in single cells, posing many computational and analytical challenges for researchers to extract biological

knowledge from scRNA-seq data [10, 11]. Facing these challenges, computational researchers have developed hundreds of computational and statistical methods for various scRNA-seq data analytical tasks, including the selection of informative marker genes [12–16], the identification of cell types and states [14, 17–23], the reconstruction of cell developmental trajectories [24–29], and the identification of cell-type-specific genes [13, 28, 30–38].

A universal analytical challenge for scRNA-seq data generated by any protocol is the vastly high proportion of genes with zero expression measurements in each cell. This data sparsity issue is apparent when scRNA-seq data are compared with bulk RNA-seq data [36, 39, 40], which contain aggregated gene expression measurements from many cells. The proportion of zeros in scRNA-seq data can be as high as 90% [41]. Such excess zeros would bias the estimation of gene expression correlations [42] and hinder the capture of gene expression dynamics [43] from scRNA-seq data. In early scRNA-seq data analyses, the high data sparsity provoked the use of zero-inflated models [36, 38, 44] and the development of imputation methods for reducing zeros [20, 42, 43, 45–60]. More recently, however, there were voices against the use of zero-inflated models for scRNA-seq data generated by UMI protocols [61]. There was even a proposal for treating zeros as useful information that researchers should embrace [62]. These mixed statements raised a fundamental question to the scRNA-seq field: are zeros good or bad for data analysis? A coupled question is, should we use or remove these zeros in scRNA-seq data analysis?

Here we offer some perspectives on these two puzzling questions by discussing the origins of zeros in scRNA-seq data, the impacts of zeros on various data analyses, the existing approaches for handling zeros, and the pros and cons of these approaches. In detail, we first define biological and non-biological zeros arising from scRNA-seq data generation, and we clarify several ambiguous terms about zeros in the scRNA-seq literature. Second, we use scRNA-seq data generated by Drop-seq, 10x Genomics, and Smart-seq2 to demonstrate the relation between zero patterns and protocols. In this case, we use simulation studies to evaluate the effects of zeros and zero-generation mechanisms on cell clustering and differentially expressed (DE) gene identification. Third, we summarize three commonly used approaches for handling zeros—direct statistical modeling, imputation, and binarization—and discuss their respective pros and cons. Last, we discuss these three approaches' comparative advantages and provide some practical advice for bioinformatics tool developers and users.

We summarize the key concepts used in this paper, including their definitions and nature (biology, technology, or modeling), in Table 1.

Origins of zeros in scRNA-seq data

Zero measurements of gene expression in scRNA-seq data should not be treated simply as missing data. They have two origins: biological and non-biological, with the latter as artifacts in scRNA-seq data. Fig. 1a provides an overview of a scRNA-seq experiment, and it highlights the biological factors and technical procedures that may lead to zeros in scRNA-seq data. Fig. 1b summarizes

key concepts	definition	nature
RNA polymerase	an enzyme that transcribes a DNA sequence into an RNA sequence	biology
mRNA degredation	the process of an mRNA sequence being destroyed	biology
biological zero	absence of mRNA of a gene in a cell	biology
GC-rich	majority of the bases in a sequence are either cytosine (C) or guanine (G)	biology
reverse transcription	enzyme-mediated synthesis of a DNA molecule from an RNA template; a step to enable DNA sequencing	sequencing technology
cDNA	complementary DNA (synthesised from reverse transcription)	sequencing technology
PCR	polymerase chain reaction; a step to amplify cDNA copy number	sequencing technology
IVT	in vitro transcription amplification; a step to amplify cDNA copy number	sequencing technology
sequence read	a short sequence read out by sequencing machine	sequencing technology
UMI	unique molecular identifier, which is used to correct amplification bias	sequencing technology
non-biological zero	absence of reads or UMIs of a gene in a cell in scRNA-seq data when the gene in fact has mRNAs in the cell	sequencing technology
techinical zero	absence of reads or UMIs of a gene in a cell due to the library-preparation steps (e.g. cDNA amplification) before sequencing	sequencing technology
sampling zero	absence of reads or UMIs of a gene in a cell due to limited sequencing depth	sequencing technology
dropouts	various meanings in the literature	ambiguous
excess zeros	various meanings in the literature	ambiguous
two-state gene expression model	a model that describes a gene's switching between active and inactive states during transcription	modeling
zero inflation	a statistical concept that depends on a specified statistical model	modeling
Poisson	a statistical model for counts; it requires the count variance to be equal to the count mean	modeling
zero-inflated Poisson (ZIP)	a statistical model for counts; it allows for a larger proportion of zeros than Poisson does	modeling
negative binomial (NB)	a statistical model for counts; it requires the count variance to be larger than the count mean	modeling
zero-inflated negative binomial (ZINB)	a statistical model for counts; it allows for a larger proportion of zeros than NB does	modeling
masking scheme	a way to mask a proportion of non-zero counts in a matrix to zeros	modeling
differentially expressed (DE) gene	a gene that has statistically significant difference in expression between two conditions (e.g., cell groups)	modeling
impute	to change the zero counts in a matrix to non-zero counts	modeling
binarize	to change the non-zero counts in a matrix to ones	modeling

Table 1: A summary of the key concepts used in this paper, including their definitions and nature.

