4   Baden[1,4*$]

5   **SUMMARY.** Many sensory systems use ribbon-type synapses to transmit their signals to
6   downstream circuits. The properties of this synaptic transfer fundamentally dictate which
7   aspects in the original stimulus will be accentuated or suppressed, thereby partially defining
8   the detection limits of the circuit. Accordingly, sensory neurons have evolved a wide variety of
9   ribbon geometries and vesicle pool properties to best support their diverse functional
10   requirements. However, the need for diverse synaptic functions does not only arise across
11   neuron types, but also *within*. Here we show that UV-cones, a single type of photoreceptor of
12   the larval zebrafish eye, exhibit striking differences in their synaptic ultrastructure and
13   consequent calcium to glutamate transfer function depending on their location in the eye. We
14   arrive at this conclusion by combining serial section electron microscopy and simultaneous
15   "dual-colour" 2-photon imaging of calcium and glutamate signals from the same synapse *in*
16   *vivo*. We further use the functional dataset to fit a cascade-like model of the ribbon synapse
17   with different vesicle pool sizes, transfer rates and other synaptic properties. Exploiting recent
18   developments in simulation-based inference, we obtain full posterior estimates for the
19   parameters and compare these across different retinal regions. The model enables us to
20   extrapolate to new stimuli and to systematically investigate different response behaviours of
21   various ribbon configurations. We also provide an interactive, easy-to-use version of this
22   model as an online tool. Overall, we show that already on the synaptic level of single neuron
23   types there exist highly specialized mechanisms which are advantageous for the encoding of
24   different visual features.

39   **AUTHOR CONTRIBUTIONS.** The manuscript was conceptualised and developed by CS, TY, TB and PB. CS
40   established the models and together with JO adapted the inference method. TY performed electron microscopy
41   and two-photon imaging, pre-processing of the data and generated transgenic lines, with support from TB. CS
42   performed additional analyses and statistical testing, with help from PB. TB and PB supervised the project. The
43   manuscript was written by CS and TB with input from TY and PB. Funding was acquired by TB, PB and TY.

44   **DECLARATION OF INTERESTS.** The authors declare no competing interests.

INTRODUCTION

Ribbon-type synapses feed high-bandwidth sensory signals into their postsynaptic networks (reviewed in e.g. (Moser et al., 2019; Sterling and Matthews, 2005)). However, depending on the species, modality, or receptor type the nature of this synaptic transfer can differ greatly. For example, auditory systems typically operate at higher frequencies than visual systems, and accordingly auditory inner hair cells tend to use "faster" ribbon synapses compared to those of photoreceptors (Baden et al., 2013a; Moser et al., 2019). Moreover, amongst photoreceptors of the vertebrate eye, rods and cones tend to differ greatly in the way they use their ribbons (Regus-Leidig and Brandstätter, 2012; Sterling and Matthews, 2005). Rods generally have large ribbons that can dock many hundreds of vesicles at a time, concentrated at a single release site, to support focussed, low-noise transmission (e.g. (Hays et al., 2021)). In contrast, cones usually use multiple smaller ribbons, often positioned at different release sites in a single pedicle, to serve diverse postsynaptic circuits (e.g. (DeVries et al., 2006; Jackman et al., 2009)). The ribbon synapses in electrosensory organs of elasmobranchs take such ribbon tuning to the extreme (Bellono et al., 2018). For example, sharks achieve high-amplitude pulsatile transmission required for predation by combining greatly elongated ribbons with an ion-channel composition that supports broad spiking. In contrast, skates drive their smaller ribbons using graded voltage signals to support low-amplitude, oscillatory transmission suitable for intraspecific communication. This suggests that ribbons and their associated molecular machinery are important structural tuning sites of synaptic function in many sensory systems.

However, the functional requirements of synaptic transmission do not only differ across neuron types, but also *within* (Baden et al., 2013b; Franceschini et al., 1981; Sinha et al., 2017; Szatko et al., 2019; Yoshimatsu et al., 2020b; Zimmermann et al., 2018). For example, in vision, different parts of the eye survey different parts of visual space, often with distinct distribution of light and visuo-ecological significance (reviewed in (Baden et al., 2020; Land and Nilsson, 2012)). Correspondingly, we hypothesised that within-type functional tuning of a sensory receptor neuron should also utilise the vast tuning potential of its ribbon.

We explored this idea in the model of larval zebrafish UV-cone photoreceptors, which exhibit profound structural, molecular and circuit differences depending on their location in the eye (Yoshimatsu et al., 2020b). First, UV-cone density varies across retinal regions and peak in the acute zone (AZ), and to a lesser extent also nasally (Yoshimatsu et al., 2020b; Zimmermann et al., 2018). Furthermore, UV-cones in the AZ combine an enlarged outer segment with molecular tuning of the phototransduction cascade, an elevated calcium baseline and strong feedback from horizontal cells to boost detection brighter-than-background stimuli. This likely supports visual prey capture of UV-bright water-borne micro-organisms such as paramecia. In contrast, UV-cones in other parts of the eye preferentially respond to darker-than-background stimuli, which may serve silhouette

detection of nearby objects against the backdrop of bright UV-scatter from the sun. Amongst themselves, non-AZ UV cones further differ in additional aspects, including their absolute light sensitivity. Building on these earlier results, we here asked if and how the actual synaptic transfer differs amongst UV-cones across the eye.

First, we used electron microscopy to reveal eye-region specific structural differences amongst UV-cone ribbons and their presynaptic distribution of vesicles. Next, we found kinetic differences in synaptic transfer using *in-vivo* simultaneous dual-colour 2-photon imaging of the same pedicles' presynaptic calcium and resultant release. We then tied these findings together in a biophysical model, which enables computationally exploring possible underlying biological mechanisms and sites of tuning within the release cascade. Finally, we generalised our findings into an online model of synaptic transfer from the ribbon that enables free control over all key parameters, including ribbon dimensions, their dynamics, and the behaviour of underlying calcium drive (available online at http://www.tinyurl.com/h3avl1ga).

**RESULTS**

UV-cone ribbon geometry and vesicle distributions differ with eye position. To establish possible structural differences amongst larval zebrafish UV-cone ribbon synapses, we obtained volumetric electron microscopy datasets of the outer retina taken from three different regions: Acute zone (AZ), Nasal (N) and Dorsal (D). For each region, we anatomically identified (Yoshimatsu et al., 2020a) and 3D-reconstructed UV-cone pedicles ($n_{AZ, N, D}$ = 6, 6, 6) including their full complement of ribbons and surrounding vesicles (Fig. 1a-c, Methods). This revealed that dorsal ribbons were smaller (Fig. 1d,e) and less numerous (Fig. 1f) compared to AZ or nasal ones. However, nasal UV-cones had the lowest vesicle density immediately adjacent to the ribbon (Fig. 1g,h, Fig. S1). In addition, further away from the ribbon, the vesicle density was lowest in dorsal UV-cones, and highest in AZ UV-cones (Fig. 1h, Fig. S1). Although it is possible that the experimental procedure distorted the vesicle distribution slightly, it is unlikely that this effect is disproportionately prominent in one eye region compared to the others. Taken together, the overall complement between ribbon number, geometry and vesicle distributions therefore markedly differed across the three regions of the eye (Fig. 1i). We next asked if and how these structural differences may translate into differences in synaptic function.

Dark purple: nucleus, light-purple: mitochondria, purple: outer segment, yellow: ribbon. **b,** Zoom-ins of UV-cone terminals from different regions, which are illustrated on the rightmost panels. Ribbons are highlighted in yellow. Each terminal is shown from the side (top) and from below (bottom). **c,** Example electron-microscopy images from each zone, with arrowheads indicating ribbons. **d,e,f** Violin plots of the ribbon geometry and number for the three different regions (two-sided shuffling test with Bonferroni correction, n_{AZ}, n_N, $n_D = 6, 6, 6$, * $p<0.05$, ** $p< 0.01$). **g,** Two-dimensional schema of the vesicle pools at a ribbon synapse. **h,** Mean and 95% confidence intervals for vesicle densities as a function of distance to the ribbon. Predictions are made from a Generalized Additive Model (GAM, Methods), (see Fig. S1 for statistical comparisons). **i,** Summary schema of observed EM-level differences between UV-cones at the level of ribbon geometry, number, and vesicle distributions. Asterisks indicate significant differences compared to AZ. The stacked ribbons (gold) indicate the ribbon number per cone, whereas the vesicles (small circles) are exemplified in a two-dimensional plane for a single ribbon.
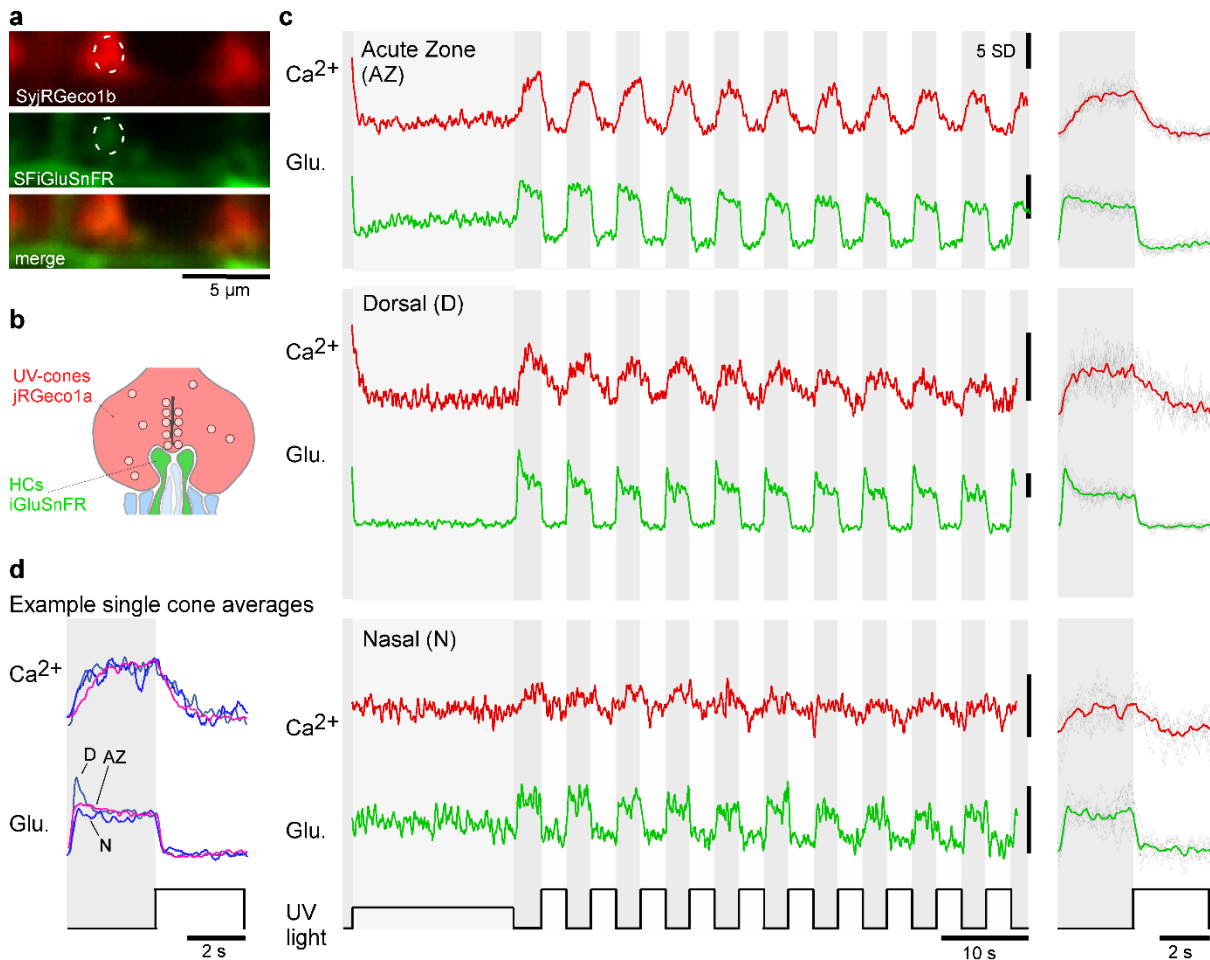

