Abstract

Visual inspection of stimulus-induced gamma oscillations (30-70 Hz) often reveals a non-sinusoidal shape. Such distortions are a hallmark of non-linear systems and are also observed in mean-field models of gamma oscillations. A thorough characterization of the shape of the gamma cycle can therefore provide additional constraints on the operating regime of such models. However, the gamma waveform has not been quantitatively characterized, partially because the first harmonic of gamma, which arises because of the non-sinusoidal nature of the signal, is typically weak and gets masked due to a broadband increase in power related to spiking. To address this, we recorded spikes and local field potential (LFP) from the primary visual cortex (V1) of two awake female macaques while presenting full-field gratings or iso-luminant chromatic hues that produced huge gamma oscillations with prominent peaks at harmonic frequencies in the power spectra. We found that gamma and its first harmonic always maintained a specific phase relationship, resulting in a distinctive shape with a sharp trough and a shallow peak. Interestingly, a Wilson-Cowan (WC) model operating in an inhibition stabilized mode could replicate the findings, but only when the inhibitory population operated in the super-linear regime, as predicted recently. However, another recently developed model of gamma that operates in a linear regime driven by stochastic noise failed to produce salient harmonics or the observed shape. Our results impose additional constraints on models that generate gamma oscillations and their operating regimes.

Significance Statement

Gamma rhythm is not sinusoidal. Understanding these distortions could provide clues about the cortical network that generates the rhythm. Here, we use harmonic phase analysis to describe these waveforms quantitatively, and show that the gamma rhythm in macaque V1, during the presentation of fullscreen plain-hues and achromatic-gratings, has a signature arch-shaped waveform, despite the variation in power and frequency reported earlier. We further demonstrate using population rate models that the non-sinusoidal waveform is dependent on the operating domain of the system generating it. Consequently, shape analysis provides additional constraints on cortical models and their operating regimes.

Introduction

53

54   Gamma rhythm refers to oscillatory neural activity in the 30-70 Hz range that changes

55   in response to different stimuli and cognitive states (Buzsaki, 2006). In the primary visual

56   cortex (V1), the gamma rhythm has been studied extensively using achromatic gratings,

57   wherein gamma power and center-frequency have been shown to vary systematically with the

58   properties of the grating (Jia et al., 2013; Murty et al., 2018). For instance, peak-frequency of

59   gamma increases with the contrast of gratings (Ray and Maunsell, 2010; Jia et al., 2013) and,

60   gamma power increases and frequency decreases with stimulus size (Gieselmann and Thiele,

61   2008; Ray and Maunsell, 2011). More recently, chromatic stimuli have also been explored,

62   which, for low-wavelength (reddish) hues, can generate huge gamma oscillations that are an

63   order of magnitude stronger than gamma produced by achromatic gratings (Shirhatti and Ray,

64   2018; Bartoli et al., 2019; Peter et al., 2019).

65   Gamma oscillations are thought to reflect the push-pull activity of interconnected

66   excitatory and inhibitory neurons, which has been demonstrated in different spiking network

67   models (Tiesinga and Sejnowski, 2009; Mazzoni et al., 2015; Chariker et al., 2018; Keeley et

68   al., 2019). However, since such large-scale network models have several parameters to be tuned

69   and can become hard to interpret, simplified population rate models are often used. One

70   pioneering model was proposed by Wilson and Cowan (WC; 1972), in which excitatory and

71   inhibitory neurons were grouped into populations, and the dynamics of these populations were

72   characterized. Variants of WC models have recently been used to explain some properties of

73   the gamma rhythm. For example, based on the observation that gamma rhythm appears in short

74   bursts and its phase does not vary linearly (Burns et al., 2010, 2011; Xing et al., 2012), a WC

75   based model was proposed in which the activation function (input-output relationship) was

76   linear but driven by Poisson noise (Kang et al., 2009; Xing et al., 2012). A variant of this model,

77   in which an additional global excitatory population was added, was used to explain the stimulus

4

78   dependence of gamma oscillations (Jia et al., 2013). On the other hand, Jadi and Sejnowski

79   (2014) used a WC model with a non-linear (sigmoidal) activation function and showed that

80   constraining the model to operate in an inhibition stabilized mode (Tsodyks et al., 1997) and

81   the inhibitory population to operate in superlinear domain can also reproduce the size and

82   contrast dependence of gamma rhythm.

83   Although both these models can explain the stimulus dependence of gamma, the shape

84   of the rhythm likely depends on the presence (and type) of non-linearity. The shape could be

85   non-sinusoidal (see, for example, Figure 11 of Wilson and Cowan, 1972), which is represented

86   in the spectral domain as peaks at harmonics of the fundamental frequency. Such distortions

87   have been observed in various brain oscillations such as theta rhythm (for a review, see Cole

88   and Voytek (2017)). For gamma rhythm, a visual inspection of raw traces reveals some

89   distortion (Henrie and Shapley, 2005; Jia and Kohn, 2011; Jia et al., 2011; Ray and Maunsell,

90   2015), which is also corroborated by the presence of peaks at the first harmonic of the

91   fundamental gamma peak in the power spectra (Gieselmann and Thiele, 2008; Ray and

92   Maunsell, 2010; Shirhatti and Ray, 2018). However, a quantitative study of the gamma

93   waveform, which could potentially constrain the type and operating regime of models, has not

94   been undertaken. This is partly because the noise in the harmonic range could offset its phase

95   estimates if the harmonic is not prominent enough. To address this, we studied gamma

96   oscillations produced by presenting full-screen hues that generated salient gamma oscillations

97   with prominent harmonics (Shirhatti and Ray, 2018), characterized the shape, and tested

98   models that could replicate the shape.

99

Materials and Methods

Data Acquisition

We used LFP data recorded by Shirhatti and Ray (2018) from V1 of two female macaque subjects, whom we refer to as M1 and M2 (correspond to M1 and M3 in the earlier paper). Both monkeys were fitted with a titanium headpost and trained to perform a visual passive fixation task, after which a Utah array (96 and 81 electrodes for M1 and M2) was implanted in V1 (details of the surgery and implants are provided in Shirhatti and Ray (2018)). The raw signals from microelectrodes were recorded using the 128-channel Cerebus neural signal processor (Blackrock Microsystems). LFP was obtained by filtering the raw signals online between 0.3 Hz and 500 Hz (Butterworth filters; first-order analog and fourth-order digital respectively), and recorded at 2 kHz sampling rate and 16-bit resolution. No further offline filtering was performed on this data before analysis.

Multiunit activity was also extracted from the raw signal by filtering online between 250 Hz and 7.5 kHz (Butterworth filters; fourth-order digital and third-order analog respectively), and subjecting the resultant signal to an amplitude threshold of ~5 SD of the signal. The recorded units were found to have receptive fields located in the lower left quadrant of the visual field with respect to fixation in both monkeys, at an eccentricity of ~3°–4.5° in M1 and ~3.5°– 4.5° in M2. Full-field iso-luminant hues did not drive the neurons well, and therefore we did not get usable spiking activity from most electrodes. Therefore, as in our previous report (Shirhatti and Ray, 2018), all the analyses were performed only using LFP data (see Supplementary Figure 1 of Shirhatti and Ray, 2018, for description of spiking activity).

Experimental setup and behavior

During the experiment, the monkey was seated in a monkey chair with its head held stationary by the headpost. The monkey viewed a monitor (BenQ XL2411, LCD, 1,280 × 720 resolution, 100 Hz refresh rate) placed ~50 cm from its eyes. The monkey and the display setup

6

125 were housed in a Faraday enclosure with a dedicated grounding separate from the main supply

126 ground to provide isolation from external electrical noise. The monitor was calibrated and

127 gamma-corrected using i1Display Pro (x-rite PANTONE) to obtain a mean luminance of 60

128 cd/m^2 on its surface and to obtain a gamma of unity for each of the three primaries of the color

129 gamut, which had the following CIE chromaticity xy coordinates: red, (0.644, 0.331); green,

130 (0.327, 0.607); blue, (0.160, 0.062). The white point was at (0.345, 0.358).

131   Each monkey performed a passive fixation task, which required them to fixate at a small

132 dot of 0.05°–0.10° radius at the center of the screen throughout the trial (3.3 or 4.8 s duration;

133 fixation spot was displayed throughout). Each trial began with fixation, following which an

134 initial blank grey screen of 1,000 ms was displayed, and then, two to three stimuli were shown

135 for 800 ms each with an interstimulus interval of 700 ms. The monkey was rewarded with juice

136 for maintaining fixation within 2° from the fixation point. Trials in which fixation was broken

137 were not considered in our analyses. Eye position data was recorded as horizontal and vertical

138 coordinates using the ETL-200 Primate Eye Tracking System (ISCAN) and monitored

139 throughout the task using custom software running on macOS, which also controlled the task

140 flow, generated stimuli, and randomized stimuli presentation.

141 <u>Stimuli</u>

142   The stimuli consisted of 36 hues and 1 achromatic grating. The hues were equally

143 spaced along the circular hue space of the standard HSV nomenclature (0° hue to 350° hue,

144 where 0°, 120°, and 240° represent red, green, and blue respectively), which were displayed

145 full screen and at full saturation and value. The achromatic grating was at an orientation of 90°

146 and had a spatial frequency of 4 cpd for M1 and 2 cpd for M2. These grating parameters were

147 optimized to capture strong fast gamma with minimal slow gamma (see Murty et al., 2018).