Figure 1: Origins of zeros in scRNA-seq data. (a) An overview of a scRNA-seq experiment. Biological factors that determine true gene expression levels include transcription and mRNA degradation (top panel). Technical procedures that affect gene expression measurements include cDNA synthesis, PCR or IVT amplification, and sequencing depth (bottom three panels). Finally, every gene's expression measurement in each cell is defined as the number of reads mapped to that gene in that cell. **(b)** How the biological factors and technical procedures in (a) lead to biological, technical, and sampling zeros in scRNA-seq data. Red crosses indicate occurrences of zeros, while green checkmarks indicate otherwise. Biological zeros arise from two scenarios: no transcription (gene 1) or no mRNA due to faster mRNA degradation than transcription (gene 2). If a gene has mRNAs in a cell, but its mRNAs are not captured by cDNA synthesis, the gene's zero expression measurement is called a technical zero (gene 3). If a gene has cDNAs in the sequencing library, but its cDNAs are too few to be captured by sequencing, the gene's zero expression measurement is called a sampling zero. Sampling zeros occur for two reasons: a gene's cDNAs have few copies because they are not amplified by PCR or IVT (gene 4), or a gene's mRNA copy number is too small so that its cDNAs still have few copies after amplification (gene 5). If the factors and procedures above do not result in few cDNAs of a gene in the sequencing library, the gene would have a non-zero measurement (gene 6). The figure is created with `BioRender.com`.

how biological factors result in biological zeros and how technical procedures cause non-biological zeros, including technical zeros and sampling zeros. It is worth noting that biological and non-biological zeros are hardly distinguishable in scRNA-seq data without biological knowledge or spike-in control (see Discussion).

Biological zeros in scRNA-seq data

A biological zero is defined as the true absence of a gene's transcripts or messenger RNAs (mRNAs) in a cell [63]. Biological zeros occur for two reasons (Fig. 1b). First, many genes are unexpressed in a cell (e.g., gene 1 in Fig. 1b), and cells of distinct types have different genes expressed—a fact that results in the diversity of cell types [64, 65]. Second, many genes undergo a bursty process of transcription (i.e., mRNA synthesis); that is, these genes are not transcribed constantly but intermittently, a well-known phenomenon in gene regulation [38, 39, 44, 66–68]. Specifically, in eukaryotic cells, transcription is initiated by the binding of specific transcription factors (TFs) and RNA polymerase to the promoter of a gene [69–71]. Due to the stochasticity of TF binding, a gene switches between active and inactive states, and its transcription only occurs during the active state [72]. Hence, systems biologists have used a two-state gene expression model to describe how the rates of three processes—active/inactive state switching, transcription, and mRNA degradation—jointly determine the distribution of a gene's mRNA copy numbers, i.e., expression levels, in cells of the same type [72–74]. Fig. 2 illustrates the model and provides three example settings of model parameters along with their corresponding gene expression distributions. Depending on the gene's switching rates between the active and inactive states, transcription rate, and degradation rate, the resulting distribution may exhibit a mode near zero, implying that the gene has no mRNA transcripts at many times, i.e., in many cells (e.g., gene 2 in Fig. 1b).

Non-biological zeros in scRNA-seq data

Unlike biological zeros, non-biological zeros refer to the zero expression measurements of genes with transcripts in a cell. There are two types of non-biological zeros [63]: (1) technical zeros, which arise from library-preparation steps before sequencing, and (2) sampling zeros, which result from a limited sequencing depth.

The leading cause of technical zeros is the imperfect mRNA capture efficiency in the reverse transcription (RT) step from mRNA to cDNA. The efficiency has a considerable variation across protocols and may be as low as 20% [75], depending on multiple experimental parameters [76]. The efficiency may even differ between mRNA transcripts. For example, if an mRNA transcript has an intricate secondary structure or is bound to proteins, it would not be reversely transcribed to cDNA efficiently [10, 33, 38]. In summary, if a gene's mRNA transcripts in a cell are not converted into cDNA molecules (cDNAs), the gene would falsely appear as non-expressed in that cell in the sequencing library, resulting in a technical zero in scRNA-seq data (e.g., gene 3 in Fig. 1b).

Figure 2: A two-state stochastic model of the expression levels of one gene. (a) A diagram of the two-state gene expression model [72–74], where a gene stochastically switches from an inactive state to an active state at rate k_a and from an active state to an inactive state at rate k_i. The gene transcribes mRNA at rate s_m only when it is in the active state. The transcribed mRNA then degrades at rate δ. **(b)** Given $s_m = 200$ and $\delta = 1$, the effects of k_a and k_i on the temporal dynamics of the gene's mRNA copy number. Three example values of k_a and k_i are provided. Left: when both k_a and k_i are small, the mRNA copy number switches between small and large values. Middle: when k_a is much larger than k_i, the mRNA copy number remains large most of the time. Right: when k_a is much smaller than k_i, the mRNA copy number remains small most of the time. **(c)** Distributions of the gene's mRNA copy number (across cells) corresponding to the three example settings in (b). Left: when the gene's mRNA copy number switches between small and large values, the resulting distribution is bimodal with two modes at zero and around s_m/δ. Middle: when the gene's mRNA copy number is large most of the time, the resulting distribution has a single mode around s_m/δ. Right: when the gene's mRNA copy number is small most of the time, the resulting distribution has a single mode at zero. In summary, when k_a is small, the gene is expected to have biological zeros in cells with non-negligible probability.