Figure 2. Simultaneous in vivo imaging of synaptic calcium and release. a,b *Simultaneously acquired two-photon scans of cone terminals and opposing horizontal cell dendrites, with cone-pedicles expressing SyjRGeco1b (red), and horizontal cell dendrites expressing SFiGluSnFR (green), and schematic representation, showing the cone-pedicle (red) with ribbon and vesicles, as well as horizontal cell processes (green) and bipolar cell dendrites (blue).* **c,** *Examples of raw calcium (red) and glutamate (green) traces recorded simultaneously from single UV-cones, one from each eye region as indicated. The averaged traces, and superimposed stimulus repetitions are shown on the right* **d,** *Overlay of the averaged traces in (c), highlighting different glutamate responses despite very similar calcium responses.*

Eye-region dependent differences in UV-cone release kinetics. To simultaneously monitor presynaptic calcium and resultant glutamate release from single UV-cone pedicles *in vivo*, we expressed the "green" fluorescent glutamate biosensor SFiGluSnFR in horizontal cells postsynaptic to the cones, and the "red" calcium biosensor SyjRGeco1b in all-cones (Fig. 2a,b, Methods). Biosensor expression appeared to be uniform across the eye, in line with previous work (Yoshimatsu et al., 2020b). Furthermore, there was no obvious spectral mixing of the two fluorescence channels (SFig. 2a,b). UV-cones were unambiguously identified based on their robust responses only to UV-light (Methods, (Yoshimatsu et al., 2020a)). We then concurrently recorded red and green fluorescence signals under two-photon during presentation of 100% contrast widefield flashes of UV-light (3 s On, 3 s Off), starting from a 50% contrast background (Fig. 2c, Methods). In example recordings from each eye region, this revealed very different glutamate signals during light offsets, despite similar appearing calcium signals (Fig.

167   2c). When scaled to their common sustained component, the dorsal cone
168   was much more transient compared to the nasal cone, with a kinetically
169   intermediate AZ-cone (Fig. 2d).
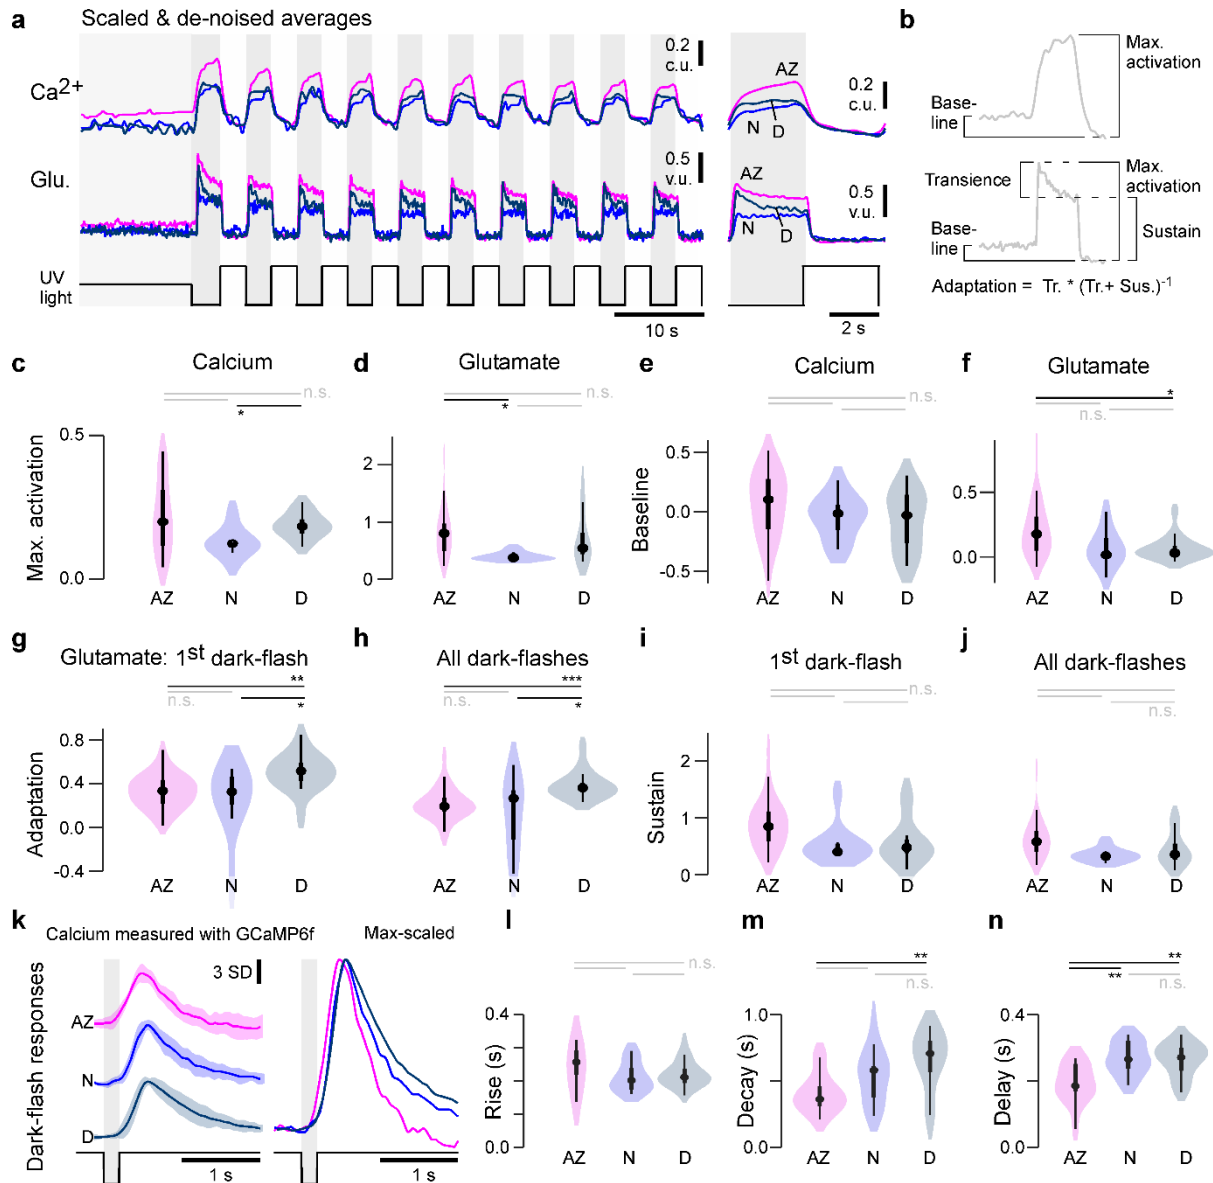

170

180   *n_{AZ}, n_N, $n_D = 13,17,22$, * $p<0.05$, ** $p< 0.01$, *** $p<0.001$).*

181   To systematically test for consistent differences between synaptic transfer in
182   the three eye regions, we recorded paired calcium and glutamate signals
183   from a total of n = 30, 16, 9 AZ, dorsal and nasal UV-cones from n = 3, 4, 4
184   fish, respectively (Fig. S2c,d). We then scaled and de-noised each recording

6

(Methods) and computed the mean traces (Fig. 3a) as well as key parameters relating to the amplitudes and kinetics of calcium and glutamate signals (Fig. 3b-j). For this, all traces where scaled such that the UV-bright stimulus intervals had a zero mean and standard deviation of one. We previously showed that these intervals correspond to the lowest possible calcium and glutamate release at the stimulus brightness used (Yoshimatsu et al., 2020b) and can therefore be used as a common baseline across zones. We present the rescaled traces (Fig. 3a) in c.u. (calcium units) and v.u. (vesicle units) respectively, to be consistent with the used units in the model later. Based on the rescaled traces we computed several indices of calcium and glutamate response amplitudes and their kinetics (Fig. 3b), which together confirmed and extended initial observations from the single-pedicle examples (cf. Fig. 2). In particular, both at the level of calcium (Fig. 3c) and glutamate (Fig. 3d), nasal UV-cones exhibited small peak-amplitudes. In addition, the glutamate release of AZ UV-cones was increased during the 50% contrast period at the start of the stimulus (Fig. 3f). In line with previous work, the AZ calcium baseline also appeared elevated (Fig. 3a), however this difference was not statistically significant (Fig. 3e). This was likely related to the lower signal-to-noise ratio of jRGeco1b signals, compared to those of GCaMP6f as used previously (Yoshimatsu et al., 2020b). Next, we quantified amplitudes of transient and sustained components at the level of glutamate (Fig. 3b,g-j). For this, we analysed the first flash response separately from the mean of subsequent ones because all regions exhibited notably stronger adaptation during the first flash (Fig. 3a). Overall, this consistently revealed the most pronounced within-pulse adaptation in dorsal UV-cones (Fig. 3g,h), but no significant differences in the sustained components (Fig. 3i,j).

