Abstract

Bacterial bloodstream infections are a major cause of morbidity and mortality among patients undergoing hematopoietic cell transplantation (HCT). Although previous research has demonstrated that pathogenic organisms may translocate from the gut microbiome into the bloodstream to cause infections, the mechanisms by which HCT patients acquire pathogens in their microbiome have not yet been described. We hypothesized that patient-patient transmission may be responsible for pathogens colonizing the microbiome of HCT patients, and that patients who share time and space in the hospital are more likely to share bacterial strains.

Here, we used linked-read and short-read metagenomic sequencing to analyze 401 stool samples collected from 149 adults undergoing HCT and hospitalized in the same unit over five years. We used metagenomic assembly and strain-specific comparison methods to investigate transmission of gut microbiota between individuals. While patients who shared time and space in the hospital did not converge in overall microbiome composition, we did observe four pairs of patients who harbor identical or nearly identical *E. faecium* strains in their microbiome. These strains may be the result of transmission between patients who shared a room and bathroom, acquisition from a common source in the hospital or transmission from an unsampled source.

We also observed identical *Akkermansia muciniphila* and *Hungatella hathewayi* strains in two pairs of patients. In both cases, the patients were roommates for at least one day, the strain was absent in the putative recipient's microbiome prior to the period of roommate overlap and the putative recipient had a microbiome perturbed by antibiotic treatment for a bloodstream infection. Finally, we identified multiple patients who harbored identical strains of several species commonly found in commercial probiotics and dairy products, including *Lactobacillus rhamnosus*, *Lactobacillus gasseri* and *Streptococcus thermophilus*. Overall, our findings indicate that pathogenic organisms from a single source are not frequently colonizing the gut microbiome of multiple patients. However, the potential transmission of commensal microbes with immunomodulatory properties raises questions about the

47   recovery of microbiome diversity after HCT, and indicates that patients in this setting may acquire new

48   microbes by sharing space with others.

Introduction

Patients undergoing hematopoietic cell transplantation (HCT), a potentially curative treatment for a range of hematologic malignancies and disorders, are at increased risk for bloodstream infections (BSIs) and associated morbidity and mortality[1]. While the bacterial pathogens that cause BSIs in HCT patients are well understood, their routes of transmission are often unclear. Determining these transmission pathways involves identifying two critical elements: the source of the infection, i.e., how the pathogen was introduced into the patient's bloodstream, and the origins of the particular pathogen causing the BSI.

The most common ways bacterial pathogens can be introduced into an HCT patient's bloodstream include contaminated central intravenous lines and translocation of intestinal microbiota across a damaged epithelium[2]. Indeed, research from our group and others has shown that strains of bacteria isolated from the blood of HCT patients with BSIs may be indistinguishable from the strains in the intestinal microbiota of these patients prior to infection[3–5]. In addition, HCT patients with a microbiome dominated by a single bacterial taxon, such as *Enterococcus* or *Streptococcus*, are at increased risk for not only BSI[6,7], but also graft-versus-host disease[8,9] and death[10–13].

Identifying the source of the BSI is only the first step. To fully understand the transmission pathways of bacterial pathogens in hospital settings, it is also essential to determine the origin of the pathogen that caused the BSI. For gut-based pathogens, there are three possibilities. First, they may exist in the HCT patient's microbiome upon admission to the hospital. Second, hospital environments and equipment may serve as unintentional reservoirs of pathogens, thereby infecting multiple patients through exposure[14]. Lastly, a pathogen could originate from the microbiome of other patients, healthcare workers or hospital visitors and be transmitted via shared spaces. In cases where traditional epidemiological links cannot be found, this patient-patient transmission of gut microbes may be the "missing link" that explains the persistence of BSIs in hospital environments[15].

Transmission of gut bacteria and phages between individuals is known to occur in specific cases, such as from mothers to developing infants[16–18]. By contrast, adults have a microbiome that is relatively

resistant to colonization with new organisms even after perturbation by antibiotics[19–21]. While adults living

in the same household or in close-knit communities may have more similar microbes than those outside

the group[22], to our knowledge, direct transmission of gut microbes between adults has not been

observed with high-resolution metagenomic methods, with the notable exception of fecal microbiota

transplantation[23–25], a drastic reshaping of the gut microbiota often used in response to *Clostridiodes*

difficile infection. Transmission of gut microbiota is thought to occur by a fecal-oral route, which could

happen in the hospital environment by exposure to contaminated surfaces or equipment, sharing a room

or bathroom, contaminated hands of healthcare workers or other sources. The perturbed microbiomes of

HCT patients, often lacking key species to provide colonization resistance, may be primed to acquire

new species from these sources.