The other type of non-biological zeros, sampling zeros, occurs due to a constraint on the total number of reads sequenced, i.e., the sequencing depth [61, 77], which is determined by the experimental budget and sequencing machine. During sequencing, cDNAs are randomly captured ("sampled") and sequenced into reads. Hence, a gene with fewer cDNAs is more likely to be undetected due to this random sampling. If undetected, the gene's resulting zero read count is a "sampling zero." There are two reasons why a gene (in a cell) may have too few cDNAs in the sequencing library: too few cDNAs before amplification and inefficient cDNA amplification. Below we explain why cDNA amplification may cause some genes to have a disproportionally low cDNA copy number in the sequencing library.

The cDNA amplification step is essential for scRNA-seq, as it increases the number of cDNA copies of a gene so that the gene is more likely to be detected by sequencing. Polymerase chain reaction (PCR) [78] is the most widely-used amplification procedure; however, its amplification is non-linear. As a remedy, *in vitro* transcription (IVT) has been developed for linear amplification, i.e., the ratio of two different cDNAs' copy numbers is expected to stay the same after amplification [79]. However, compared with PCR, IVT requires more input cDNAs to ensure successful amplification; thus, PCR is still the dominant amplification procedure for scRNA-seq [80].

Though indispensable, cDNA amplification is known to introduce biases into cDNA copy numbers because the amplification efficiency depends on cDNA sequence and structure [81, 82]. For example, GC-rich cDNA sequences are harder to be amplified [63]. The amplification efficiency also depends on the design of cell barcodes, adapters, and primers; overlaps or complementarity of barcode, adapter, and primer sequences would induce cDNA secondary structures and thus reduce the amplification efficiency [83, 84]. Moreover, cDNA copy number biases would accumulate as the number of amplification cycles increases [81, 85]; that is, the more cycles, the larger the difference of two genes (with different amplification efficiency) in cDNA copy numbers [86, 87]. Since different scRNA-seq experiments may use different numbers of amplification cycles (e.g., 18 cycles in a Smart-seq2 experiment [88] and 14 cycles in a 10x Genomics experiment [89]), the degrees of cDNA copy number biases differ among scRNA-seq datasets. In addition, the non-linear amplification nature of PCR would exaggerate the expression level differences between lowly-expressed and highly-expressed genes. Altogether, due to amplification biases, cDNA copy numbers in a sequencing library may not reflect cDNAs' actual proportions before amplification. As a result, the genes with small cDNA proportions in the sequencing library are likely to be missed by sequencing and result in sampling zeros (e.g., gene 4 suffering from inefficient amplification and gene 5 having too few cDNAs in Fig. 1b)

Granted, the use of UMIs can correct the amplification biases in non-zero gene expression measurements [90]; that is, UMIs can be used to identify and remove reads from cDNA duplicates that are results of amplification, and thus some non-zero gene expression measurements would be reduced. However, UMIs cannot help recover sampling zeros, whose corresponding cDNA copy numbers stay unknown despite the use of UMIs [91]. In fact, UMIs cannot reduce any zeros, including biological and non-biological ones.

Clarification of zero-related terminology

We have summarized the biological and non-biological origins of zeros in scRNA-seq data. In the current scRNA-seq literature, much ambiguity exists in the use of terms including "dropouts," "excess zeros," and "zero-inflation" to describe the prevalence of zeros in scRNA-seq data [92]. We clarify the three terms by summarizing their various uses in the scRNA-seq field to facilitate our discussion.

"Dropouts" is the most widely used term regarding the prevalence of zeros in scRNA-seq data. It was first introduced in the SCDE method paper: "dropout describes zero gene expression for the genes that show moderate or high expressions in only a proportion of cells [38]." Hence, dropouts, as a data-driven concept, are not equivalent to either biological or non-biological zeros. Nevertheless, the use of "dropouts" in later papers became inconsistent and confusing: most papers meant non-biological zeros [20, 36, 40, 50, 53, 93, 94]; some meant non-biological zeros and low expression measurements [43, 95]; some meant all zeros [44, 45, 96]. In addition, "dropout" was often used as an adjective to mean the existence of many zeros [97]. Such inconsistent uses of "dropouts" are emphasized in a recent work [92]. To avoid possible confusion, we will not use "dropout" or "dropouts" in the following text.

"Excess zeros" is another phrase used in various ways: some papers referred to the larger proportion of zeros in scRNA-seq data than in bulk RNA-seq data [40]; some meant non-biological zeros [43, 94]; some meant the additional zeros that cannot be explained by the negative binomial (NB) model [95]. To avoid confusion, we will not use "excess zeros" in the following text.

"Zero inflation," unlike the first two terms, is a statistical concept that depends on a specified model, i.e., a count distribution such as the Poisson distribution and the NB distribution [93]. It means the proportion of zeros that exceeds what is expected under the specified model [40]. We will use "zero inflation" in the following discussion because its definition has no ambiguity.