To investigate the differences in presynaptic calcium in more detail, we reanalysed previously published data of calcium recordings with SyGCaMP6f in response to a 200 ms "dark flash" (Yoshimatsu et al., 2020b). The kinetics of calcium responses were similar to each other across the three zones (Fig. 3k), thus broadly supporting our previous results based on jRGeco measurements. First, we found similar rise kinetics across all zones (Fig. 3l) which therefore unlikely linked to the differences observed at the level of glutamate. Nevertheless, the response in the AZ was weakly but significantly advanced (i.e. it occurred earlier) compared to nasally or dorsally (Fig. 3n). Moreover, decay kinetics were significantly faster in AZ cones compared to dorsal cones (Fig. 3m) contrary to the adaptation index of the glutamate recordings (Fig. 3g, i), hinting that the release dynamics were shaped differentially by the synaptic machinery across zones.

Taken together, our results so far highlight a range of structural (Fig. 1) and functional (Figs. 2,3) differences in the synaptic machinery of UV-cones across different regions of the eye.

7
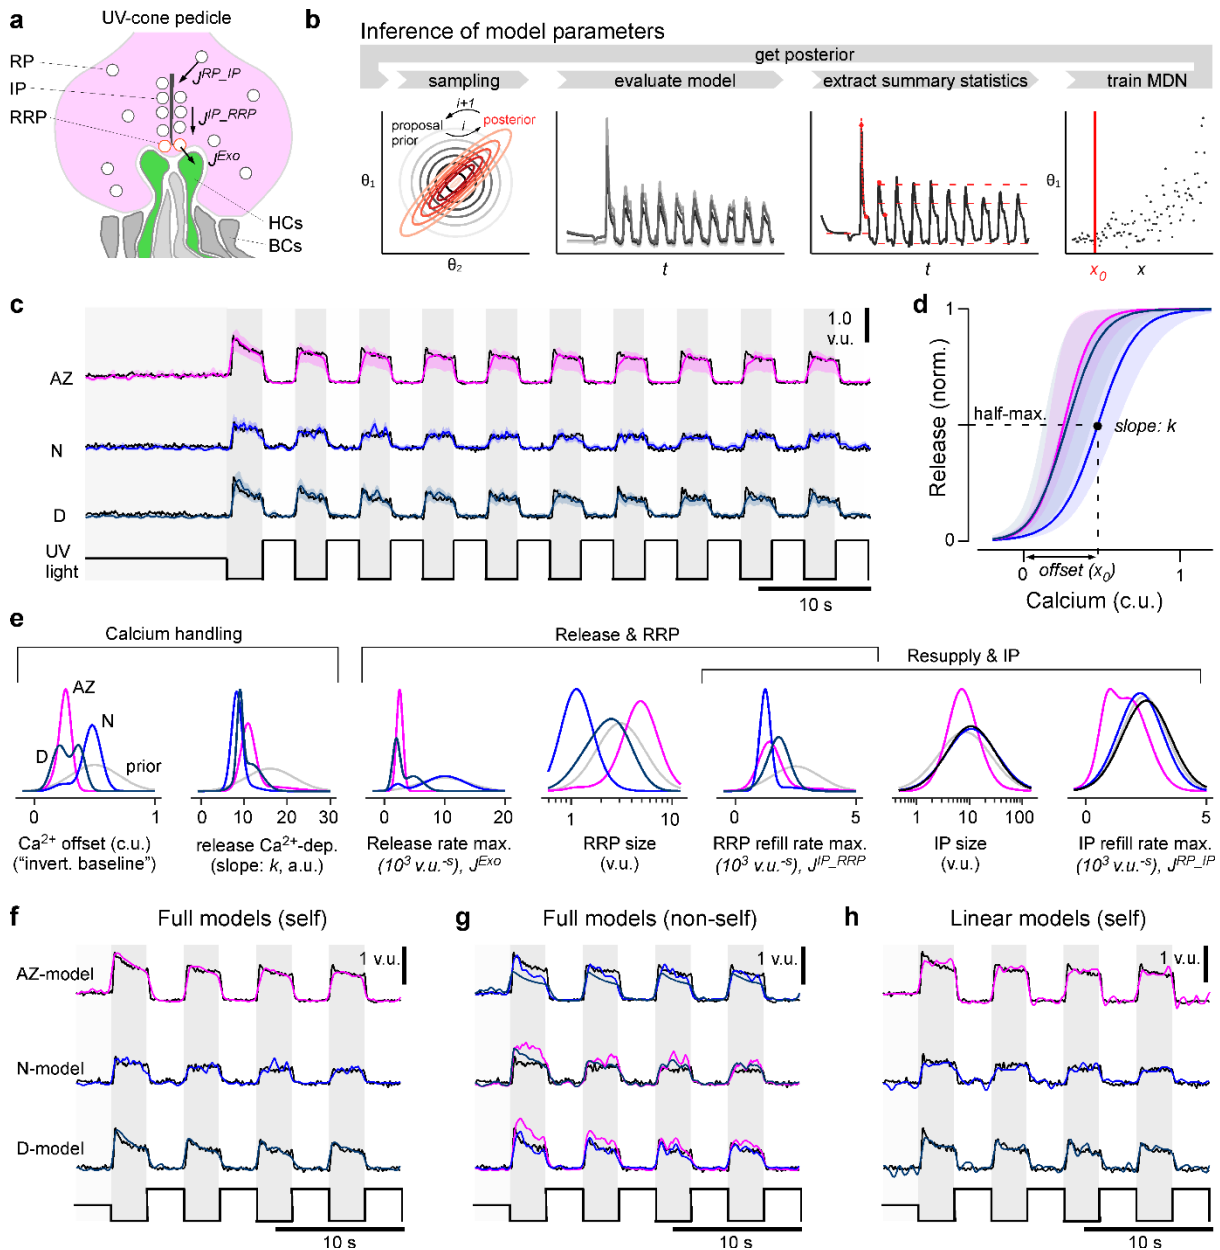

Figure 4. A model of calcium evoked release from the ribbon. a, *Schema of the movement of vesicles at a ribbon synapse. The vesicles move from the reserve pool (RP) to the intermediate pool (IP) at the ribbon and finally to the readily releasable pool (RRP) close to the membrane before they are released into the synaptic cleft to activate the dendrites of invaginating horizontal cells (HC).* **b,** *Schema of the parameter inference: Over several rounds, samples are first drawn from a prior, the model is then evaluated and summary statistics on which the relevant loss function is calculated are extracted. See Fig. S3b for a quantification of the goodness of the fits.*

A model of glutamate release at the ribbon synapse. To systematically explore the possible mechanistic basis of the observed eye-wide variations in UV-cone synaptic functions, we next modelled the release machinery of

the ribbon with a biophysical interpretable model that converts calcium signals to glutamate release (Baden et al., 2014; Schröder et al., 2019). The model consisted of three different vesicle pools (reserve pool (*RP*), intermediate pool (*IP*) and readily releasable pool (*RRP*)), the changing rates between these pools (J^{RP_IP}, J^{IP_RRP}, J^{Exo}) and a sigmoidal non-linearity with slope *k* and offset x_0 which converts the calcium concentration into the final glutamate release (Fig. 4a, Methods). Building on recent advances in simulation-based Bayesian inference (Gonçalves et al., 2020; Lueckmann et al., 2017), we estimated posterior distributions over the model parameters for each of the region-specific datasets. In summary, the inference methods iterated the following steps over several rounds (Fig. 4b): First we draw samples from a prior distribution, evaluated the model and extracted summary statistics on which the relevant loss was computed. Based on these loss values and the sampled parameters a mixture of density network was trained and finally evaluated to get the posterior of one round which was used as the prior for the next round. For the summary statistics, we defined features which captured all essential components of the release dynamics, such as transient and sustained components or peak heights (Fig. 4b, Methods). The model fitted the functional data well and accurately modelled the pronounced first UV-flash response differences between zones (Fig. 4c). From here, the inferred posteriors (see Fig. S4a for two dimensional marginals) allowed us to compare the likely parameters between the different zones, including the estimated uncertainties. This allowed pinpointing possible key differences: For example, the calcium offset (x_0, which can be understood as the inverted calcium baseline, Methods) was markedly increased in the nasal model (Fig. 4d,e). In contrast, in case of maximal release rate, the posterior for the nasal data stayed close to the prior, indicating that this parameter was not essential to reproduce the traces. For RRP sizes and associated maximal refill rates the model required the smallest values nasally (Fig. 4e). The posteriors for IP size and associated refill rates were rather broad and did not allow to identify regional differences. Interestingly, with few exceptions (e.g. the maximal release rate and calcium offset), the parameter posteriors were mostly uncorrelated (Fig. S4a), indicating that there is only little structure in the optimal parameter landscape. This also suggests that the model and data leave little room for possible compensatory mechanisms, as this would result in a clear correlation of the involved parameters.