Previous studies of the microbiome in HCT patients have often used 16S rRNA sequencing[10,26–

28], which is sufficient for taxonomic classification but cannot differentiate specific strains in a mixed

community. By contrast, short-read shotgun metagenomic sequencing can capture information from all

bacterial, archaeal, eukaryotic and phage DNA in a stool sample. While short-read sequencing data is

accurate on a per-base level, it is often insufficient to assemble complete bacterial genomes due to the

presence of repetitive genetic elements. Linked-read sequencing captures additional long-range

information by introducing molecular barcodes in the library preparation step. This technology allows for

significant increases in assembly contiguity[29,30] while retaining high per-base accuracy. Both of these

technologies also capture information about strain diversity, genetic variation within the population of a

species[31,32], which is critical for measuring transmission between microbiomes.

Here, we use a collection of short-read and linked-read metagenomic sequencing datasets from 401

stool samples to analyze bacterial transmission between HCT patient microbiomes at a single, high-

volume hospital. We apply strain-resolved comparison methods to show that transmission of bacteria

between adults hospitalized in the same unit at the same time is likely a rare event, usually occurring

when recipients have extremely perturbed microbiomes, such as after exposure to broad-spectrum

antibiotics. Bacterial strains shared between individuals include both pathogenic and commensal

organisms, demonstrating that transmission may depend more on niche availability than pathogenicity or

antibiotic resistance capacity. We find that pathogens colonizing HCT patient microbiomes are present in

the first sample in a time course roughly 60-70% of the time in our cohort. This suggests that in most

cases, prior colonization, rather than direct transmission from other patients or the hospital environment,

is responsible for pathogenic organisms in the gut microbiomes of this patient population. Even though

patients were frequently placed into double occupancy hospital rooms with a shared bathroom, we

observe relatively few putative transmission events. This implies that sharing a room with another patient

may not place a patient recovering from HCT at a greatly increased risk of acquiring pathogens in their

gut microbiome.

Results

Sample characteristics and patient geography

We collected weekly stool samples (see methods) from adult patients undergoing hematopoietic cell transplantation (HCT) at Stanford University Medical Center from 2015-2019. At the time of the study, our biobank contained over 2000 stool samples from over 900 patients. Samples from October 2015 to November 2018 were considered for this study. Relevant patient health, medication, demographic, hospital admission and room occupancy data were extracted from electronic health records (Table 1, Table S1). All patients stayed in a single ward of the hospital during treatment, which contained 14 single-occupancy and four double-occupancy rooms, the latter of which included shared bathrooms (Figure S1a). Patients spent a median of 18 days on the ward and were frequently moved between rooms: 42% of patients spent at least one day in three or more rooms during the course of treatment (Table 2, Figure S1c). 73% of patients shared a room with a roommate for ≥24 hours. Over the course of their hospital stays, many patients had several roommates, though never more than one at a time (Figure S1d). Patients with multi-resistant Gram-negative infections were always placed into single rooms with contact precautions.

To understand how geographic overlap may influence transmission of gut microbes, we created a network from patient-roommate interactions (Figure S1b). 535 patients (77% of patients with at least one roommate, 56% of all patients) fell into the largest connected component of the network. Although the largest component was not densely connected (mean degree 2.2 ± 1.6 standard deviation (SD)), it links together patients over three years and may represent a risk for infection transmission. We used the network to select samples for further analysis with metagenomic sequencing, as described in the methods.

Metagenomic sequencing, assembly and binning

For an overview of the steps used in the generation and processing of sequence data, see Figure 1a. 328 stool samples from 94 HCT patients were subject to short-read metagenomic sequencing as part

of previous projects (for references and SRA IDs of these samples, see Table S2). 96 additional samples

from 62 patients were selected for linked-read sequencing to span periods of roommate overlap between

patients. Samples were subjected to bead beating-based DNA extraction and bead-based DNA size

selection for fragments ≥2 kb (see methods). We prepared linked-read sequencing libraries with the 10X

Genomics Chromium platform from 89 samples with sufficient DNA concentration. Samples were

sequenced to a median of 116 million (M) (± 37 M SD) read pairs on an Illumina HiSeq4000. In total, 401

stool samples from 149 patients were sequenced (Table 3), with a median of 2 and maximum of 13

samples per patient (Figure 1b).

We processed all existing short-read data and newly generated linked-read data by first trimming

and then removing low quality reads, PCR duplicates (short-read data only) and reads that aligned

against the human genome (see methods). After quality control, newly sequenced linked-read samples

had a median 104 M (± 40 M SD) read pairs, while short-read data had a median 7.6 M (± 4.4 M SD)

read pairs. Metagenomic assembly was conducted using metaSPAdes[33] for short-read data, and

MEGAHIT[34] followed by Athena[29] for linked-read data. Short-read assemblies had a median N50 of 17.2

kb ± 24.8 kb, while linked-read assemblies had a median N50 of 147.6 ± 165.8 kb. We binned

metagenome-assembled genomes (MAGs) using Metabat2[35], Maxbin[36] and CONCOCT[37] and

aggregated across results from each tool using DASTool[38]. MAG completeness and contamination was

evaluated using CheckM[39] and MAG quality was determined by previously established standards[40]. The

vast majority of short-read and linked-read MAGs were at least medium quality, and 27% of linked-read