Debate on zero-inflated modeling of scRNA-seq data

Since the advent of scRNA-seq, zero-inflated models have been widely used in bioinformatics tools for scRNA-seq data [36, 38, 44, 91]. Zero-inflated models are mixture probabilistic models with two components: a point mass at zero and a common distribution, including the Poisson and NB distributions for read or UMI counts and the normal distribution for log-transformed read or UMI counts. More recently, however, researchers have found that UMI-based data are not zero-inflated [6, 63, 89, 92]. This observation is consistent with the definition of "zero inflation" as a statistical concept instead of a biological phenomenon. Since we have already discussed that the use of UMIs cannot reduce zeros [91], then the change of modeling choice—from zero-inflated models for non-UMI data to non-zero-inflated models for UMI data—indicates that whether or not to use zero-inflated models has nothing to do with the prevalence of zeros. In other words, the modeling choice is a statistical consideration and says nothing about the proportions of zeros or

the distinction between biological and non-biological zeros.

Four count distributions—Poisson, zero-inflated Poisson (ZIP), NB, and zero-inflated NB (ZINB)—have been widely used to model a single gene's read or UMI counts across cells in scRNA-seq data. In fact, the former three models are special cases of the ZINB model (Fig. 3a). Poisson only has one parameter (λ) equal to both mean and variance (Fig. 3b). Compared with Poisson, ZIP has one more zero-inflation parameter (p) to indicate the proportion of additional zeros that do not come from Poisson (Fig. 3c); when this zero-inflation parameter is zero, ZIP reduces to Poisson. Also, compared with Poisson, NB has one more dispersion parameter (ψ) that indicates the over-dispersion of variance relative to the mean (i.e., unlike Poisson, NB has variance greater than mean; Fig. 3d); when this dispersion parameter is positive infinity, NB reduces to Poisson. Compared with NB, ZINB has one more zero-inflation parameter (p) to indicate the proportion of additional zeros that do not come from NB (Fig. 3e); when this zero-inflation parameter is zero, ZINB reduces to NB.

For a fair comparison, we illustrate these four distributions, with example parameters such that they all have the same mean as one (Fig. 3b–e). With the same mean, ZIP and NB have more zeros than Poisson does, and ZINB has the most zeros. Between ZIP and NB, which one has more zeros depends on their parameter values, and when they have the same zero proportion, their non-zero distributions are still different. Moreover, when the four distributions have the same mean, compared with Poisson and ZIP, NB and ZINB have heavier right tails, i.e., greater probabilities of taking larger values.

To study the recent debate about whether zero-inflated modeling is suitable for scRNA-seq data, we fit the above four count distributions—two zero-inflated (ZIP and ZINB) and two non-zero-inflated (Poisson and NB)—to a non-UMI-based dataset generated by Smart-seq2 and two UMI-based datasets generated by 10x Genomics and Drop-seq. These three datasets are ideal for studying how the modeling choice depends on the experimental protocol, as they were generated by a benchmark study [41] that applied multiple scRNA-seq protocols to measure peripheral blood mononuclear cells (PBMCs) from the same batch, and the benchmark study labeled cells using the same cell types and curated genes to be the same across protocols. We first compare the three datasets in terms of their distributions of cell library size (i.e., the total number of reads or UMIs in each cell), numbers of cells, and distributions of the number of genes detected per cell. Fig. 4a–c show that, compared with the two UMI-based datasets, the Smart-seq2 (non-UMI-based) dataset has larger cell library sizes, fewer cells, and more genes detected—a phenomenon consistent across the five cell types (B cells, CD14+ monocytes, CD4+ T cells, cytotoxic T cells, and natural killer cells).

Next, for each gene in each dataset, we fit the four distributions to its read or UMI counts in cells of each type, and we choose its distribution among the four distributions by likelihood ratio tests (see [98] for detail). The rationale is to choose the least complex distribution that fits the data well. Fig. 4d shows that non-zero-inflated distributions (Poisson and NB) are chosen for almost all genes in the 10x Genomics and Drop-seq datasets, while zero-inflated distributions (ZIP and ZINB) are

a

distribution	mean	variance	zero proportion, i.e., P(X=0)
Poisson(λ)	λ	λ	$\exp(-\lambda)$
ZIP(λ, p)	$\lambda \cdot (1-p)$	$\lambda \cdot (1-p) + \lambda^2 \cdot (1-p) \cdot p$	$\exp(-\lambda) \cdot (1-p) + p$
NB(λ, ψ)	λ	$\lambda + \frac{\lambda^2}{\psi}$	$(\frac{\psi}{\psi+\lambda})^\psi$
ZINB(λ, ψ, p)	$\lambda \cdot (1-p)$	$\lambda \cdot (1-p) + \lambda^2 \cdot (1-p) \cdot (p + \frac{1}{\psi})$	$(\frac{\psi}{\psi+\lambda})^\psi \cdot (1-p) + p$

Figure 3: Four count distributions: Poisson, zero-inflated Poisson (ZIP), negative binomial (NB), and zero-inflated negative binomial (ZINB). (a) Parameterization, mean, variance, and zero proportion of each of the four distributions. **(b)**, **(c)**, **(d)**, and **(e)** Illustration of the probability mass functions of Poisson (b), ZIP (c), NB (d), and ZINB (e) distributions that all have mean equal to 1. The horizontal axis indicates each possible value, and the vertical axis indicates the probability of taking each possible value. For each distribution, the parameter values are listed on the top right, and the zero proportion is listed at the bottom.