To confirm that the different model outputs do not simply rely on differences in the calcium inputs but rather on the differences of the inferred parameters, we compared the performance of the zone-specific models by shuffling the inferred parameters and glutamate datasets pairwise across zones (Fig. 4f,g, Fig. S4b). The match between the model output and measured glutamate release for a calcium input was generally worse for parameters corresponding to a different region, confirming that our release models were indeed regionally specific. For example, the sustained component of the AZ could not be captured by either the dorsal or nasal models (Fig. 4g). Moreover, the models produced different transient behaviours independent

9

of the calcium inputs (Fig. 4f,g). A quantification of this model comparison shows that the shuffled models achieved lower loss values when evaluated on self-, compared to non-self calcium inputs (Fig. S4b,c). The model differences were especially high on the relevant loss (Fig. S4b), which was based on the summary statistics and paid special attention to features like transiency. However, already the mean squared error (MSE) as loss function confirmed this difference: the region-specific models evaluated on self calcium inputs outperformed the models on non-self inputs (Fig. S4c). Additionally, we compared the biophysical model to a statistical linear baseline model (Methods). While as expected the linear model captured the general shape of the flash responses, it was not able to model glutamate transients nor adaptation over several flashes (Fig. 4h). This also resulted in much higher loss values for the relevant loss function compared to the best biophysical model, which indicates the mismatch for essential features such as transiency (Fig. S4b). The biophysical model also outperformed the linear model in terms of the MSE (Fig. S4c). Together, this indicates that our modelling approach was sufficiently detailed for the posed problem, suggesting that the posterior distributions of each regional model can usefully inform about the differences that underpin region-specific transfer functions from synaptic calcium to release via the ribbon.

Predicting region-specific processes. An important strength of our modelling approach was that it allowed systematically exploring the possible influence of parameters such as vesicle pool sizes, their vesicle movements, and their calcium dependence, on the model output. To this end, we conducted a sensitivity analysis by computing the first order Sobol indices (Methods), a measure of the direct effect of each parameter on the variance of the model output. More specifically, it denotes the expected reduction in relative variance of the model output if we fix one parameter. For the computation of the Sobol indices, broadly speaking, a large number of parameters were drawn from the posterior distribution and the model was evaluated on these parameters. Afterwards the reduction in variance of the model evaluations was computed if one dimension of the parameter space was fixed (for details see Methods).The Sobol indices revealed a generally high influence of the calcium parameters (x_0 and k) during UV-bright periods and around light-dark transitions in all three zones (Fig. 5a-c, top row). In contrast, beyond an initial key role of the RRP size for shaping the first dark-flash response, pool sizes generally played only relatively minor roles (Fig. 5, bottom row). Instead, the most obvious region-wise differences occurred amongst vesicle transition rates between the pools. For example, the refilling rate of the IP from the RP (J^{RP-IP}) was increasingly critical for shaping dark flash responses in the AZ-model (Fig. 5a, blue) but had comparatively little influence in the nasal model (Fig. 5b, blue). In contrast, the maximal release rate (J^{Exo}) particularly influenced the variance in early dark flash responses in the dorsal model (Fig. 5c, green), while nasally refilling of the RRP from the IP (J^{IP-RRP}) played a greater role (Fig. 5b, yellow). Together, this analysis suggests that particularly the rates of vesicle transfer between pools, rather than the pool sizes themselves or their calcium dependence, may underpin

342 the experimentally observed region wise differences in release properties
343 from zebrafish UV-cones *in vivo*.
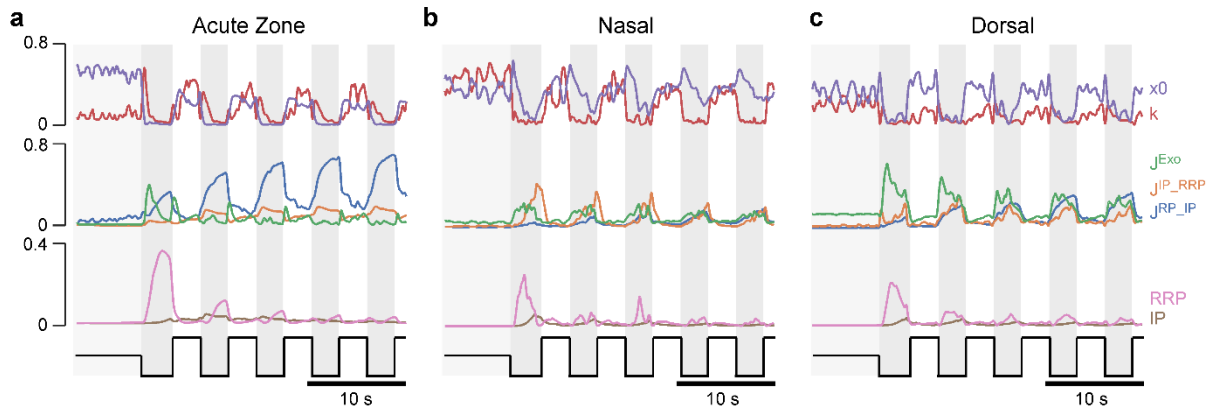

344

346 *Index (Methods). The Sobol Index measures the expected reduction in relative variance for the fixation of parameter*
347 *θ_i. It depends on the posterior distribution and is therefore different for the fits to the three regions.*
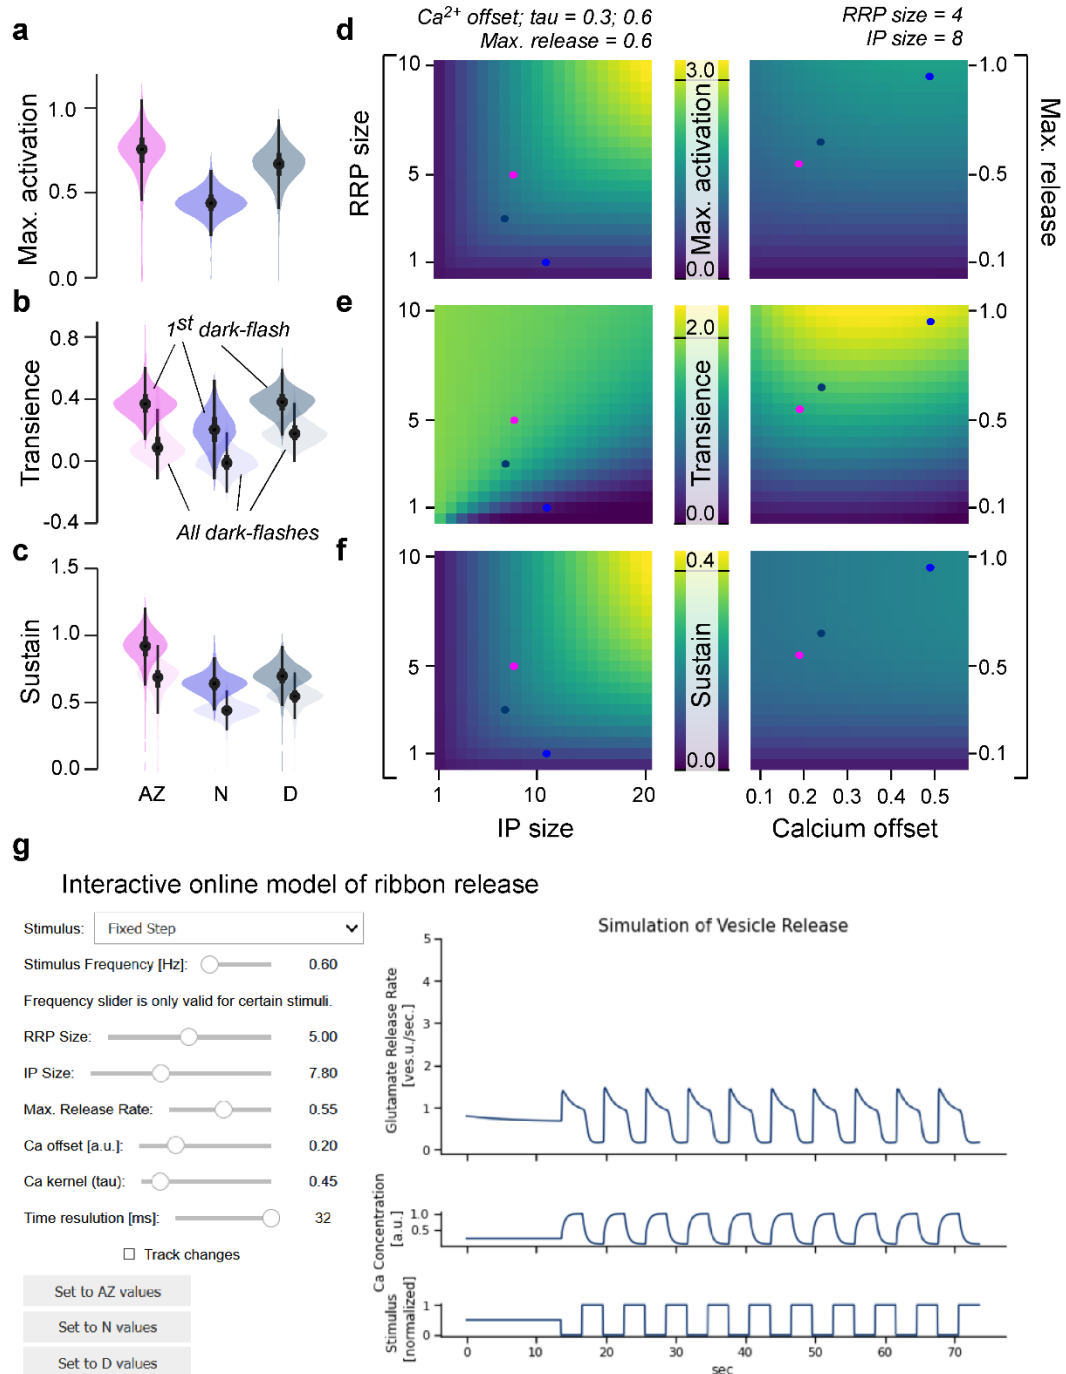

General rules of ribbon tuning. We next sought to explore the general
parameter landscape underlying release from the ribbon. For this, we
calculated the same indices as in the corresponding data from 2P imaging
(Fig. 3), but this time on the model output obtained by simulating the model
with parameters drawn from the posterior distributions. As expected, this
reproduced the trends previously measured *in vivo*, including the low
maximal activation nasally (Fig. 6a), the largest transient component dorsally
(Fig. 6b), and the largest sustained component in the AZ (Fig. 6c).