7

148   The full-screen stimuli, in our setup, subtended a visual angle of ~56° in the horizontal

149   direction and ~33° in the vertical direction.

150   Electrode selection

151   As with our previous report (Shirhatti and Ray, 2018), electrodes were considered for

152   analysis only if they gave consistent stimulus-induced changes and reliable receptive field

153   estimates across sessions, determined by a receptive field mapping protocol that was run across

154   multiple days (Dubey and Ray, 2019). Further, we discarded signals from electrodes with

155   unusable or inconsistent signals, a high degree of crosstalk with other electrodes, or impedances

156   outside the range of 250–2,500 KΩ for monkey M1 and 125–2,500 KΩ for M2. This resulted

157   in 64 and 16 usable electrodes for M1 and M2, respectively.

158   Data Analysis

159   Stimulus presentations with excessive artifacts (<5.9% and <5.0% of presentations of

160   each stimulus in M1 and M2) were discarded for each session, yielding 19.9±6.2 repeats in M1

161   and 20.2±1.0 repeats in M2 per stimulus.

162   Spectral analysis of LFP

163   For each stimulus, LFP recorded from -500 to 0 ms from stimulus onset was taken as

164   the 'baseline period' and 250 to 750 ms from stimulus onset was taken as the 'stimulus period'

165   to avoid the transient responses to the stimulus onset. This yielded a frequency resolution of 2

166   Hz in the Power Spectral Density (PSD). PSD was computed using the Multitaper method

167   using the Chronux toolbox (Bokil et al., 2010), with three tapers. The change in power was

168   calculated as 10 times the difference between base-10 logarithm of PSDs at stimulus period

169   and baseline period, expressed in decibels (dB). Estimation of peak frequencies was done on

170   these baseline-corrected PSDs.

8

171   Gamma range was taken as 30-70 Hz, and 'gamma peak frequency' was estimated as

172   the highest peak within this range. In most stimulus conditions tested, a discernible 'second

173   bump' was observed in the baseline-corrected PSD. The peak frequency of the second bump

174   was estimated as the highest peak occurring beyond 12 Hz after the estimated gamma peak

175   frequency up to 140 Hz, to exclude higher frequency bumps.

176   <u>Analysis of gamma and harmonic phases</u>

177   To compute the phase difference of gamma and its first harmonic, gamma and harmonic

178   signals were extracted from LFP during the stimulus period by bandpass filtering using separate

179   Butterworth filters (zero-phase; order 4). The passband for gamma was 20 Hz wide, centered

180   around the gamma peak frequency, identified from trial-averaged PSD for a given stimulus and

181   an electrode. The passband for the first harmonic of gamma was also 20 Hz wide but centered

182   around twice the corresponding gamma peak frequency. The phases of these signals (φ_{gamma}

183   and $\varphi_{harmonic}$) were then computed using Hilbert transform. The phase difference between

184   gamma and its harmonic was calculated as:

185   Phase difference = $|2*\varphi_{gamma} - \varphi_{harmonic}|$ (1)

186   The above phase difference estimate was computed at each timepoint within the

187   stimulus period of every trial for each electrode.

188   Effect of harmonic phase on gamma waveform

189   To illustrate the effect of the gamma-harmonic phase relationship on the shape of

190   gamma waveform, gamma and its first harmonic were mimicked using sinusoids and the initial

191   phase of gamma (φ_G) was varied. The formulation of gamma and harmonics were as follows:

192   Gamma wave, $G = \cos(2\pi\ 45\ t + \varphi_G)$

193   Harmonic wave, $H = \frac{1}{4}*\cos(2\pi\ 90\ t)$

9

194   Sum of gamma and harmonic = G + H   (2)

195   These waveforms are displayed in Figure 4C along with the phase difference (Figure

196   4D) obtained by applying equation (1).

197   <u>Experimental Design and Statistical Analysis</u>

198   First, we tested our hypothesis that the second bump in PSD accompanying gamma was

199   indeed its harmonic by computing the ratio of harmonic to gamma peak-frequencies, obtained

200   from the trial-averaged change in power (dB) from baseline spectra for each electrode. The

201   ratios were subsequently subjected to a non-parametric Wilcoxon signed rank test (Null

202   hypothesis: median ratio = 2). The standard error (SE) of the median of the gamma-harmonic

203   frequency ratio was estimated by bootstrapping over N iterations (where N is the number of

204   datapoints). This involved random sampling with replacement of the ratio data N times and

205   estimating their median each time, which resulted in N medians, whose standard deviation (SD)

206   is reported as the standard error (SE).

207   Circular statistics on the gamma-harmonic phase difference data were computed in

208   Matlab using the Circular Statistics toolbox (Berens, 2009). The mean phase differences are

209   reported as MEAN ± CI in Figure 5, where MEAN is the circular mean and CI is the 95%

210   confidence interval of MEAN, under a Von Mises distribution (implemented in *circ_mean* and

211   *circ_confmean* functions of the Circular Statistics toolbox).

212   To validate that the distribution of gamma-harmonic phase differences was non-

213   uniform and, thus, assess the validity of circular mean estimates in Figure 5, we subjected trial-

214   averaged phase-differences gathered from all electrodes for a given stimulus to a Rayleigh test

215   of non-uniformity (Null hypothesis: uniform distribution of phases). When the gamma activity

216   recorded for a given stimulus has a specific waveform across electrodes, the corresponding

10

217   distribution of gamma-harmonic phase-differences will be unimodal. We considered this to be

218   the case when the p-value of the Rayleigh test was less than 0.01.

Studying non-sinusoidal waveforms in mean-field models of gamma

220   To understand the factors resulting in the characteristic waveform of gamma, we

221   investigated the gamma-harmonic phase relationship emerging in mean-field models

222   introduced in earlier works, which produced gamma oscillations with power and frequency

223   trends as observed in experiments. We explored the waveform in these models by identifying

224   input regimes that produced a first-harmonic with a specific phase difference from the

225   fundamental of gamma, as required for its arch-shape. We assessed the presence of such

226   regimes in two models. The first model operated linearly and produced oscillations by virtue

227   of stochastic time-varying inputs (Jia-Xing-Kohn or JXK model; Jia et al., 2013), while the

228   second model had non-linear dynamics, which gave rise to gamma frequency limit cycles in

229   response to constant inputs (Jadi and Sejnowski or JS model; Jadi and Sejnowski, 2014).

Jia-Xing-Kohn (JXK) model

231   Jia et al. (2013) defined a linear EI rate-model and extended it by adding a Global

232   Excitatory Population (G) to approximate recurrent excitatory feedback within V1. The model,

233   when subjected to step input, acts as a damped oscillator but produces oscillations by virtue of

234   constant perturbation from the Poisson inputs. The original model, formulated in the paper,

235   incorporates detailed stimulus descriptions, namely Masked Noise (MN) level and stimulus

236   size (r). The stimulus size parameter (r) scales the extent of Network recurrence in steady-state

237   proportionally as larger size stimuli excite a larger area of cortical cells, increasing the global

238   feedback. In our simulations, the Masking Noise level (MN) has been set to 0, resulting in the

239   following reduced formulation.

240    $$\tau_E \frac{dr_E}{dt} = -r_E + W_{EE}\lfloor r_E \rfloor - W_{EI}\lfloor r_I \rfloor + W_{EG}\lfloor r_G \rfloor + E_{inp}$$

11

241 $\quad \tau_I \dfrac{dr_I}{dt} = -r_I + W_{IE}\lfloor r_E \rfloor - W_{II}\lfloor r_I \rfloor + W_{IG}\lfloor r_G \rfloor + I_{inp}$

242 $\quad \tau_G \dfrac{dr_G}{dt} = -r_G + r^2 . W_{GE}\lfloor r_E \rfloor$

243 where $\lfloor x \rfloor = x \; if \; x > 0 \; and \; 0 \; otherwise,$ and E_{inp} and I_{inp} approximate a Poisson process

244 with average rates IE and II respectively, which vary with stimulus contrast (c) as:

245 $\quad I_E = 40. \dfrac{c^2}{c^2 + 0.3^2}; \; I_I = 32. \dfrac{c^2}{c^2 + 0.3^2}$ $\hfill (3)$

246 Parameter values of this model are given in Table 1.

247 <u>Jadi-Sejnowski (JS) model</u>

248 $\quad$ Jadi and Sejnowski (2014) used a simple rate model consisting of an excitatory and an

249 inhibitory population with sigmoidal activation, operating as an Inhibition Stabilized Network

250 (ISN) and constrained the input drives to the populations to reproduce the increase in power

251 and decrease in peak frequency of gamma with increasing stimulus size as earlier studies have

252 observed in V1 (Gieselmann and Thiele, 2008; Ray and Maunsell, 2011).