Figure 4: Statistical modeling of 10x Genomics, Drop-seq, and Smart-seq2 data for the same PMBC sample.
10x Genomics and Drop-seq data are UMI-based, while Smart-seq2 data are non-UMI-based. **(a)** Violin plots showing the distribution of cell library sizes for each of five PMBC cell types measured by each protocol [41]. For the UMI-based protocols (10x Genomics and Drop-seq) and Smart-seq2, a cell's library size is defined as the total number of UMIs and reads, respectively, in that cell. **(b)** Barplots showing the number of cells detected for each cell type by each protocol. **(c)** Violin plots showing the distribution of the number of genes detected per cell. **(d)** Barplots showing the proportions of genes for which zero-inflated (ZI) models are chosen (black) and genes for which non-zero-inflated models are chosen (non-black). The model selection is done by likelihood ratio tests. **(e)** Four example genes' distributions of UMI counts in B cells measured by 10x Genomics. The original count distributions are shown in histograms. Non-zero-inflated (no ZI) models are chosen, and the fitted model distributions are shown in cyan curves. **(f)** The same four example genes' distributions of UMI counts in B cells measured by Drop-seq. **(g)** The same four example genes' distributions of read counts in B cells measured by Smart-seq2. ZI models are chosen for two genes.

chosen for about half of the genes in the Smart-seq2 dataset. This result is consistent with the recent advocate for not using zero-inflated models for UMI-based data [61, 92], and it suggests that zero-inflated modeling is still useful for Smart-seq2 data. For illustration purposes, in Fig. 4e–g, we plot the read or UMI count distributions for four genes (*EEF1A1*, *ACTB*, *CD79B*, and *LCP1*) in B cells in these three datasets, and we also plot the fitted chosen distribution for each gene. Specifically, non-zero-inflated distributions are chosen for all the four genes in the UMI-based datasets, while zero-inflated distributions are chosen for *CD79B* and *LCP1* in the Smart-seq2 dataset. Our results show that the same gene's expression distribution under the same biological condition may be described by different statistical models for data generated by different protocols, confirming that zero inflation provides no direct information on biological zeros, whose existence does not depend on protocols (Fig. 1b).

How non-biological zeros affect scRNA-seq data analysis

To evaluate the effects of non-biological zeros on scRNA-seq data analysis, such as cell clustering and DE gene identification, we need access to true cell types and true DE genes. Hence, we use scDesign2 [98], a probabilistic, flexible simulator we developed to generate realistic scRNA-seq count data from any protocol with gene correlations captured. First, we train scDesign2 on the three benchmark PBMC datasets (10x Genomics, Drop-seq, and Smart-seq2) [41], which all contain the same five cell types (B cells, CD14+ monocytes, CD4+ T cells, cytotoxic T cells, and natural killer cells) and are used in Fig. 4. Second, we simulate the corresponding non-zero-inflated synthetic datasets, one for each protocol, in the form of gene-by-cell count matrices. In detail, after the first training step, every gene in each cell type has a fitted count distribution (Poisson, ZIP, NB, or ZINB) by scDesign2; in the second simulation step, we generate read or UMI counts for every gene in each cell type from the non-zero-inflation component (Poisson or NB). Note that we set the number of synthetic cells generated by scDesign2 equal to the number of real cells for each cell type. Hence, for each gene, this simulation procedure removes the statistical zero inflation, which we define in the last section, and provides the gene's expected expression level in each cell type (as the mean of its non-zero-inflation component).

Based on the three non-zero-inflated synthetic datasets (10x Genomics, Drop-seq, and Smart-seq2), we define the positive controls for two typical analyses: cell clustering and DE gene identification, which are ubiquitous in scRNA-seq data analysis pipelines. For cell clustering, the positive controls are provided by scDesign2 as the cell types from which it generates synthetic cells. For DE gene identification, the positive controls are provided by scDesign2 as the genes whose expected expression levels differ between cell types.

Next, given the three synthetic datasets without zero inflation, we use five masking schemes to introduce a varying number of non-biological zeros into each dataset. Since there is no consensus on the generation mechanism of non-biological zeros, we design the five masking schemes to reflect two fundamental questions: whether the occurrence of non-biological zeros (1) depends

Figure 6: Effects of non-biological zeros on cell clustering and DE gene identification. We introduce a varying number of non-biological zeros, which correspond to masking proportions 0.1–0.9, into the simulated **(a)** Smart-seq2, **(b)** Drop-seq, and **(c)** 10x Genomics datasets using five masking schemes. The horizontal axes show (top) the total zero proportion (including the zeros before masking and the non-biological zeros introduced by masking) and (bottom) the masking proportion (i.e., the proportion of non-zero counts masked by a masking scheme). After introducing non-biological zeros, we apply Monocle 3 and Seurat to each dataset to perform cell clustering and identify DE genes. For the two analyses, we evaluate their accuracy using the adjusted rand index (ARI) and F_1 score (given the false discovery rate 5%), respectively. **(d)** Technical definitions of the ARI and F_1 score.

on the actual gene expression levels and/or (2) is gene-specific. As the five masking schemes cover the extreme answers to both questions (Fig. 5a), we expect that they together cover the unknown generation mechanism of non-biological zeros and would thus reveal the realistic effects of non-biological zeros on cell clustering and DE gene identification.