From here, we simplified the model by fixing the slope of the calcium non-
linearity (*k*) and defining vesicle change rates as fractions of the
corresponding pool sizes (Methods). To be able to stimulate the model with
arbitrary "light" stimuli, we moreover implemented a linear calcium model
based on a convolution with a biphasic kernel to reflect cone-activation by
light (Schnapf and Baylor, 1987), and monophasic kernel to reflect calcium
kinetics (Baden et al., 2014). This latter kernel was varied in subsequent
simulations to explore the impact of calcium kinetics on synaptic
performance (Methods). Together, this allowed us to reduce the parameter
space while at the same time identifying underlying computational principles.
In the following, we always included the three fitted eye-region specific
parameter sets as a point of comparison (coloured "dots" on top of heatmaps
in Figs. 6,7). These dots should be treated with some caution, since in the
simplified model they do not necessarily match the original ones in every
dimension.

Exploring this model (Fig. 6d-f), we found that both maximal activation (Fig.
6d) and the size of the sustained component (Fig. 6f) could be tuned by
varying RRP and/or IP pool sizes (left column), with negligible contributions
from the maximal release rate or the calcium offset (right column). In
contrast, the transient component primarily hinged on the maximal release
rate (Fig. 6e, right column), with more complex additional contributions from
the interplay of vesicle pool sizes (left column). Accordingly, our generalised

378 model suggests that transient and sustained responses can be defined
379 largely non-overlapping properties of the ribbon, possibly providing a
380 powerful handle in for their independent tuning. For further exploration, the
381 full model is available online as an interactive tool (Fig. 6g) via *google colab*
382 (http://www.tinyurl.com/h3avl1ga) or on *github*
383 (https://github.com/coschroeder/cone_ribbon).

384

Figure 6. General rules of ribbon tuning: Basic response parameters. a-c. *The same indices as in Fig. 3, but here calculated on 10,000 model evaluations on samples from the posteriors. The model has learned the differences between the retinal regions and reproduces these differences (see Fig. 3 for comparison). **d-f,** Indices as in (a-c), calculated on different parameter combinations as indicated. For this analysis, a step-stimulus feeding into a linear calcium model was added as the input to the release model (Methods). For definition of the indices see also Fig. 3b. **g,** Screenshot of the interactive online model, available at http://www.tinyurl.com/h3avl1ga.*

Frequency dependence and event detection. In a final step, we explored the model behaviour on new stimuli and investigated the influence of the model parameters on different coding properties of the synapse. First, we measured the detectability of a high amplitude dark-event amongst an otherwise noisy stimulus sequence (Fig. 7a, Methods). This highlighted the calcium offset (x_0) as a key parameter (Fig. 7b). Once x_0 is set, additional benefits could be gained from increasing RRP-size but only small benefits from increasing IP size (Fig. 7c), ideally in further combination with a high maximal release rate (Fig. 7d). We next measured the detectability of light-events in the same way (Fig. 7e, Methods). This showed that beyond an inverse dependence on calcium baseline (Fig. 7f cf. Fig. 7b), the ribbon parameters that benefitted the detection of On- and Off-events were in fact virtually identical (Fig. 7g,h, cf. Fig. 7c,d). The low calcium offset (i.e. high baseline) supporting the detection of On-events is in line with our previous work (Yoshimatsu et al., 2020b), where the AZ showed highest calcium baseline and an enhanced ability to detect visuo-ecologically important UV-On events such as the presence of prey.
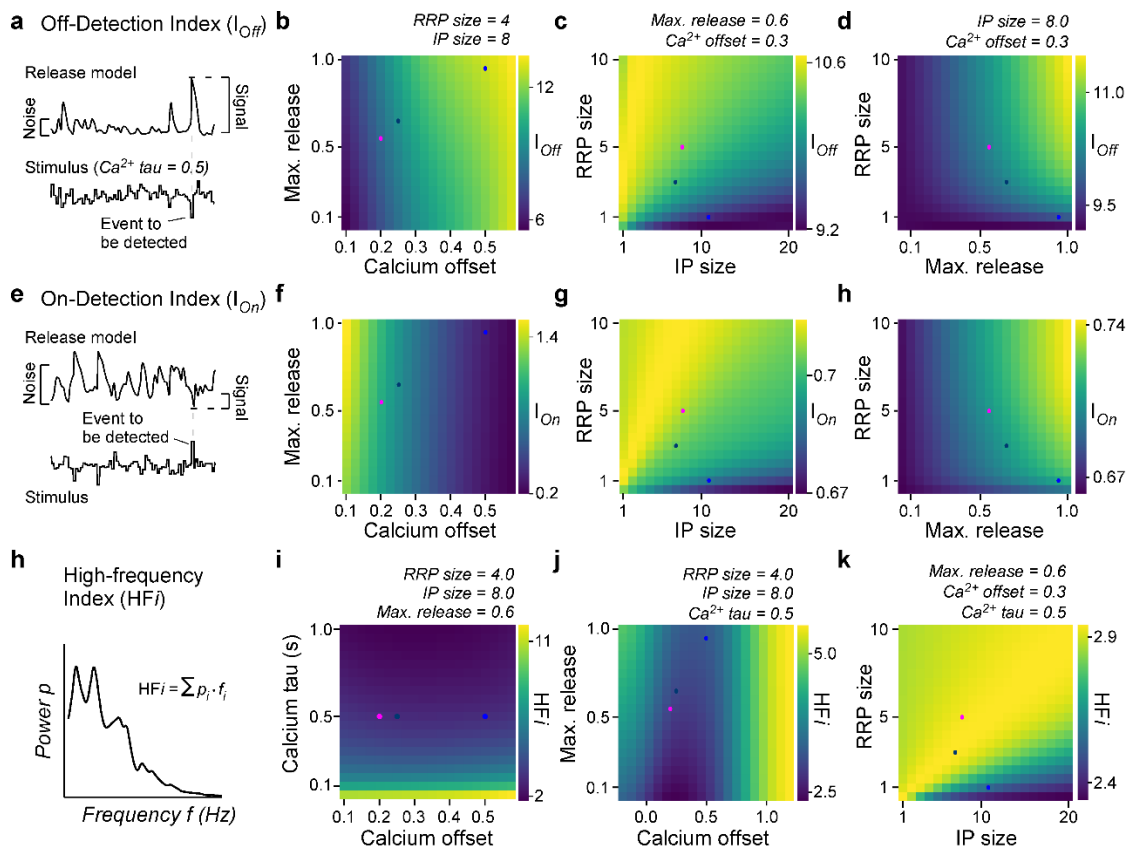

Figure 7. General rules of ribbon tuning: Event detection and high-frequency encoding. a, An Off-Detection index (I_{Off}) measures the model's baseline-noise normalised response amplitude to an Off-event in the stimulus as indicated (Methods). **b-d,** I_{Off} for different parameter combinations. **e-h,** as (a-d), but for an On-detection index (I_{On}). **h,** The high-frequency index (HFi) is a weighted sum of the discretized power spectrum and indicates the behaviour in a high frequency regime. **i-k,** HFi for different parameter combinations. The fixed parameters are shown as titles in each panel. Note the different colour scales between panels. Further note that in (j) we explored the x_0 parameter space up to extreme response behaviour, which may not be physiologically plausible.

Finally, we explored how well different ribbon models could transmit fast temporal flicker, here summarised by a high-frequency index (HFi) (Fig. 7h,

Methods). This revealed that this property primarily depended on the calcium kinetics, rather than the specific tuning of the ribbon itself (Fig. 7i-k). Beyond calcium dynamics (here, fixing the time constant τ for calcium at 0.5 s), again the calcium offset (Fig. 7j) as well as an approximate balance of medium-sized pools for both the RRP and IP (Fig. 7k), could provide additional support for encoding high-frequency components.

DISCUSSION

Combining ultrastructural evidence (Fig. 1), *in vivo* dual-colour 2-photon imaging (Figs. 2,3) and computational modelling (Figs. 4,5) we have shown how ribbon synapses belonging to the same neuron type can be regionally tuned to support distinct synaptic transfer functions depending on their location in the eye. Our findings complement and extend our recent demonstration that also upstream properties of these UV-cones, are regionally tuned to support different visuo-ecological functions (Yoshimatsu et al., 2020b). We then further generalised this model to explore how specific properties ribbon function can be principally used and traded off against one another to achieve a broad range of synaptic properties (Fig. 6,7).

Linking ribbon structure and function. Our findings that both UV-cone ribbon ultrastructure (Fig. 1) and their effective synaptic transfer (Fig. 2,3) systematically differed between regions supports the notion that these two sets of properties are linked (Regus-Leidig and Brandstätter, 2012; Sterling and Matthews, 2005; Wichmann and Moser, 2015). However, building a direct bridge between them remains difficult. This difficulty is part related to the absence of a direct experimental link between our EM- and 2P-datasets, which we did not attempt in view of its extreme technical challenges (Holler et al., 2021) that to our knowledge have not been overcome for any ribbon synapse. Moreover, there is often more than one possible interpretation between a finding from EM and its functional consequence. For example, the size of a ribbon is expected to be linked to the number of vesicles it can hold. However, this link presumes that ribbon-attached vesicle density is fixed, which may not be the case, for example due to conceivable variations in available binding sites, or amongst vesicle-transfer rates between pools (e.g. Fig. 4).