253 $\quad$ The model defines the population firing rates of Excitatory and Inhibitory populations

254 as follows:

255 $\quad \tau_E \dfrac{dr_E}{dt} = -r_E + \sigma_E(W_{EE}r_E - W_{EI}r_I + I_E)$

256 $\quad \tau_I \dfrac{dr_I}{dt} = -r_I + \sigma_I(W_{IE}r_I - W_{II}r_I + I_I)$

257 $\quad \sigma_P(x) = \dfrac{1}{1+exp(m_P.(\theta_P - x))} - \dfrac{1}{1+exp(m_P.\theta_P)}$ $\hfill (4)$

258 In this model, larger stimuli cause an increased inhibitory drive to the population, owing to

259 suppression from the surrounding populations. Since the model operated close to a supercritical

260 Hopf bifurcation, the amplitude and frequency of oscillations in firing rates could be closely

12

261   approximated by linearization of the model. The authors deduced and demonstrated that the

262   model gave rise to the observed trends in the gamma when the inputs were such that the

263   inhibitory population was strongly 'superlinear'. This means that the summed inputs to the

264   inhibitory population (from recurrent and external sources; argument of σ_I in equation 4) must

265   lie in a certain range of values where the activation function σ_I curves upwards (increasing in

266   slope with increasing summed input). For the sigmoidal activation function used in equation 4,

267   the summed inputs must operate in the lower half of the sigmoid. Superlinear activation of the

268   excitatory population, on the other hand, was antagonistic (not strongly superlinear). The set

269   of such inputs constitute the operating regime of the model, which we refer to as the

270   'superlinear' regime.

271   <u>Identifying the operational input regimes using gamma-harmonic phase difference</u>

272   Because the gamma-harmonic relationship was studied using LFP recordings in real

273   data while the model simulations yielded firing rates of excitatory and inhibitory populations,

274   these firing rates had to be converted to a 'proxy' LFP. The relationship between the two is

275   complex (Hasenstaub et al., 2005; Einevoll et al., 2013; Mazzoni et al., 2015). For simplicity,

276   we used the negative sum of population firing rates of the excitatory and inhibitory populations

277   in the models as a proxy for LFP, since the LFP, being the extracellular potential, could be

278   approximated to vary inversely with the depolarization (excitability) of these populations. We

279   also approximated the LFP as the negative of just the excitatory or inhibitory populations,

280   which yielded qualitatively similar results. We elaborate this further in the Discussion section.

281   The environment used for simulation was Matlab 2019b (Mathworks,

282   RRID:SCR_001622), where the models were simulated by a forward Euler method, with

283   parameters as in Table 1. Simulations were run for a duration of 2 seconds in time-steps of 0.1

284   ms, on all pairs of 41 excitatory and 41 inhibitory input values sampled from the ranges

285   specified in Table 1. In each case, PSD of the LFP proxy was computed between 1-2 seconds

13

286   to avoid the initial slow transient. The gamma and harmonic peak frequencies were identified

287   as frequencies containing maximum power in the 30-70 Hz range and twice the gamma peak

288   frequency, respectively. For further analyses in the JS model, only those input combinations

289   were considered for which gamma and harmonic frequency amplitudes were greater than 1e-3

290   and 1e-6 units respectively, to ensure phase analysis of oscillatory activity was not dominated

291   by simulation errors or noise (grey region in Figure 7F). The LFP proxy signal was filtered

292   using 20 Hz passbands centered at each frequency identified above. The gamma-harmonic

293   phase difference (equation 1) was computed, just as for LFP in macaque data. An input point

294   (pair of values supplied as excitatory and inhibitory input drives; stimulus parameters in the

295   case of JXK) was said to be 'in-regime' if the gamma-harmonic phase difference was within

296   22.5 degrees from 180-degrees (ideal for arch shape; Figure 4).

297   Since JXK takes stochastic inputs, to assess if there is indeed a unique gamma-harmonic phase

298   difference at each of the mean input-drive combinations tested and whether the model can

299   indeed exhibit in-regime behavior, we ran the simulation 50 times (analogous to 50 different

300   trials) for each stimulus condition. In each iteration, we considered the mean phase-difference

301   over the 1-2 second interval. For every selected input combination, the mean phase difference

302   over this interval in each iteration was taken and the resultant pool of 50 mean phase differences

303   was subjected to Rayleigh test of uniformity to identify those inputs that have a 'consistent'

304   gamma-harmonic phase relationship across iterations (p-value < 0.01). Among the qualifying

305   input combinations, those input drive pairs for which the circular mean of mean phase

306   differences across iterations lay within 180±22.5 degrees were deemed to be 'in-regime'. For

307   JXK, the gamma-harmonic phase reported in Figure 6 is the circular average of the phase

308   differences from all the iterations. The amplitudes of gamma and its first harmonic in the figure

309   are estimated from the average PSD (examples in Figure 6C-D), computed as the mean of the

310   PSDs obtained from 50 iterations for a given stimulus combination.

14

Results

311 We collected spikes and LFP from 96 and 81 electrodes from two monkeys, M1 and

313 M2, while they viewed full-screen color patches of different hues. Limiting our analysis to

314 electrodes with reliable estimates of RF centers (see "Electrode selection" section in Methods)

315 yielded 64 and 16 electrodes from the two monkeys.

First harmonic of gamma oscillation

317 In Figure 1A-D, the top row shows the power spectral density (PSD; averaged across

318 all trials and subsequently across all electrodes) of the LFP signal in subject M1 during baseline

319 period (-500 to 0 ms from stimulus onset; black trace) and during stimulus period (250 to 750

320 ms from stimulus onset; color/grey trace; the color indicates the hue that was presented and

321 grey trace represents gratings). The corresponding change in power (dB) from baseline (Figure

322 1A-D bottom row) shows a prominent peak in the gamma range, along with another prominent

323 peak near twice the frequency. Figure 1E-H show the same plots from subject M2. We first

324 tested whether this second peak was indeed at twice the frequency. For each electrode and

325 stimulus, we measured the gamma peak frequency from trial-averaged baseline-corrected

326 PSDs as the highest peak within the 30-70 Hz band, and the peak of the second bump as the

327 highest peak occurring after 12 Hz past the identified gamma peak frequency but before 140

328 Hz (the identified peaks are highlighted by black crosses in Figure 1).

329 Figure 2 presents the medians of the frequency ratios of second bump to gamma peak

330 frequencies for each stimulus (hues indicated by color, gratings by grey color), computed

331 across all electrodes in each subject, with error bars indicating the standard error of the median

332 computed by bootstrapping. The stimuli are arranged along the horizontal axis by the average

333 gamma power across electrodes. The frequency ratios were tightly clustered around 2,

334 especially for stimuli that produced strong gamma oscillations. To test whether the ratio for a

335 given stimulus was significantly different from 2, the frequency ratios computed in different

15

336   electrodes for the stimulus were subject to a Wilcoxon signed rank test. Stimuli for which the

337   ratios were found to be significantly different from 2 (p < 0.01) are indicated by open circles.

338   Estimates of peak-frequency ratios for stimuli producing less gamma power were more

339   susceptible to noise and showed larger deviations in frequency ratios. However, frequency

340   ratios were distributed more narrowly around 2 for stimuli inducing stronger gamma. The

341   median ratio value for M1 was 2.00±0.021, not significantly different from 2 (p = 0.26 for M1;

342   Wilcoxon signed rank test). For M2, the median ratio was 1.95±0.026, significantly different

343   from 2 (p = 9.96e-6; Wilcoxon signed rank test). However, note that because we computed

344   PSDs over a 500 ms window, the frequency resolution was 2 Hz, which introduced some error

345   in the estimated ratio. For example, if the true gamma and harmonic peaks are at 41 and 82 Hz,

346   the estimated gamma will either be at 40 or 42 Hz, yielding a ratio of either 82/40 = 2.05 or

347   82/42 = 1.95. These margins of error are shown as dotted lines in Figure 2. Most of the points

348   lay within these error margins, especially for electrodes with higher gamma power. When we

349   restricted the analysis to the top ten hues for each monkey in terms of gamma power, the ratios

350   were 1.98±0.046 (p=1; Wilcoxon signed rank test) and 1.99±0.014 (p=0.38; Wilcoxon signed

351   rank test). These results confirm that the second peak was indeed the first harmonic of gamma.

352   We also note that achromatic gratings failed to produce a salient harmonic in M2 (Figure 1H),

353   yielding a ratio that was much less than 2 (Figure 2). Although the frequency ratios for

354   achromatic gratings in most electrodes were concentrated near 1.5 (as indicated by the very

355   small errorbars), a few electrodes (2 out of 16) gave ratios greater than 2, causing the Wilcoxon

356   signed rank test to fail in rejecting the Null hypothesis (albeit with a small p-value of 0.042).

357   Shape of the gamma waveform

358   Figure 3 shows LFP traces from example trials corresponding to each stimulus case

359   presented in Figure 1. These traces revealed a characteristic arch shape of gamma waveform,

360   featuring narrower troughs separated by much broader crests, hinting at a characteristic

16

361   alignment of gamma fundamental and its harmonic in these cases (best observed in M2 when

362   colored patches were shown).