We provide a toy example to demonstrate the five masking schemes in Fig. 5b and summarize their technical detail in Fig. 5c. In short, for a dataset with n non-zero counts, given a masking proportion p, all schemes would mask approximately np non-zero counts. However, the five schemes differ in masking which np non-zero counts, and they can be categorized in two ways corresponding to the two aforementioned questions.

The first categorization is whether masking depends on the non-zero count values: random masking vs. quantile masking. While the two random masking schemes assume the independence between whether a non-zero count would be masked and the count value itself, the three quantile masking schemes assume a complete dependence by truncating non-zero values below a quantile (which corresponds to the masking proportion) to zero. Specifically, the two random masking schemes differ in the definition of independence: `random mask (all genes)` assumes the complete independence between masking and count values; `random mask (per-gene, specific %)` only assumes the conditional independence between masking and count values given each gene, and the masking proportion is gene-specific. Note that we define each gene's specific masking proportion as a function of the gene's non-zero counts based on an empirical formula in the literature [43, 44] (Fig. 5c); in short, the larger a gene's non-zero counts are, the smaller the gene's masking proportion is. Besides the two random masking schemes, the three quantile masking schemes differ in how they perform the truncation: `quantile mask (all genes)` truncates the lowest $100p\%$ non-zero counts of all genes; `quantile mask (per-gene, same %)` truncates the lowest $100p\%$ non-zero counts of each gene; `quantile mask (per-gene, specific %)` truncates the lowest non-zero counts of each gene based on the gene's specific masking proportion determined by the empirical formula.

The second categorization is regarding whether the masking proportion is gene-specific. Two schemes mask the same expected proportion $100p\%$ of non-zero counts for all genes: `random mask (all genes)` and `quantile mask (per-gene, same %)`. Three schemes use gene-specific masking proportions: `quantile mask (all genes)`, `random mask (per-gene, specific %)`, and `quantile mask (per-gene, specific %)`. Specifically, although `quantile mask (all genes)` does not use the empirical formula to determine gene-specific masking proportions as in `random mask (per-gene, specific %)` and `quantile mask (per-gene, specific %)`, it still truncates different proportions of non-zero counts for different genes. The reason is that its truncation threshold is set to the p-th quantile of all genes' non-zero counts, and different genes have different numbers of non-zero counts below that threshold. It is also worth noting that we do not include `random mask (per-gene, same %)` because it is theoretically equivalent to `random mask (all genes)`—both schemes are expected to randomly mask $100p\%$ of every gene's non-zero counts (Fig. 5a).

Using each of the five masking schemes, we introduce a varying number of non-biological zeros, corresponding to masking proportions $p = 0.1, \ldots, 0.9$, into the three synthetic datasets corresponding to 10x Genomics, Drop-seq, and Smart-seq2 protocols, creating three suites of zero-inflated datasets, one suite per protocol. Note that each suite contains one non-zero-inflated dataset and $45 = 9$ (# of masking proportions) $\times 5$ (# of masking schemes) zero-inflated datasets. Then we apply Monocle3 (R package version `0.2.3.0`) [28] and Seurat (R package version `3.2.1`) [13], two popular multi-functional software packages, to the three suites of datasets. We use the two packages to perform cell clustering and DE gene identification, and we evaluate the analysis results based on our previously defined positive controls. Fig. 6a–c summarizes how the accuracy of the two analyses deteriorates as the masking proportion increases under each masking scheme and for each protocol.

The clustering results (top rows in Fig. 6a–c) show that the clustering accuracy (measured by the adjusted rand index; Fig. 6d) is robust to the introduction of non-biological zeros up to the masking proportion $p = 0.6$ (i.e., 60% non-zero counts are masked as zeros) for most masking schemes. Compared with Monocle3, Seurat is more robust to non-biological zeros under all the five masking schemes. Among all schemes, the two schemes that assume (1) dependence between masking and count values and (2) gene-specific masking proportions—`quantile mask (all genes)` and `quantile mask (per-gene, specific %)` (Fig. 5b)—have the least deteriorating effects on cell clustering. This result is reasonable as these two schemes tend to mask low counts to zeros so that the relative order of gene expression counts (from low to high) is better preserved than by the other three schemes. A recent article argues that zeros in scRNA-seq data carry biological meanings and should be embraced, and its argument is based on the assumption that most zeros correspond to low expression levels [62], an assumption aligned with these two masking schemes. Finally, among the three protocols, clustering on Smart-seq2 data is most robust to non-biological zeros, likely because Smart-seq2 data contain fewer zeros than the two UMI-based protocols' data do. It is worth noting that, between the two UMI-based protocols, clustering accuracy is better on 10x Genomics data than Drop-seq data.