Such possible complexity is illustrated in case of UV-cone regional variations: For example, dorsal ribbons were by far the smallest and least numerous (Fig. 1d,f). From here, it is tempting to speculate that therefore their effective IP size, and perhaps also their RRP size, might be comparatively small. However, dorsal UV-cones also had a particularly high vesicle density near the ribbon, while instead nasal UV-cones had markedly reduced vesicle density here despite their otherwise large ribbons (Fig. 1g, Fig. S1). This strongly suggest that looking at ribbon geometry alone may be insufficient to accurately predict effective pool sizes. Instead, joint consideration of ribbon area and vesicle density may be more informative as supported by our model, which produced a near-identical IP size and generally low RRP sizes for both nasal- and dorsal UV-cones (Fig. 4e). In

agreement, AZ-cones combined large ribbons with a high vesicle density near the ribbon, and in their case the model did predict the largest RRP size (though a similar IP size). Although the differences of RRP sizes which were inferred by the model did not match the anatomical numbers quantitatively, we were able to infer the trends of the differences in the anatomical structures from pure functional data. Notably, model IP sizes generally stayed near the prior (Fig. 4e) and exhibited low Sobol indices (Fig. 5), which suggests that this property was not critical for explaining the glutamate responses to our relatively slow and simple test stimulus which was necessitated by the generally low SNR of jRGeco1b signals (Fig. 2). It remains possible that regionally distinct IP-size estimates would emerge in response when fitted to responses to different stimuli.

Beyond ribbon sizes, our ultrastructural analysis further highlighted an elevated vesicle density further away from the ribbon in AZ UV-cones (Fig. 1g, Fig. S1), potentially indicative of an increased RP and/or an increased rate of IP refilling. However, the model produced only minor differences in IP refill rates between regions, but in the reversed order (Fig. 4e), and for simplicity RP size was fixed because it did not strongly affect function within the tens of seconds timescales interrogated (Baden et al., 2014). Accordingly, a direct link between UV-cone RP vesicle density and function remains outstanding. Conceivably, this property could be helpful for supporting the particularly high total vesicle turnover in AZ-cones (Fig. 3d,f,i) at longer timescales.

At the level of measured function, dorsal cones stood out in that their release was particularly transient (Fig. 3a,g,h) as would be suited for pulsatile, rather than continuous transmission. Their generally small but densely populated ribbons and small RP may be well suited to support this property. In possible agreement, the model predicted a faster RRP refill rate in dorsal cones, which might be useful to ensure the RRP is rapidly replenished after each pulse. Conversely, the effective absence of any transient component nasal UV-cones (Fig. 3a,g,h) in the model resulted in the lowest RRP refill rate, which may appear counterintuitive, but paired with a small nasal RRP resulted in the sustained response behaviour observed in Fig. 4f. Additionally, this may further link to the abovementioned low IP occupancy in nasal UV-cones, as observed under EM (Fig. 1g). Moreover, the nasal model simultaneously predicted the smallest RRP but the largest RRP release rate, which resulted in a situation where the very few vesicles ready for release were immediately dumped, thus preventing the build-up of vesicles that enable the transients of dorsal and AZ UV-cones. Importantly, most functional differences across retinal regions appeared at the level of glutamate, whereas only subtle differences in the dynamics were observed at the level of calcium. The faster decay in AZ (Fig. 3m) is linked to horizontal cells as reported previously (Yoshimatsu et al., 2020b), and the temporally advanced calcium signals measured in the AZ by GCaMP6f (Fig. 3n) cannot explain the differences in the glutamate dynamics. Moreover, while it remains possible that the iGluSnFR recordings slightly distorted the time-

courses of glutamate signals, it is unlikely to strongly affect our conclusions, because any such effects would apply equally to all measured eye regions.

Taken together, while it remains difficult to make definitive links between ribbon structure and function, a number of inferences can be drawn which may usefully inform our understanding of the ribbon's role in moulding synaptic transmission to specific needs.

In the future it will be interesting to explore to what extent the differential ribbon tunings described here for larvae are also a characteristic of UV-cones in adult zebrafish. Adults feature a crystalline cone mosaic (reviewed in (Baden, 2021)), meaning that numerical anisotropies in cones as they occur in larvae (Zimmermann et al., 2018) are not expected. However, this does not preclude the possibility that UV-cones have different properties across the retina. While adult zebrafish display a much broader array of visual behaviours compared to larvae, their visual ecology remains poorly explored, which makes it difficult to predict what UV-cone tunings – if any - might be expected.

Model and simulation-based inference. The presented model (Fig. 4a) is a modified version of the basic framework used in (Baden et al., 2014). Here we extended the approach by combining simulation-based inference with simultaneous calcium and glutamate recordings to extensively expand the analysis of the model. Moreover, rather than modelling discrete vesicle movements as in (Schröder et al., 2019), our continuous model enabled the use of available software toolboxes (Methods). With the simulation-based inference approach (Fig. 4b) we obtained full posterior distributions (Fig. 4e) rather than point estimates which can lead to overconfident or incorrect conclusions in the case of an under-constrained model or "sloppy" model parameters. At the same time, posterior estimates can be seen as a global method to identify sloppy and stiff parameters (in contrast to local methods as in (Gutenkunst et al., 2007)), and additionally allowed us to conduct a sensitivity analysis by computing the first Sobol indices (Fig. 5). These focus on the variance of the model output rather than on the variance of the posterior distributions and showed zone dependent, biologically interpretable time courses. This highlighted a time varying dependence of the release on the model parameters. It indicates that already a simple step stimulus is sufficient to show the influence of different anatomical properties on features of the signal. Finally, by establishing an interactive online model we encourage further exploration of the model and testing of hypotheses.

General rules of ribbon tuning. Bringing together the model and observed differences in response behaviour, we tested our model on new stimuli and computed indices (Fig. 7) which might be relevant to a broad range of sensory scenarios. For all investigated properties, we observed that the baseline and dynamics of the calcium signal were critical (Fig. 7b,f,i), whereupon the anatomical ribbon properties allowed fine-tuning the final output behaviour (Fig. 7c,g,k).

16

Interestingly, the influence of the calcium baseline for the detection of high-frequency events followed a bimodal distribution (Fig. 7j) with intermediate values offering the poorest performance. In combination with the approximately equal and opposite effects of calcium baseline on the detectability of On- and Off-events (Fig. 7b,f), this suggest that the calcium baseline may present a key variable that enables ribbons to trade-off the transmission of high frequency stimuli against providing an approximately balanced On- and Off- response behaviour. Vice versa, it also suggests that the transmission of high-frequency events benefits from the use of a highly non-linear synapse that is either balanced to On- or Off-events, but not both. Finally, and perhaps unsurprisingly, the time-course of calcium decay was pivotal for defining the possible working range of high-frequency transmission regardless of the properties of the ribbon itself (Fig. 7i, cf. Fig. 7j,k). This effect was especially strong for a fast calcium decay (< 100 ms) which is generally associated with nanodomains (Jarsky et al., 2010) rather than decay dynamics >>100 ms for microdomains (Beaumont et al., 2005). To what extent nano- or microdomain signalling dominates in larval zebrafish UV-cones remains untested. However, in view of their similarity in pedicle architecture to mammalian rods (e.g. small, single invagination site), it seems likely that also here already low micromolar calcium concentrations that are typically associated with microdomains can evoke substantial release (Thoreson et al., 2004). In any case, a primary determinant for tuning a ribbon's high-frequency response is the local stimulus-driven calcium environment around the ribbon, rather than properties of the ribbon itself (see also (Baden et al., 2014, 2013a)). Nevertheless, once this is set, large pool sizes paired with a high release rate were generally preferable for all explored forms of signal detection. Taken together, our model therefore suggests that while the pre-synaptic calcium is a critical variable, even with a fixed calcium model the ribbon can be shifted into different response behaviours.

The effect and importance of calcium handling has also been shown in ribbon synapses of inner hair cells, where even within an individual synaptic compartment a local variation in calcium channels can lead to different transfer functions at different release sides (Özçete and Moser, 2021). Similar to the presented differences in UV-cones, such local heterogeneity in inner hair cells might help to diversify the sensory signal and highlight different features for downstream neurons.

METHODS

Animals. All procedures were performed in accordance with the UK Animals (Scientific Procedures) act 1986 and approved by the animal welfare committee of the University of Sussex. Animals were housed under a standard 14:10 day/night rhythm and fed three times a day. Animals were grown in 0.1 mM 1-phenyl-2-thiourea (Sigma, P7629) from 1 *dpf* to prevent melanogenesis. For 2-photon *in-vivo* imaging, zebrafish larvae were immobilised in 2% low melting point agarose (Fisher Scientific, BP1360-100), placed on a glass coverslip and submerged in fish water. Eye movements were prevented by injection of a-bungarotoxin (1 nL of 2 mg/ml; Tocris, Cat: 2133) into the ocular muscles behind the eye.

For all experiments, we used *6-7 days post fertilization* (*dpf*) zebrafish (Danio rerio) larvae. The following previously published transgenic lines were used: *Tg(cx55.5:nlsTrpR),* and *Tg(tUAS:SFiGluSnFR)* (Yoshimatsu et al., 2020b). In addition, *Tg(gnat2:SyjRGco1a)* lines were generated by injecting pTol2CG2-gnat2-SyjRGeco1a, plasmids into single-cell stage eggs. Injected fish were out-crossed with wild-type fish to screen for founders. Positive progenies were raised to establish transgenic lines.

The plasmid was made using the Gateway system (ThermoFisher, 12538120) with combinations of entry and destination plasmids as follows: pDESTtol2CG2 (Kwan et al., 2007), p5E-gnat2 (Lewis et al., 2010; Yoshimatsu et al., 2016), pME-SyjRGeco1a, p3E-pA. Plasmid pME-SyjRGeco1a was generated by inserting a polymerase chain reaction (PCR)-amplified jRGeco1a (Chen et al., 2013; Dana et al., 2016) into pME plasmid and subsequently inserting a PCR amplified zebrafish synaptophysin without stop codon at the 5' end of jRGeco1a.