363   To visualize how phase differences between gamma and its first harmonic components

364   affected the shape of the summed signal, we added two sinusoids to emulate the fundamental

365   and the first harmonic of gamma, at frequencies 45 Hz and 90 Hz respectively, and varied the

366   initial phase of the 45Hz component (as described in equation 2; shown in Figure 4A). Figure

367   4B shows the waveforms produced at each of these phases, and Figure 4C indicates the

368   corresponding values of our phase difference measure (computed as in equation 1) between

369   gamma and its harmonic. Using our convention (equation 1), a phase difference of 180 degrees

370   (Figure 4A-C row 3) gave the desired shape as troughs of both sinusoids aligned to produce a

371   steeper overall trough.

372   <u>Gamma waveform is similar in different hues</u>

373   In Figure 5, we show the distribution of trial-averaged gamma-harmonic phase

374   differences in all electrodes, for each stimulus (indicated by color), arranged horizontally in

375   order of average gamma power produced. For each stimulus, the trial-averaged phase

376   differences from all electrodes were subject to Rayleigh test, and the stimuli with non-uniform

377   phase difference distributions (p-value < 0.01) are indicated by filled circles. The error bars in

378   each case represent the 95% confidence interval of mean phase differences. The phase

379   differences at higher gamma generating stimuli were distributed close to $180°$ in both subjects,

380   as predicted from the arch-shaped waveforms (Figure 4). Stimuli that produced low power had

381   high dispersion of phase differences, likely originating from higher influence of noise, as is

382   visible from the larger confidence intervals in M1, resulting in some hues with nearly uniform

383   phase difference distributions (unfilled circles; some cases lack error bars as confidence

384   intervals could not be computed due to their near-uniform distributions). For hues that

385   generated high gamma power, gamma-harmonic phase differences were concentrated slightly

17

386   higher than 180° for M1 and close to 180° for M2. The circular mean of electrode-averaged

387   phase difference between gamma and its first harmonic across those stimuli which showed

388   unimodal distribution (filled circles in Figure 5; 29 stimuli in M1 and all stimuli in M2) was

389   185.33±16.66 degrees for M1 (176.60±16.32 degrees if all stimuli were considered) and

390   153.90±5.56 degrees for M2. When restricted to the ten hues with the highest gamma power

391   for each monkey, the phases were 206.02±4.65 degrees for M1 and 170.23±3.00 degrees for

392   M2.

393   <u>Gamma waveform in a linear population rate model with stochastic inputs</u>

394   To test whether the stereotypical gamma waveforms observed in the data could be

395   modeled, we focused on two recently developed rate models by Jia, Xing and Kohn (2013;

396   abbreviated as the JXK model) and Jadi and Sejnowski (2014; JS model), both of which can

397   explain the contrast and size dependence of gamma oscillations (see Methods for details).

398   The JXK model, which is a piecewise linear model, operates as a damped oscillator in

399   its linear domain and produces sustained oscillations by virtue of time-varying input drives

400   generated by a Poisson process causing the responses to be stochastic as well. Hence, we

401   simulated the model over 2 seconds repeatedly for 50 iterations and analyzed the interval from

402   1-2 seconds ('analysis' window). Figure 6A shows the gamma peak amplitude obtained from

403   the average PSD of the LFP proxy across iterations for each stimulus size and contrast; Figure

404   6B shows the corresponding mean gamma peak frequencies. These plots show the model

405   replicating the stimulus size/contrast effects on gamma as demonstrated by Jia et al. (2013):

406   gamma frequency decreased and power increased as stimulus size increased, and gamma peak

407   frequency increased when contrast increased. Figure 6C shows the average PSD from all

408   iterations for different stimulus sizes (r) at a fixed contrast (c) of $10^{-0.25}$, showing a distinct

409   bump of activity in gamma range, whose peak frequency decreases but peak power increases

410   as we go from small to larger values of stimulus size (r). Likewise, Figure 6D shows the average

18

411 PSD for different contrasts and a fixed size of 4.375. The gamma peak frequency in the LFP

412 proxy increased with contrast as demonstrated by Jia et al. (2013). However, the gamma bumps

413 were broad, as expected of a noisy pseudoperiodic signal, and no prominent harmonic band

414 activity was discernible in the PSDs. We performed phase analysis, considering the activity in

415 the band centered around twice the gamma peak frequency (Figure 6B) as the harmonic band

416 activity. Figure 6E shows the harmonic amplitudes and Figure 6F shows the mean gamma-

417 harmonic phase differences of LFP proxy traces from different iterations. We searched for

418 stimulus size and contrasts which yielded arch-shaped gamma, or equivalently a gamma-

419 harmonic phase differences close to 180 degrees (Figure 4C, middle) consistently across

420 iterations. Such domains of inputs are shown by black contours in Figure 6F and are identified

421 as 'in-regime' stimuli (see Methods; *Identifying the operational input regimes using gamma-*

422 *harmonic phase difference*). Such regimes were few and scattered sparsely. An example LFP

423 proxy trace for the highest contrast condition in Figure 6D, which was in-regime, is shown in

424 Figure 6G. The top panel shows the LFP proxy trace and the bottom panel shows the gamma

425 (blue) and harmonic (red) band signals. The LFP traces exhibited bursts of gamma oscillations

426 with randomly distorted waveforms, with no consistent relationship between gamma and the

427 harmonic.

428 Gamma waveform in JS model

429 Jadi and Sejnowski (2014) simulated visually evoked gamma using a firing rate model

430 with only an Excitatory and an Inhibitory population and demonstrated gamma as self-

431 sustained oscillations in response to steady constant input drives. As a result, any waveform

432 shape found in a cycle of the oscillations is repeated throughout. We studied whether this model

433 could produce realistic gamma waveforms by identifying the input regime (pairs of input drives

434 to Excitatory and Inhibitory population) that would give rise to gamma-harmonic phase

435 difference around 180° in LFP.

19

436   We implemented the model with the parameters specified in Jadi and Sejnowski (2014)

437   for different input drives as listed in Table 1, and computed the LFP proxy in each case. Figure

438   7A-B shows the gamma peak amplitude and frequency respectively computed from the LFP

439   proxy for each input-combination. The region within the white contour indicates an inhibition-

440   stabilized network in which the inhibitory inputs are superlinear (for details, see Jadi and

441   Sejnowski (2014)). Figure 7C shows the PSDs of LFP proxies obtained for different inhibitory

442   input drives and a constant excitatory drive (input-combinations marked by same colored

443   markers in Figures 7A-B), simulating the variation of stimulus size at a fixed contrast, as

444   simulated in Jadi and Sejnowski (2014). The PSDs demonstrate the decrease in peak frequency

445   and increase in power of gamma in our LFP proxy signal with increasing stimulus size. To

446   demonstrate the contrast effect, we chose a set of input-combinations where both excitatory

447   and inhibitory input drives linearly increased with contrast (colored markers in Figures 7A-B).

448   The PSDs of LFP proxy generated for increasing contrasts are shown in Figure 7D. The gamma

449   frequency increased for higher contrasts mimicking gamma in LFP recordings (Jia et al., 2013).

450   Importantly, this model showed prominent harmonics as well.

451   Figure 7F plots the gamma-harmonic phase differences in the LFP proxy trace

452   generated for each input combination. Regions in the input drives where the phase difference

453   fell within $22.5°$ from $180°$ are enclosed by contours (Figure 7F, black contours) and identified

454   as 'in-regime'. Interestingly, this identified regimes fell inside the region predicted by Jadi and

455   Sejnowski, (2014) where inhibition was superlinear (Figure 7F, white contours), and hence

456   both validated their earlier findings and constrained the model to operate in more restricted

457   regions. Figure 7G presents an example LFP proxy trace in the top panel, corresponding to the

458   largest size condition in Figure 7C (in-regime), whose gamma fundamental (blue) and first

459   harmonic (red) components are shown in the bottom panel. The troughs of gamma and

460   harmonic were indeed aligned, adding up to a wider crest and a sharper trough overall.

20

461   Figure 8 shows the gamma-harmonic phase differences and regimes found in both the

462   models when the activity of only one population was taken as the LFP proxy. Figure 8A show

463   the phase differences in the JXK model using -rE as LFP proxy and Figure 8B shows the results

464   using -rI. As before, no connected region of in-regime stimuli could be found (similar to the

465   case in Figure 6F). Figure 8C-D show the phase differences found in the JS model using these

466   LFP proxies. While the location and number of in-regime inputs identified were different, the

467   superlinear regime was still found to contain a connected region of in-regime inputs in either

468   case. This suggests that an LFP proxy chosen as any non-negative linear combination of -rE

469   and -rI, would give rise to 'in-regime' inputs within the superlinear regime of the JS model.

470

Discussion

472   We show quantitatively that gamma oscillations produced by different hues possess a

473   distinctive arch-shaped waveform, which leads to a distinct peak at the first harmonic of gamma

474   in the PSD, and a specific phase relationship between gamma and its harmonic. Further, we

475   show that a linear, stochastically forced model proposed by Jia et al. (2013) does not produce

476   distinct harmonics with consistent phase relationship and hence does not retain a specifically-

477   shaped gamma waveform. On the other hand, a non-linear, self-oscillating model proposed by

478   Jadi and Sejnowski (2014) produces prominent harmonics, and in a subdomain of inputs within

479   the previously identified superlinear regime, the model generates the observed gamma

480   waveform as well.