The DE gene identification results (bottom rows in Fig. 6a–c) show that the F_1 scores (at 5% false discovery rate; Fig. 6d) are robust to non-biological zeros for Seurat, but not as much for Monocle3. The reason is that Seurat uses MAST [36], a method built upon a zero-inflated model, for DE gene identification, while Monocle3 uses non-zero-inflated models (including Poisson, quasi Poisson, and NB) that cannot account for additional non-biological zeros. Among the five masking schemes, the two random schemes that assume independence between masking and count values—`random mask (all genes)` and `random mask (per-gene, specific %)` (Fig. 5b)—have the most deteriorating effects on DE gene identification. This result is reasonable as these two schemes may mask high counts to zeros, so they disrupt every gene's count distribution more than the other three schemes do. Interestingly, although `quantile mask (per-gene, same %)` is unlikely a realistic generation mechanism of non-biological zeros as it masks the same proportion of non-zero counts for every gene, we observe that Seurat has robust F_1 scores as non-biological

zeros are introduced by this scheme. This seemingly unexpected result reflects that zero-inflated models are robust for DE gene identification under quantile masking, even though the masking proportion may not be reasonable. Finally, regarding the three protocols, Seurat has better F_1 scores for Smart-seq2 data than Monocle3 does, a reasonable result given the observed zero-inflation in Smart-seq2 data (Fig. 4d). For the two UMI-based protocols, Monocle3 and Seurat have comparable performance in terms of F_1 scores. We have also observed that the DE analysis results for UMI data are better than for non-UMI data. One possible reason is the larger sample sizes (larger numbers of cells) in Drop-seq and 10x data that increase the power in statistical testing. To supplement the F_1 scores, we show the corresponding precision and recall rates in Supplementary Fig. S1. It is worth noting that although the false discovery rate is set to 5%, the precision rates of both Monocle3 and Seurat are far below the expected precision 95%, which is equal to one minus the false discovery rate. This phenomenon calls for better false discovery rate control in scRNA-seq DE analysis [99]. In addition, compared to Seurat, Monocle3 shows a greater fluctuation in both precision and recall as the masking proportion increases.

In summary, compared with DE gene identification, cell clustering is more robust to non-biological zeros. This result suggests that the sparsity in scRNA-seq data affects gene-level analyses more than cell-level analyses because the latter jointly uses all genes' expression levels. Overall, Seurat is more robust than Monocle3 is to non-biological zeros for both analyses. For cell clustering, Seurat has better accuracy regardless of protocols. For DE gene identification, Seurat is preferable for Smart-seq2 data, while Monocle3 has better accuracy for UMI-based data.

It is worth noting that many imputation methods evaluate their imputation accuracy based on only the `random mask (all genes)` scheme [47, 60, 100]. Our results indicate that non-biological zeros introduced by different masking schemes have different effects on cell clustering and DE gene identification, and quantile masking may be more realistic given previous reports that genes with lower expression values have more zeros than genes with higher expression [39, 44]. Hence, we urge that quantile masking schemes be considered in the future evaluation of computational methods that deal with non-biological zeros.

Input data: original vs. imputed vs. binarized counts

Current scRNA-seq data analysis typically takes three types of input data: original, imputed, and binarized counts. Although logarithmic transformation is commonly applied to counts before further analysis, this practice is under controversy [89, 101, 102] and is not the focus of our discussion. Here we summarize advantages, disadvantages, and suitable users (bioinformatics tool developers vs. users) for each input data type.

Direct modeling of original, observed counts is the most common practice for bioinformatics tool developers [13, 28, 30–33, 36, 103]. An obvious advantage of direct modeling is that original counts are not biased by any data pre-processing steps. Hence, original counts are the preferred input data type for most tool developers unless they cannot be easily modeled. However, unlike

developers, tool users need to apply existing bioinformatics tools to scRNA-seq data. If the original counts do not work well with existing tools, for practical reasons, tool users must consider data pre-processing steps such as imputation and binarization so that existing tools can output reasonable analysis results.

Since the sparsity in scRNA-seq counts has posed a great hurdle for many existing tools, imputation has been proposed as a practical data pre-processing step, and many imputation methods have been developed [20, 42, 43, 45–60]. Of course, imputation has the risk of biasing data, leading to false signals [97] or reducing meaningful biological variation [43, 104]. However, imputation has two practical advantages for single-cell biologists, most of whom are tool users. First, many imputation methods have shown that their imputed counts, in which many zeros in the original counts become non-zeros, have better agreement with biological knowledge and/or biologists' expectations. For example, the effectiveness of imputation has been supported by evidence that scRNA-seq data after imputation agree better with bulk RNA-seq data or single-cell RNA fluorescence in situ hybridization (FISH) data [46, 60, 105]. Second, imputation builds a bridge that connects sparse scRNA-seq data to many powerful tools designed for non-sparse data. For example, DESeq2 [35] and edgeR [31] are two popular DE gene identification methods for bulk RNA-seq data; however, they are not directly applicable to scRNA-seq data because their models do not account for data sparsity. Hence, if tool users cannot find a DE gene identification method that works well for their scRNA-seq data, they may consider reducing zeros using imputation methods to make DESeq2 or edgeR applicable [58, 59, 106].