Electron Microscopy. We used a previously published EM dataset of the larval zebrafish outer retina for this study (Yoshimatsu et al., 2020a). In the original paper, we only used one image stack from the acute zone, but here we have in addition included two further stacks from nasal and dorsal regions, respectively. Image stacks were concatenated and aligned using TrackEM (NIH). The cones and ribbons were traced or painted using the tracing and painting tools in TrackEM2 (Cardona et al., 2012). Vesicle density on the ribbons was measured in 6 representative sections per cone. We selected sections where ribbons were aligned perpendicular to the sections. Ribbon release site length and area were measured in the 3D reconstruction of the ribbons.

2p imaging. All 2-photon imaging was performed on a MOM-type 2-photon microscope (designed by W. Denk, MPI, Martinsried; purchased through Sutter Instruments/Science Products) equipped with a mode-locked Ti:Sapphire laser (Chameleon Vision-S, Coherent) tuned to 980 nm. We used two fluorescence detection channels for iGluRSnFR (F48x573, AHF/Chroma) and jRGeco1a (F39x628, AHF/Chroma), and a water immersion objective (W Plan-Apochromat 20x/1,0 DIC M27, Zeiss). For image acquisition, we used custom-written software (ScanM, by M. Mueller,

18

637   MPI, Martinsried and T. Euler, CIN, Tuebingen) running under IGOR pro 6.3
638   for Windows (Wavemetrics). Recording configuration was 124 x 32 pixels
639   (2ms per line, 15.6 Hz). Light stimuli were delivered through the objective,
640   by band-pass filtered light emitting diodes (LEDs, 'red' 588 nm, B5B-434-TY,
641   13.5cd, 8°, 20 mA; 'green' 477 nm, RLS-5B475-S; 3-4 cd, 15°, 20mA; 'blue'
642   415 nm, VL415-5-15; 10-16 mW, 15°, 20 mA; 'ultraviolet, UV' 365 nm,
643   LED365-06Z; 5.5 mW, 4°, 20 mA, Roithner, Germany).

644   All LEDs were jointly further filtered using FF01-370/36 (AHF/Chroma) and
645   synchronized with the scan retrace at 500 Hz using a microcontroller as
646   described in (Zimmermann et al., 2020). The LED intensity was 1.10^5, and
647   2.10^5 photons per cone per second for adaptation period and UV flash,
648   respectively, which corresponds to a low-photopic regime. A stimulus time
649   marker embedded in the recording data was aligned the traces with a
650   temporal precision of 2 ms. For all experiments, animals were kept at
651   constant background illumination for at least 5 s at the beginning of each
652   recording to allow for adaptation to the laser. Regions of interest (ROIs),
653   corresponding to individual presynaptic terminals of UV-cones were defined
654   manually. For calcium, we restricted ROIs within 1 µm from the release site
655   at a terminal, while for glutamate we placed ROIs on the horizontal-cell
656   dendrites immediately adjacent to a given cone, as previously (Yoshimatsu
657   et al., 2020b). To unequivocally identify UV-cones, responses to the 'red',
658   'green', 'blue' and 'UV'-flashes were always recorded (always 1 s flash, 1 s
659   darkness). Only cones that preferentially responded to the UV-LED were
660   kept for further analysis (Yoshimatsu et al., 2020a).

661

662   **Scaling and Denoising.** We preprocessed the recorded and z-scored
663   fluorescence traces as follows (see Fig. S3 for a visualization): First, we
664   applied a linear baseline correction to the calcium traces to correct a linear
665   baseline decay. Then we rescaled the calcium and glutamate traces by z-
666   scoring the traces with respect to the mean and standard deviation of the
667   UV-bright stimulus intervals, resulting in a mean of zero and a standard
668   deviation of one in these intervals. By doing so we assumed that within these
669   periods calcium channels are closed and recorded activity is either due to
670   noise in the recording process or inherent channel/vesicle noise in the
671   synapse. With this normalization, we achieved a similar scaling for all traces
672   independent of the level of indicator expression. Based on these
673   preprocessed data (Fig. S3a,b second rows), the indices in Fig. 3c-j were
674   computed.

675   For the model input, we further averaged each zone over the trials and then
676   applied a Butterworth filter of order three with a cut-off frequency of 5 Hz to
677   denoise the signals. Since the output of the model was in vesicles per
678   second, we finally shifted the processed glutamate data by its minimal value
679   such that it had only positive values. To use the calcium concentration as
680   input to the model, we additionally applied a Wiener deconvolution with the
681   kernel of the calcium indicator JRGeco1 to the data (assuming a SNR of 10
682   for $f < 1$Hz and a SNR of 1/20 for $f > 1$ Hz). The resulting pair of

calcium/glutamate data per zone (Fig. S3 last row, also Fig. 3a) was finally used in the subsequent model.

Analysis of the SyGCaMP6f data from (Yoshimatsu et al., 2020b)*.* The z-scored (GCaMP6f) calcium data was smoothed with a sliding average (window size of 100ms). Then two exponential functions ($f(x) = c + a \cdot \exp(-\frac{1}{\tau} \cdot x)$) were fitted to the rise and decay periods. The time shift was defined via the start of the calcium rise, more precisely as $\min_t(Ca(t) > 3 \cdot std(Ca))$.

Data indices. *Maximal activation, Sustain and Transience:* To be less prone to noise we used the 90th- and 50th-percentiles (p_i) to calculate the maximal activation, transience and sustain:

$$\text{max} = p_{90}\big(x_{[t_0,t_1]}\big),$$

$$\text{sustain} = p_{50}\big(x_{[t_2,t_3]}\big),$$

$$\text{transience} = \frac{\text{max} - \text{sustain}}{\text{max}},$$

where *x* was the calcium/glutamate recording, respectively. The t_i were chosen such that the first (for *max*) or the last (for *sustained*) second after the onset of the dark period is included.

Off-, On-Detection index (I_{off}, I_{on}) and high frequency index (HFi): For the detection indices we used a Gaussian noise stimulus ((μ, σ) $= (0.5, 0.3)$) with 2 Hz and a length of 150 s. This stimulus was shown for 120 s before the event to detect occurred with an amplitude of plus or minus four times the standard deviation and a duration of 500 ms. The detection indices of the simulation *x* were finally computed as

$$I_{\text{off}}(x) = (\text{max}\big(x_{[t_0,t_1]}\big) - \text{mean}\big(x_{[t_0,t_1]}\big))/\text{std}\big(x_{[t_0,t_1]}\big),$$

$$I_{\text{on}}(x) = \text{abs}(\text{min}\big(x_{[t_0,t_1]}\big) - \text{mean}\big(x_{[t_0,t_1]}\big))/\text{std}\big(x_{[t_0,t_1]}\big)),$$

with $t_0 = 60$ s and $t_1 = 150$ s.

For the HF*i* we used uniformly distributed noise of 100 s at 20 Hz and computed the discretized power spectrum *p* of the simulation *x* with Welch's method, and defined the HF*i* on the by the standard deviation normalized data *x* as

$$HFi(x) = \sum_{i=1}^{n} p_i(x) \cdot f_i,$$

with *n* such that $f_n < 25$Hz.

Model. We modelled the synaptic release by a cascade-like ribbon synapse model (Fig. 4a) with three vesicle pools (reserve pool *RP*, intermediate pool *IP* and readily releasable pool *RRP*) and changing rates which were dependent on the occupancy of the pools (Baden et al., 2014; Sterling and Matthews, 2005). In this model, the glutamate release *e(t)* was driven by the intracellular calcium *Ca(t)*:

$$e(t) = e_{max} \cdot f\big(Ca(t)\big) \cdot \frac{RRP(t)}{RRP_{max}}$$

with

$$f(Ca) = \frac{1}{1 + \exp(-k \cdot (Ca - x_0))}.$$

As $f(x_0) = 0.5$, the parameter x_0 specifies the operating point of the non-linearity. It can be seen as an inverted baseline: the smaller x_0 the less additional calcium is needed to trigger a vesicle release. If we assume a fixed calcium affinity for vesicle release, this implies an increased baseline level in the synapse.

The changing rates *r(t)* (between *RP* and *IP*) and *i(t)* (between the *IP* and *RRP*) were independent of calcium:

$$r(t) = r_{max} \cdot \left(1 - \frac{IP(t)}{IP_{max}}\right) \cdot \frac{RP(t)}{RP_{max}}$$

$$i(t) = i_{max} \cdot \left(1 - \frac{RRP(t)}{RRP_{max}}\right) \cdot \frac{IP(t)}{IP_{max}}.$$

Additionally, the refilling *d(t)* of the reserve pool was modelled by a constant factor of the available exocytosed vesicles *Exo(t)*:

$$d(t) = d_{max} \cdot Exo(t)$$

Therefore, the number of vesicles in the pools changed as:

$$\frac{dRP(t)}{dt} = d(t) - r(t)$$

$$\frac{dIP(t)}{dt} = r(t) - i(t)$$

$$\frac{dRRP(t)}{dt} = i(t) - e(t)$$

$$\frac{dExo(t)}{dt} = e(t) - d(t).$$

In the original model in (Baden et al., 2014) there was also a non-linear influence of calcium for *i(t)* in terms of $\frac{Ca}{Ca+c}$. But initial runs of the fitting procedure resulted in $c \approx 0$ which indicated no calcium dependency for the changing rate *i* and we excluded this term in the presented model. Since the endocytosis constant d_{max} and the size of the reserve pool *RP* did not affect

21

the output of the model, our fitting procedure was constrained to the remaining seven parameters: the changing rates (r_{max}, i_{max}, e_{max}) the non-linearity parameters (k and x_0), and the remaining pool sizes (*IP* and *RRP*). We call these parameters $\theta = (r_{max}, i_{max}, e_{max}, k, x_0, IP, RRP)$. From the equation above it follows that the model is scale invariant: a scaling of the parameters (except the parameters for the non-linearity, x_0 and k) results in a scaled model output and thus only an arbitrary scale in vesicle units (v.u.) to the experimental traces can be fitted.