481   One important point to note is that this arch shaped gamma waveform with prominent

482   harmonics were categorized for hue induced gamma, whereas most previous reports have used

483   achromatic stimuli. In the achromatic stimulus used here, harmonics were not salient,

484   especially for M2. However, although earlier experimental studies using achromatic gratings

21

485 did not describe or quantify the gamma waveform, visual inspection of raw LFP traces

486 containing gamma bursts reveal a similar shape in some studies (Jia and Kohn, 2011, Fig. 2;

487 Jia et al., 2011, Fig. 1A; Xing et al., 2012, Fig. 2; Brunet et al., 2014, Fig. 2D) showing that the

488 arch-shape of gamma is observed for at least some achromatic stimuli. The arch shape

489 described here is also visible when monkeys viewed colored natural images (Brunet et al.,

490 2015, Fig. 2). Interestingly, some papers (Gieselmann and Thiele, 2008, Fig. 1; Jia et al., 2011,

491 Fig. 9) have shown traces with an inverted arch shape. It is unclear why this is the case;

492 potential reasons could be due to differences in the position of the reference wire, cortical depth

493 of recording, or differences in the conductance level. For example, arch-shaped gamma

494 waveform is observed in biophysical ING-PING and spiking models as well (Mazzoni et al.,

495 2015, Fig. 4; Lowet et al., 2016, Fig. 4), in which non-sinusoidal gamma arises from the

496 dynamics of the voltage-gated conductances, and the specific shape produced by the model

497 varies when the conductances are varied. LFP waveform also changes with the recording depth

498 (Figure 4B versus 4C of Mazzoni et al., 2015). Non-sinusoidal waveforms are common in

499 neural rhythms, such as the sawtooth-shaped theta rhythm in the hippocampus and comb-

500 shaped beta rhythm, arising from a variety of different biophysical phenomena (Cole and

501 Voytek, 2017).

502 <u>Gamma oscillations in the JXK model</u>

503 JXK model, like another model proposed by Kang and colleagues (Kang et al., 2010),

504 explains the "bursty" nature of gamma oscillations, which was shown in previous studies

505 (Burns et al., 2010; Xing et al., 2012). These studies observed that gamma band power varied

506 during a trial, with short intervals (~130 ms) of high gamma power, interspersed by durations

507 of no prominent power. Based on these, Xing et al. (2012) suggested that gamma rhythms were

508 the outcome of cortical network resonating to the stochastic component in the inputs. During

509 periods in a trial when stochastic variations in input are less, the cortical network would tend

22

510   to asymptotically stabilize and oscillations would get weaker over time. Xing et al. (2012)

511   demonstrated this mechanism in a piecewise linear asymptotically stable model with noisy

512   inputs. The JXK model (Jia et al., 2013) emulated gamma burst-activity exhibiting the observed

513   dependencies of gamma power and frequency on stimulus parameters such as size and contrast

514   by varying input drives and recurrent excitation to the neural populations. However, the JXK

515   model does not produce a consistent waveform shape, because despite the presence of a

516   rectification component, the model operates mostly in a linear (post-rectification) domain for

517   all inputs simulated. In this domain the step response would be sinusoidal oscillations damping

518   exponentially over time. Although the presence of Poisson inputs distorted the waveform and

519   prolonged oscillations for a longer duration, these distortions are not consistent across different

520   cycles of oscillation. This was reflected as wide band of activity around the gamma band in the

521   PSD (Figure 6C-D), and a lack of discernible harmonic activity. Therefore, while these models

522   adequately explained the bursty nature of gamma oscillations, it is not surprising that they

523   failed to produce a specific gamma waveform.

524   However, a recent study has shown that the duration of gamma 'burst' activity reported

525   in Xing et al. (2012) could have been underestimated (Chandran KS et al., 2017). This error

526   arises because the spectral estimator that is used to compute gamma power is itself noisy,

527   causing the rhythm to appear bursty in the spectral domain (see Chandran KS et al. (2017) for

528   details). Chandran KS et al. (2017) used Matching Pursuit algorithm with a Gabor dictionary,

529   which chooses the best-matching template to estimate the duration of a gamma burst in the

530   time domain itself to show that gamma bursts during presentation of achromatic grating were

531   longer than reported earlier (median of ~300 ms, although the mode was ~100 ms). Along with

532   the results presented here, this suggests that the gamma rhythm could have more temporal

533   regularity than what is predicted by these stochastic models.

23

534 However, we note that the non-sinusoidal nature of gamma rhythm described here could

535 be introduced in the JXK model by changing the activation function. Specifically, if a non-

536 linear activation function is used in the place of the piece-wise linear rectifier, the step response

537 of the system would itself be a specific non-sinusoidal waveform in subsequent cycles of the

538 resulting damped oscillation. When stochastic perturbations are added, the resultant bursts of

539 oscillatory activity will contain both irregular distortions caused by the noisily fluctuating

540 inputs and more regular distortions induced by non-linearity at specific parts of the trajectory

541 in each cycle. Therefore, although we show that our results are more consistent with JS instead

542 of the JXK model, it is possible that the JXK model with a suitable activation function can also

543 replicate our findings. Indeed, while the JS model generates the proper gamma shape within a

544 sub-regime, the duration of gamma is as long as the duration of the stimulus itself. Therefore,

545 some stochasticity may be necessary to replicate all features of gamma rhythmicity, including

546 duration and shape.

547 In the JXK model, there were a few inputs that qualified our phase-difference criteria

548 for 'in-regime' behavior. However, a close examination of the 'in-regime' trace (example in

549 Figure 6G) revealed that, in addition to the irregularly distorted gamma cycles, these inputs

550 had occasional isolated steep troughs. These steep troughs could be approximated by a negative

551 impulse, which could be decomposed as a series of sinusoids with their troughs aligned,

552 resulting in sporadic 180-degree phase-difference estimates. Since these distortions are of

553 lower frequency than gamma, the JXK model does not operate 'in-regime' for any input

554 combination.

555 <u>Relationship between firing rates and LFP</u>

556 JXK and JS models used excitatory cell activity to study the power and frequency trends

557 of gamma. Here, we converted these firing rates to a "proxy" LFP to be compatible with the

558 real data. Because the extracellular potential is generated due to the spatial separation of

24

559   transmembrane currents (generating dipoles or multi-poles), as well as alignment of such

560   dipoles across neurons, LFPs are thought to mainly reflect the transmembrane currents of

561   pyramidal neurons (Einevoll et al., 2013). But Hasenstaub et al. (2005), in their in-vivo study

562   of ferret prefrontal cortex, found that the postsynaptic potentials and the firing of regular-

563   spiking excitatory neurons and fast-spiking interneurons were both synchronized to the

564   extracellular gamma rhythm, but the activation of interneurons was more aligned with the

565   troughs of the oscillation. A modelling study (Mazzoni et al., 2015) simulated LFP using

566   various outputs of a Leaky Integrate-and-Fire (LIF) network (such as firing rates, membrane

567   potential and synaptic currents) and found that the sum of absolute values of synaptic currents

568   (with both AMPA and GABA currents weighted nearly equally) served as the best proxy for

569   LFP. As far as gamma oscillations are concerned, some studies have shown that spikes tend to

570   occur just before the trough of gamma (Chalk et al., 2010; Vinck et al., 2010; Das and Ray,

571   2018), with the pyramidal cells leading the interneurons by a few milliseconds (Csicsvari et

572   al., 2003; Hasenstaub et al., 2005; Vinck et al., 2013). In the JS model as well, we found that

573   the E population led the I population by about 50º or 2-3 ms in the superlinear regime. Further,

574   the results were qualitatively similar when just E or I or the sum of both were used as the LFP

575   proxy (Figure 7 and Figure 8).

576   <u>Gamma and Harmonics vs slow/fast gamma</u>

577   Murty et al., (2018) showed that fullscreen achromatic gratings produced two different

578   oscillations simultaneously – a fast gamma (40-70 Hz), which has been observed previously

579   for smaller sized gratings, and a slow gamma (20-40 Hz) which is prominent only for large

580   stimuli. Even though this also generates two bums in the PSD, fast gamma is not a harmonic

581   of the slow gamma. First, the center frequency of fast gamma was not twice that of slow

582   gamma. Second, slow and fast gamma were not co-tuned: they had distinct orientation,

583   contrast, temporal frequency and size tuning preferences.

25

584   The arch-shape shown here poses additional problems for phase coding schemes in

585   which spike position relative to the gamma phase is used to code information (Fries et al., 2007;

586   Vinck et al., 2010), because spikes tend to occur near the trough of the rhythm and having a

587   sharper trough reduces the operating range. Other studies have proposed that gamma

588   oscillations may not play a role but could be a useful marker/indicator of cortical processing

589   (Ray and Maunsell, 2015). In that framework, properties such as shape and duration along with

590   stimulus tuning could provide additional clues about the underlying circuitry.