Moreover, a recent article provides a new view by proposing to use only binarized counts (with all non-zero counts truncated as ones) for cell clustering [62]. It argues that, by removing the magnitudes of non-zero counts, binarization alleviates the need for normalizing individual cells' sequencing depths. Further, its key message is that zeros are biologically meaningful because binarized counts can lead to reasonable cell clustering results. Other works also suggest that binarized counts can serve as useful data, in addition to original counts, and be incorporated into scRNA-seq data modeling and analysis [23, 107]. However, it remains unclear whether binarized counts can replace original counts in scRNA-seq data analysis. Our intuition says that the answer is unlikely yes for all analyses because the magnitudes of non-zero counts reflect expression levels of genes in each cell. Existing works that use binarized counts only deal with cell-level analyses such as clustering, which, as we have shown in Fig. 6, is robust to non-biological zeros. For gene-level analyses such as DE gene identification, binarized counts are unlikely to be more suitable than original counts. For example, if a gene has similar percentages of zero counts in two cell types, but its non-zero counts are much larger in one cell type than the other, then this gene should be identified as DE using original counts, but it would be missed as DE using binarized counts. For tool developers, it would be beneficial to consider using binarized counts in addition to original counts for developing new analysis tools. For tool users, binarized counts can be used for exploratory data analysis because some efficient computational tools are applicable to binary counts but not original counts, e.g., scalable probabilistic principal component analysis [108].

Discussion

ScRNA-seq technologies have advanced the revelation of genome-wide gene expression profiles at the cell level. Accordingly, many computational algorithms and statistical models have been developed for analyzing scRNA-seq data. A well-known challenge in scRNA-seq data analysis is the prevalence of zeros, and how to best tackle zeros remains a controversial topic. Modeling and analysis may be performed on original, imputed, or binarized scRNA-seq counts. However, the relative advantages and disadvantages of these three strategies remain ambiguous. In this article, we attempt to address this controversy by discussing multiple intertwined topics: the biological and non-biological origins of zeros, the relationship between zero prevalence and scRNA-seq technologies, the extent to which zero prevalence affects various analytical tasks, and the three strategies' relative advantages, disadvantages, and suitable users.

The prevalence of biological and non-biological zeros is a mixed result of intrinsic biological nature and complex scRNA-seq experiments. In particular, the generation mechanism of non-biological zeros is protocol dependent. Hence, it is infeasible to distinguish non-biological zeros from biological zeros purely based on observed counts. As a result, existing imputation methods have a glass ceiling if they use only observed counts as input. To better distinguish non-biological zeros from biological zeros, researchers need to utilize spike-in RNA molecules, whose true counts are known (e.g., External RNA Control Consortium spike-ins [109]), to investigate the generation mechanism of non-biological zeros. Such investigation requires consortium efforts such as the work by the Sequencing Quality Control (SEQC-2) consortium [110]. With a better understanding of how the generation of non-biological zeros depends on mRNA sequence features such as GC contents, statistical and mechanistic models may be developed to better distinguish non-biological zeros from biological zeros and thus to improve imputation accuracy.

Given the relative advantages and disadvantages of using original, imputed, and binarized counts in scRNA-seq data analysis, systematic benchmarking of the three strategies is critical [111]. Benchmarking has been performed to evaluate 18 imputation methods [112], but no benchmarking has been done to evaluate the effectiveness of using binarized counts instead of original counts in various scRNA-seq analyses. It is widely acknowledged that benchmarking is crucial for evaluating scRNA-seq experimental protocols [10, 113–118] and computational methods [29, 30, 112, 119–130]; we summarize current benchmark studies of scRNA-seq data analysis in Table 2. Hence, more benchmarking is needed to address the debate about the best strategy for handling zeros in data generated by various scRNA-seq protocols.

The prevalence of biological and non-biological zeros is only one of the many obstacles in using scRNA-seq data for scientific discoveries. As scientific discovery is a trial-and-error process, scRNA-seq data analysis is unavoidably multi-step. Hence, bioinformatics tool developers must consider the pre-processing steps applied to input data and the downstream analyses users may perform on output data. Taking the popular Seurat package as an example, many data pre-processing steps are used before DE gene identification. These steps include filtering low-quality

scRNA-seq data analysis	benchmark work
DE gene identification	[30, 122]
cell clustering	[120, 123–125]

genes and cells, data normalization, gene selection, cell dimension reduction, and cell clustering. Hence, if tool developers are not aware of these pre-processing steps, their bioinformatics tools may not fit into the state-of-the-art scRNA-seq data analysis pipelines. Ultimately, the transparency and reproducibility of scRNA-seq data analysis call for a community collaboration between tool developers and users. Towards this goal, every research article, regardless of being tool development or data analysis, should contain a detailed description of each step and the underlying justifications [131].

Supplementary Figure

Figure S1: Effects of non-biological zeros on DE gene identification in terms of precision and recall. We introduce a varying number of non-biological zeros, which correspond to masking proportions 0.1–0.9, into the simulated **(a)** Smart-seq2, **(b)** Drop-seq, and **(c)** 10x Genomics datasets using five masking schemes. The horizontal axes show (top) the total zero proportion (including the zeros before masking and the non-biological zeros introduced by masking) and (bottom) the masking proportion (i.e., the proportion of non-zero counts masked by a masking schemes). After the introduction of non-biological zeros, we apply Monocle 3 and Seurat to each dataset to identify DE genes. We evaluate the accuracy using the precision and recall (given the false discovery rate 5%; defined in Fig. 6d), respectively.