The described coupled ODE was solved with *scipy*'s (version 1.5.1) implementation of the Bogacki–Shampine method (Bogacki and Shampine, 1989), an explicit Runge-Kutta method of order 3 with adaptive step-sizes, where the maximal step size was set to the step size of the (calcium) input signal.

Simplified Model. To reduce the parameter space to identify general rules or ribbon tuning (Fig. 6d-f, Fig. 7 and online tool) we fixed k to 10.2 (equal to the mean of the fitted parameters across zones) and additionally coupled the maximal changing rates to the pool sizes as follows:

$$r_{max} = 0.2 \cdot IP_{max}$$
$$i_{max} = 0.4 \cdot IP_{max}$$
$$e_{max} = \tilde{e}_{max} \cdot RRP_{max}$$

where $\tilde{e}_{max}$ can take values between 0 and 1.

For the general rules of ribbon tuning (Fig. 6d-f, Fig. 7 and online tool) the calcium concentration evoked by a light stimulus $s(t)$ is simulated as following:

$$Ca(t) = \kappa_2 * \exp(\kappa_1 * s(t))$$

where κ_1 is a biphasic kernel from (Baden et al., 2014) and κ_2 is a double exponential kernel with fixed time constant τ_{rise} (30 ms) and variable decay parameter τ_{decay}.

Parameter Inference. For the inference of the model parameters, we iterated the following steps over several rounds: First we draw samples from a prior, evaluated the model and extracted summary statistics on which the loss was computed. Based on these loss values and the sampled parameters a mixture of density network (MDN) was trained and finally evaluated to get the posterior of this round which was used as the prior for the next round (Fig. 4b).

Summary statistics and relevant loss

A key ingredient in simulation-based Bayesian inference is to define problem and domain specific summary statistics to project the data to a low dimensional feature space. For our setting, we identified the following fourteen features x_i: baseline during adaption as well as period of UV-bright

22

801   stimulus, mean during UV-dark period as well as mean of the maximal
802   release rates in this periods, maximal and minimal (as maximal value and
803   25th percentile) amplitude during the first flash, maximal and minimal (as
804   maximal value and 25th percentile) amplitude of the second peak, total
805   number of released vesicles during first, second and the last activation.

806   To pay special attention to the decay after the initial UV-dark flash, which we
807   found to be informative about the different pool sizes of the ribbon, we fitted
808   an exponential decay to this period. We used the inferred time constant τ
809   and the evaluation of the exponential function at the time point before the
810   next light onset as additional features along with an extra penalty if an
811   exponential rise instead of a decay was fitted.

812   To calculate the relevant loss R of a simulated trace e we normalized the
813   features in each component with the mean and standard deviation of the
814   recorded traces. We then took a weighted mean squared error of this
815   normalized summary vector x to the normalized summary vector x_0 of the
816   recorded trace as the relevant loss:

817
$$R(e) = \frac{1}{14} \sum_{i=1}^{14} w_i \left(x_{0,i} - x_i \right)^2.$$

818   The weights w_i were not systematically optimized, but within reasonable
819   ranges the results were relatively insensitive to the exact values. We chose
820   w = (0.5,0.5,5,1,1,1,1,1,1,1,2,1,1,(0.01 for decay and 10·(1+ceil(τ)) for rise))
821   for the features in the order mentioned as above, where the last value is the
822   extra penalty for the exponential rise instead of a decay.

823   *Prior distribution and parameter normalization*
824   The modes of the prior were chosen as *(r, i, e, k, x₀, IP_max, RRP_max)* = (2.5,
825   2.5, 10, 14, 0.5, ≈13.8, ≈4.0), but as the model was scale invariant, the
826   absolute values are uninformative and only the relative values are of interest.
827   For technical reasons we normalized the prior distributions such that the
828   means of the uncorrelated multivariate normal distribution were 0.5 and the
829   standard deviations were 0.2 in each dimension. For the IP and RRP pool
830   sizes, we additionally exponentially scaled the sampled parameters, such
831   that no negative values could occur.

832

833   *Parameter Inference*
834   We applied the Sequential Neural Posterior Estimation method described in
835   (Lueckmann et al., 2017) (code available at
836   https://github.com/mackelab/delfi) (also called SNPE-B) with some
837   modifications which were also applied in (Oesterle et al., 2020; Yoshimatsu
838   et al., 2020a). In brief, SNPE-B draws over several rounds samples $\{\theta i\}_{i \in I}$
839   from a prior $\tilde{p}(\theta)$ and evaluates the model for these parameters. For each
840   evaluation e_i the relevant loss function $x_i = R(e_i)$ is computed and a mixture
841   density network (MDN) $q_\phi(\theta, x)$ is trained on the data pairs $\{(\theta_i, x_i)\}_{i \in I}$. The
842   posterior $p(\theta | x_0)$ is then calculated as $q_\phi(\theta | x = x_0)$ and used as a new
843   prior $\tilde{p}(\theta)$ in the next sampling round. Instead of $x_0 = 0$ we calculated the

844   new prior $\tilde{p}(\theta)$ in round n as $q_\phi(\theta|x = \beta_n)$ where β_n is the 0.1$^{\text{th}}$ percentile ρ
845   of the relevant loss function of all samples. It turned out that this is an efficient
846   way to get a more stable behavior of the MDN since it has not to extrapolate
847   to unreached loss values but is converging nevertheless. This evaluation of
848      $q_\phi(\theta|x = \beta_n)$ at $\beta_n = \rho$ can be seen as the posterior over the parameters for
849   the "best-possible" model evaluations. Testing for different percentiles in a
850   reasonable range did not change the results. We took the same approach
851   for setting an adaptive bandwidth for the kernel. As an additional post-hoc
852   verification of the posteriors, we took as final posterior distributions the
853   posterior of the round with the smallest median loss of its samples ("early
854   stopping").

856   *Technical details*
857   We ran the inference algorithm over 5 rounds, with 300.000 samples per
858   round. We chose three Gaussian components for the mixture of Gaussian
859   distribution and a MDN with two hidden layers with 120 nodes each. In each
860   round the network was trained for 800 epochs with a minibatch size of 1000.
861   To let the MDN focus on regions of low relevant loss values, we used a
862   combined half-uniform-half-Gaussian kernel which was constant up to the
863   pseudo observation β_n and decayed then as a half Gaussian. The scale of
864   this half-Gaussian part of the kernel was in each round chosen as the 25$^{\text{th}}$-
865   percentile of the relevant loss function.

867   **Sensitivity Analysis.** Sensitivity analysis was performed using *uncertainpy*
868   (Tennøe et al., 2018) by using the *GaussianMixture* probability distribution
869   class of *chaospy* (Feinberg and Langtangen, 2015). Since model evaluations
870   are computationally cheap and could run in parallel, we took the (quasi-)
871   Monte Carlo Method with 10e5 samples, resulting in 450.000 simulations.
872   With uncertainpy we calculated the first order Sobol sensitivity index S_i which
873   is defined as

874
$$S_i = \frac{\mathbb{V}[\mathbb{E}[Y|\theta_i]]}{\mathbb{V}[Y]},$$

875   where $\mathbb{E}$ and $\mathbb{V}$ are the expected value and the variance, respectively. S_i
876   measures the direct effect each parameter has on the variance of the model
877   output (Saltelli et al., 2008; Tennøe et al., 2018). It tells us the expected
878   reduction in relative variance if we fix parameter θ_i. The sum of the first-order
879   Sobol indices cannot exceed one and is equal to one if no interactions are
880   present (Glen and Isaacs, 2012; Tennøe et al., 2018). We also calculated
881   the total-order indices which gives the sensitivity due to interactions of the
882   parameters. But since already the sum of the first-order indices is almost one
883   for our model, the total order indices look quite similar and we omit their
884   analysis.

885   It is important to remark, that the Sobol indices are not a way to show how
886   'important' parameters are. A parameter which is overbearingly influencing
887   the model would in the limit of the posterior estimation accumulate the mass
888   on one single point. But this means that for samples from the posterior this

889 parameter is not responsible for any variance of the model output and thus
890 its Sobol index would be zero. The Sobol indices are therefore the result of
891 a complex interplay of the model and the posterior estimation, but especially
892 its temporal changes give us insight into the time dependent influence on the
893 model output. However, the posteriors are an adequate probability
894 distribution to calculate the Sobol indices, as they provide all parameter
895 combinations which are in agreement with the experimental data and are
896 more expressive as commonly used uniform distributions, where each
897 marginal is simply defined as the mean ±10% of the fitted parameters.

898 **Linear baseline model.** To evaluate the performance of the biophysical
899 model, we compared it to a simple linear model. For this, we performed a
900 regularized least square regression (ridge regression using *scikit-learn,*
901 *version 0.23.1, https://scikit-learn.org)* to fit the calcium to glutamate
902 response. In lack of a diverse enough dataset, we set the regularization
903 coefficient alpha to 0.1 and allowed the model to include the data from the
904 past 0.5 second to predict the next time point.

905 **Statistical Analysis**

906 *Vesicle Densities*

907 We used Generalized Additive Models (GAMs) for the comparison of the
908 vesicle densities (Fig. 1g, Fig. S1). GAMs are an extension to generalized
909 linear models by allowing linear predictors that depend on smooth functions
910 of the underlying variables (Wood, 2017). We used the mgcv-package
911 (version 1.8-33) in R on an Windows 10 workstation with default parameters,
912 if not specified differently below. We modelled the dependence of the vesicle
913 density as a smooth term dependent on the distance with 100 degrees of
914 freedom and grouped by "zone". We further used "zone" as additional
915 predictive variable. The model explained ~65% of the deviance. Statistical
916 significance for differences between the dependence on the vesicle density
917 in the different retinal regions were obtained using the *plot_diff* function of
918 the *itsadug*-package for R (version 2.4) with a 95% confidence level.

919 *Hypothesis Testing*

920 For comparisons between regional properties (ribbon geometry (Fig. 1) and
921 functional indices (Fig. 3)) we used two-sided shuffling tests with Bonferroni
922 correction. Sample sizes and significant levels are stated in the figure
923 captions.