693   **Figures**
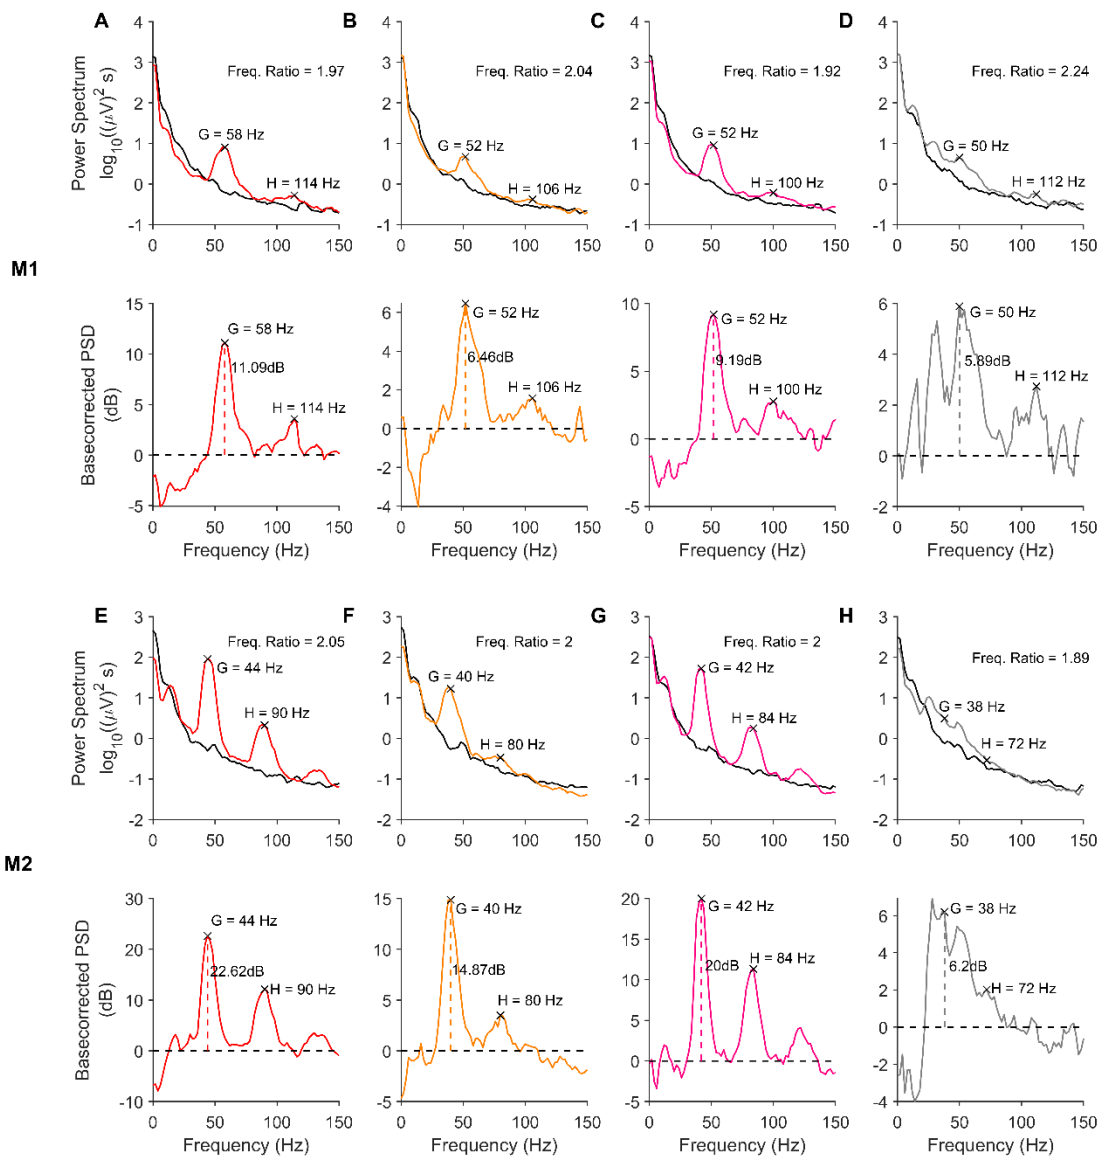

694

695   **Figure 1: Visual Stimulation induces narrowband activity in gamma and its harmonic**

696   **bands.** (A-D, *top row*) PSDs for baseline (-500 to 0 ms; 0 indicates stimulus onset) and

697   stimulus (250 to 750 ms) periods for different stimuli, averaged across trials and electrodes,

698   from monkey 1 (M1). The baseline PSDs are plotted in black, while the stimulus period PSDs

699   are colored (corresponding to the hue presented) or grey (for fullscreen grating). (A-D, *bottom*

700   *row*) show the change in power (dB) in the stimulus period from the baseline, computed from

701   the PSDs in the top row. The gamma power computed from the change in power spectrum is

32

702   represented by vertical dashed line). The peaks in gamma range and the second bump activity

703   are marked in each plot. (E-H) Same as A-D, for monkey M2.

704
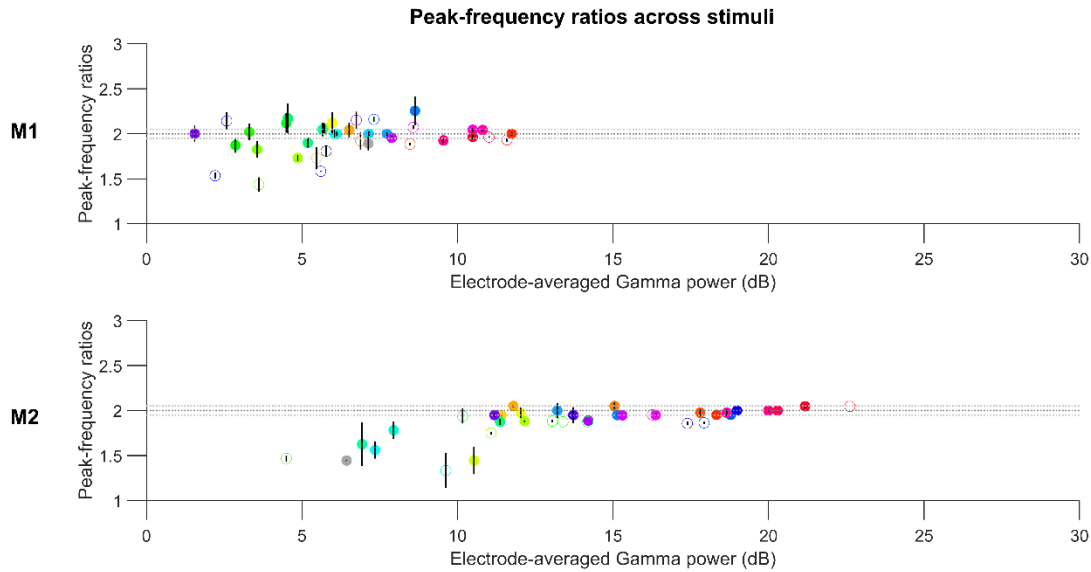

Figure 2: Second bump in PSD corresponds to the first harmonic of gamma. Median of peak frequency ratios of the second bump with respect to the gamma band, scattered against average gamma power for each stimulus (circles are colored to represent the presented hues; grating stimulus is represented by the grey circle). Error bars indicate the standard error of median (estimated by bootstrapping). Open circles mark stimuli whose ratios were found to be significantly different from 2 (p-value < 0.01 without any Bonferroni correction; Wilcoxon signed-rank test). The dotted horizontal lines correspond to the least-error margin 2±0.05.

714
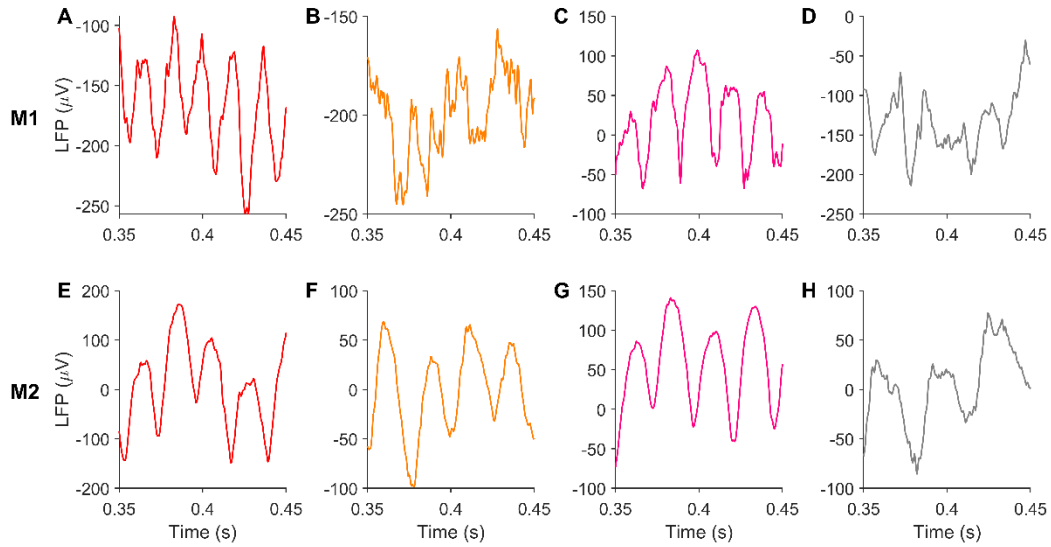

Figure 3: Gamma waveform has consistent non-sinusoidal shape under different stimuli.

(A-D) present LFP traces for different stimuli, shown in Figure 1, from an example trial and electrode in M1. (E-H) shows LFP traces obtained from M2 for corresponding stimuli.

718

719
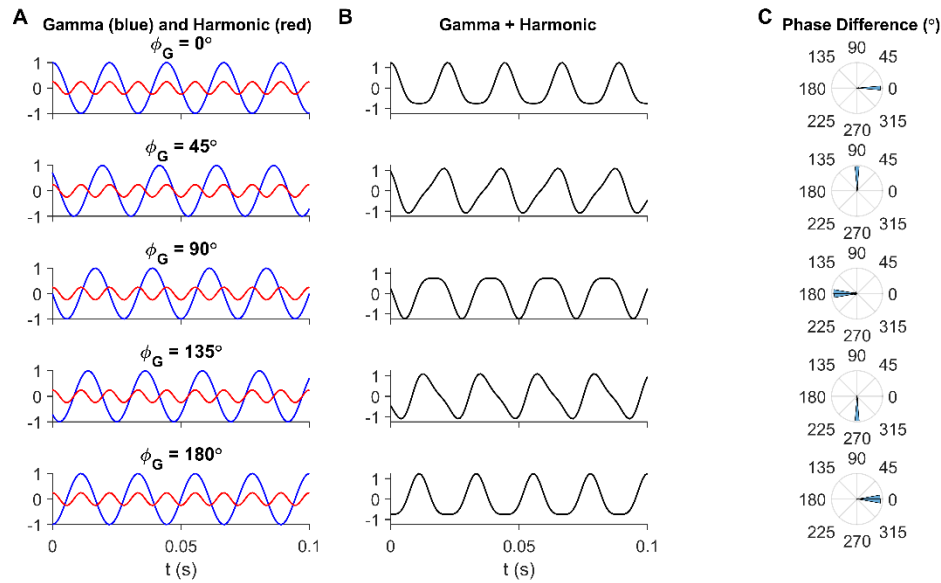

Figure 4: Observed arch-shape of gamma corresponds to gamma-harmonic phase difference of 180°. (A) Gamma (blue) and harmonic (red) components, mimicked using sinusoids as in equation (2) with different initial gamma phases (φ_G) in each row. (B) Gamma waveform resulting from summation of gamma and its harmonic from the corresponding row in (B). (C) Phase difference of gamma and its first harmonic, as given in equation (1), computed from filtering and Hilbert transforming gamma and harmonic bands from the summed waveform in (B) in each row. Note that the arch-shaped gamma observed in recordings arises from a phase difference of 180° (middle row).

728

36

Figure 5: Gamma-harmonic phase differences in different stimuli are concentrated near 180°. Circular mean of trial-averaged gamma-harmonic phase differences (across all electrodes) are scattered against the average gamma power for each stimulus (circles are colored to represent the presented hues; grey for grating stimulus). For each stimulus, the pool of trial-averaged phase differences from all electrodes is subject to Rayleigh test of non-uniformity to check if phase-difference is consistent across electrodes so that circular mean estimates are reliable (p-value < 0.01). If found reliable (even though it could be different from 180º), the stimulus is represented by a filled circle. Error bars represent the 95% confidence interval of circular mean.

37

740

38
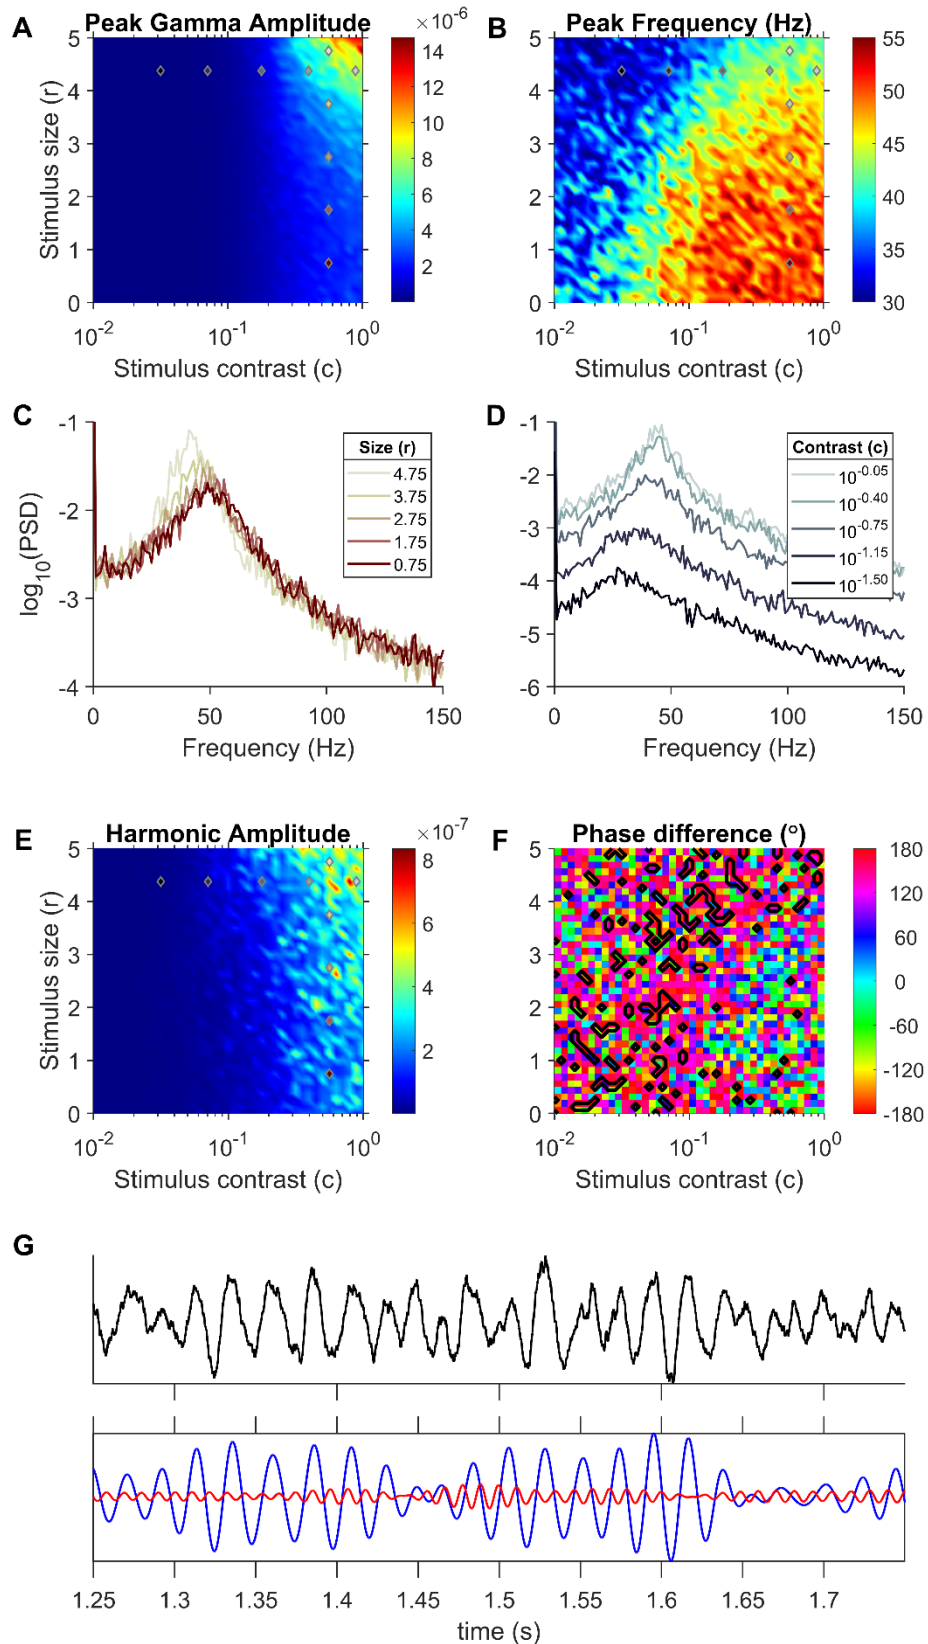

741 **Figure 6: Gamma properties for the JXK model** (A) Gamma peak amplitude and (B)

742 frequency found in the average PSD from 50 iterations at each stimulus size (r) and contrast

743 (c) combination. (C) Average PSD of LFP proxy traces generated at fixed contrast and different

744 sizes, across all iterations. (D) Average PSD of LFP proxy traces generated at different

745 contrasts at a fixed size. The stimuli values that generated these PSDs are indicated in plots

746 (A), (B) and (E) using colored markers (same colors as the plots in C and D). (E) Harmonic

747 band peak amplitude in the average PSD. The harmonic is taken to be twice of gamma

748 frequency. (F) Mean gamma-harmonic phase difference (equation (1)) across multiple

749 iterations, with in-regime inputs encircled by black contours. (G) Example LFP proxy activity

750 (top panel) and its gamma and first harmonic components (bottom panel) generated at the

751 highest contrast condition in (D) (identified as in-regime). This trace shows occasional steeper

752 troughs (bottom trace; near 1.35 s, 1.52 s and 1.58 s timepoints) although there is no consistent

753 trend between gamma and the harmonic.

754
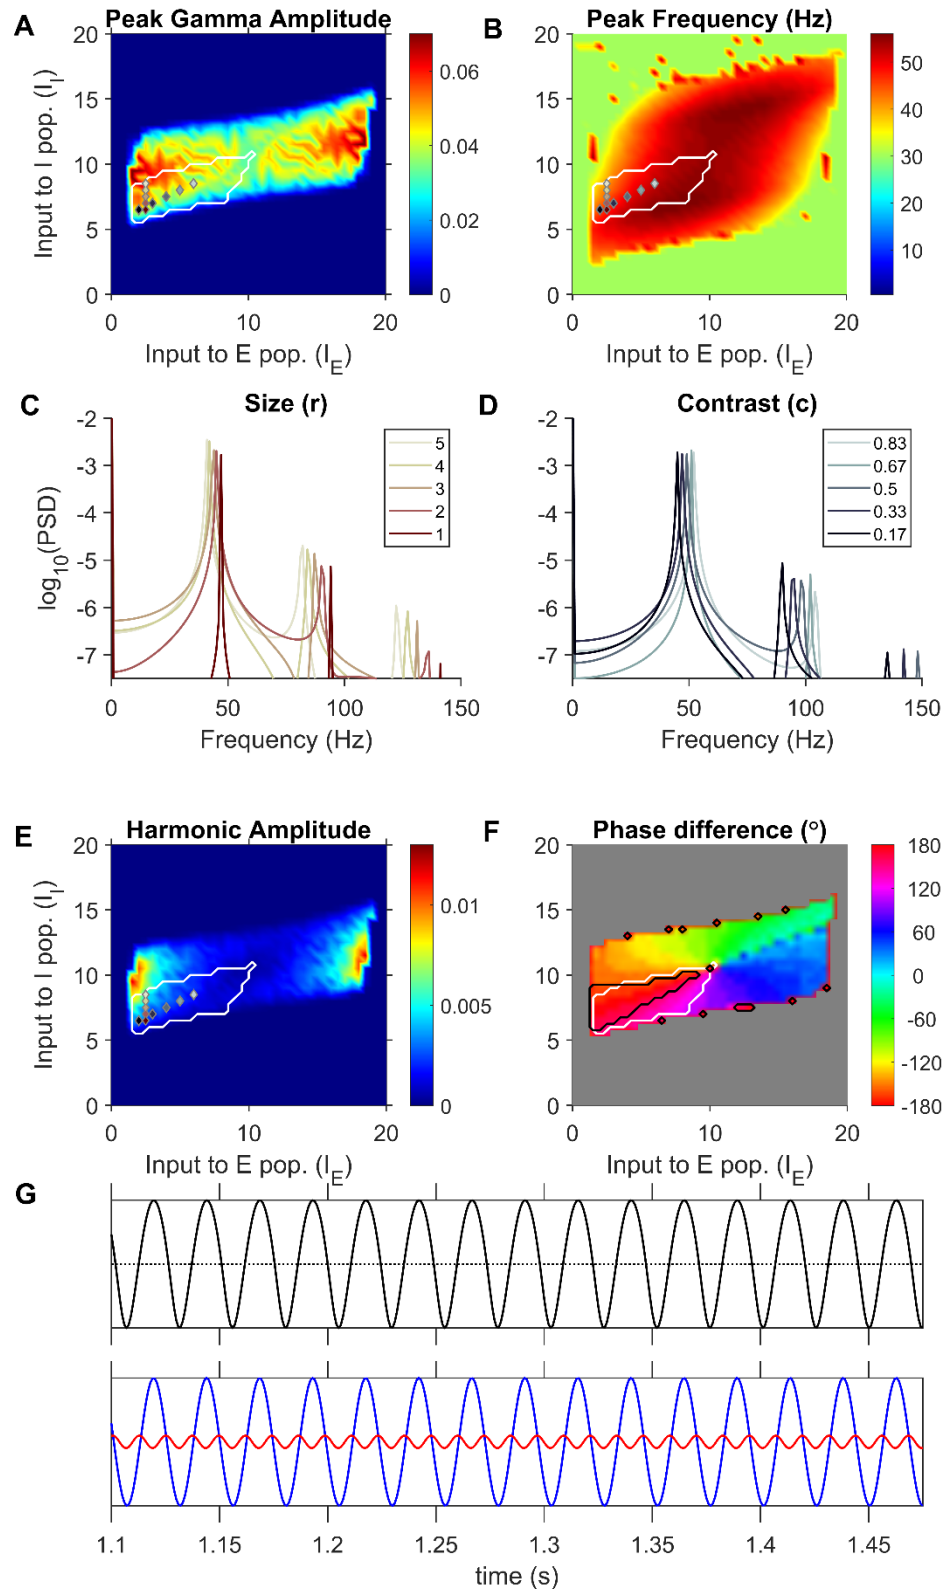

Figure 7: JS model produces sustained arch-shaped gamma oscillations within the previously identified superlinear inhibitory regime. (A) Peak gamma amplitude and (B)

758   Peak gamma frequency in the LFP proxy generated by the JS model for each input-drive

759   combination. (C) PSD of LFP proxy generated for different stimulus sizes. (D) PSD of LFP

760   proxy generated for different contrast. Input combinations used in (C) and (D) are indicated by

761   markers, with same colors as traces, in (A), (B) and (E). (E) Harmonic amplitude identified

762   from the PSD of LFP proxy for each stimulus condition. (F) Phase difference of gamma and

763   its harmonic (equation (1)) computed for each simulated input drive pair. The black contours

764   encircle input drives identified to be 'in-regime' from their phase differences. The white

765   contour in each figure enclose the input domain identified by Jadi and Sejnowski (2014) to

766   replicate gamma power increase and peak frequency decrease in response to increasing

767   stimulus size, and it can be seen to enclose a significant portion of the 180° phase difference

768   regime (black contour). (G) LFP proxy activity trace corresponding to the largest stimulus size

769   shown in Figure 7C. The dotted horizontal line shown is equidistant from the minima and

770   maxima of the traces. A sinusoidal oscillation would have the same crest and trough width on

771   this line. The bottom panels show the gamma and its first-harmonic components, plotted in

772   blue and red respectively, filtered from the LFP proxy traces.

773
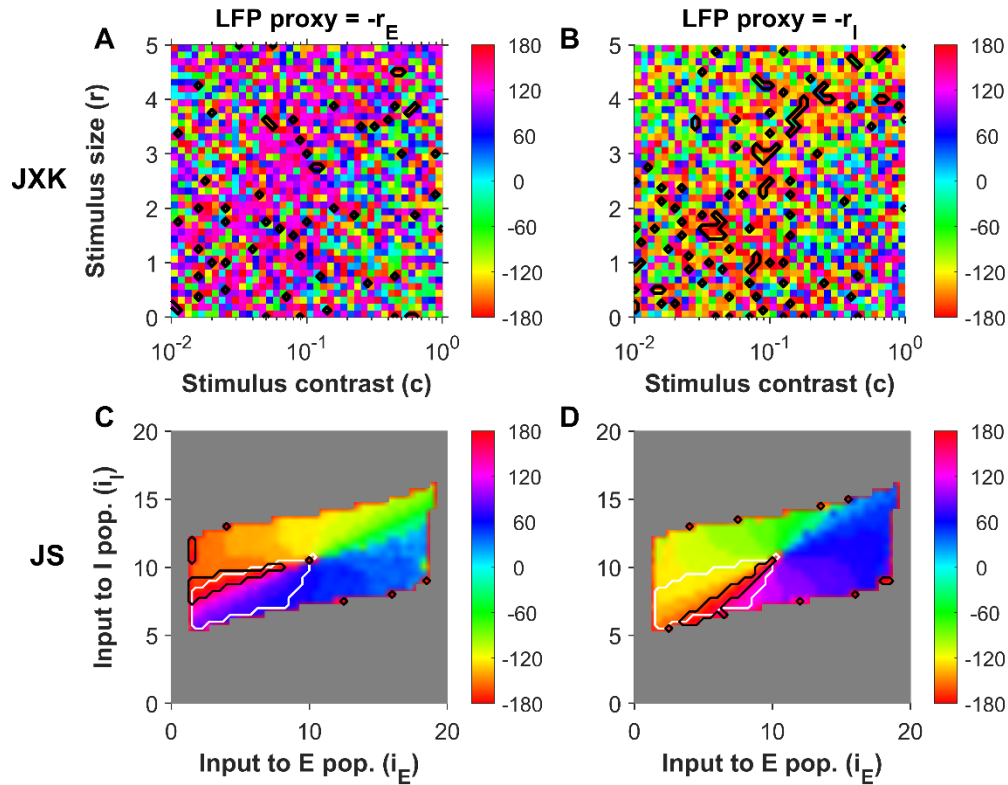

Figure 8: Gamma-harmonic phase difference in rate models using different LFP proxies.

(A) Phase difference of gamma and its harmonic in the JXK model computed for each stimulus condition (as in Figure 6F) but using only E population activity to compute the LFP proxy. (B) Gamma-harmonic phase differences in JXK using I population activity alone. (C) Phase differences in JS model using E population activity only. (D) Phase differences in JS using I population activity only. Black contours encircle stimulus conditions identified as 'in-regime'. White contours in (C) and (D) mark the superlinear regime of the JS model.