MAGs contained the 5S, 16S and 23S rRNA genes and at least 18 tRNAs to be considered high-quality

(Figure 1c, Table S3). Linked-read MAGs had higher quality than the 4,644 species-level genomes in the

Unified Human Gastrointestinal Genome collection[41], where 573 genomes (12.3%) are high-quality, and

only 38 (6.6%) of those came from metagenomes rather than isolates. Sequencing dataset type (short-

read vs linked-read) did not have a linear relationship with MAG length (linear regression, $p > 0.9$); the

increase in quality was mainly due to the inclusion of ribosomal and transfer RNA genes in the linked-

read MAGs, which often do not assemble well with short-read sequencing data alone. To understand the

diversity of strains present in the microbiomes of our patients, we clustered all medium- and high-quality

MAGs at 95% and 99% identity thresholds (roughly "species" and "strain" level, see methods) using

dRep[42], yielding 1615 unique genomes representative of the microbial diversity in this sample set.

Figure 1: Overview of the methods, data generated, and clinical features of this sample set.

a) Overview of the experimental and computational workflow used to generate sequencing datasets, bin

MAGs and compare strains between patients.

b) Number of stool samples sequenced per patient.

c) Percentage of MAGs meeting each quality level[40], stratified by sequencing method.

d) Of patients who have the given organism detected (≥50% coverage breadth) in a time course sample,

percentage of patients where the organism was below the detection threshold (<50% coverage breadth)

in the first sample.

e) Percentage of patients with at least one sample positive with (≥1% relative abundance) or dominated

177 by (≥30% relative abundance) hospital acquired infection (HAI) organisms, as identified by Kraken2- and

178 Bracken-based classification.

179 f) Percentage of bloodstream infections (BSIs) identified with each organism or group in HCT patients

180 and hospital-wide.

Classification of abundant Healthcare-associated Infection organisms

We performed taxonomic classification of sequencing reads with Kraken2[43] and abundance estimation with Bracken[44] using a custom database of bacterial, fungal, archaeal and viral genomes in NCBI Genbank (see methods) (Table S4, S5). A median of 33% ± 15% SD reads were classified to the species level with Kraken2 (72% ± 15% SD at the genus level), which was improved to 96% ± 7% SD using Bracken (97% ±8% SD at the genus level). Organisms that cause healthcare-associated Infections (HAI) were identified from the CDC list of pathogens[45]. Here, we report organisms as present if they achieve 1% relative abundance, but acknowledge that many microbes typically exist at lower concentrations, which may be undetectable with metagenomic sequencing.

Many HAI organisms were prevalent in the microbiomes of the studied HCT patients. 152 samples (38%) from 79 patients (53%) had at least one HAI organism identified at 1% relative abundance or above (Figure 1e). *Escherichia coli* was the most common HAI organism (present at ≥1% in 42/149 patients, 28.2%; 0.1%=80/149, 53.7%), followed by *Klebsiella pneumoniae* (39/149 patients, 26.2%; 0.1%=70/149, 47%) and *Enterococcus faecium* (26/149 patients, 17.4%; 0.1%=73/149, 49%). Rates of colonization with HAI organisms were much higher than in stool samples from healthy individuals in the Human Microbiome Project[46] where *E. coli* reaches 1% relative abundance in 2.1% of samples, and *K. pneumoniae* and *E. faecium* are never found at greater than 1% (present at 0.1% in 18.4%, 1.4% and 0.7% of samples, respectively).

HCT patient microbiomes can become dominated by HAI organisms, often as a result of antibiotic usage. 24 patients (16%) have at least one sample with a dominant HAI organism (≥ 30% relative abundance), which may place them at increased risk for bloodstream infections (BSI)[6]. BSI in this cohort of HCT patients is most frequently caused by *E. coli*, viridans group Streptococci and *E. faecium*; these organisms less frequently cause BSI among the entire inpatient population at our hospital (Figure 1f). We focused further analysis on *E. coli* and *E. faecium*, as these species are both frequently detected in stool and frequently cause BSIs. While viridans group Streptococci frequently cause BSIs in HCT patients,

207 these species are typically much more prevalent in the oral cavity[2,47] compared to the gut microbiome

208 (individual species in the group only reach 1% relative abundance in 8/149 patients, 5%).

Detection of *E. coli* and *E. faecium* becomes more common during a patient's hospital stay

We investigated the detection of *E. coli* and *E. faecium* in patients with time course samples

(82/149 patients, 55%) as a proxy for understanding if these organisms were acquired or became more

abundant during the observed hospital stay. Of the 1615 de-replicated MAGs, nine were identified as *E.*

coli and five were identified as *E. faecium*. We mapped sequencing reads from all samples to these

MAGs and evaluated the maximum coverage breadth, the fraction of the reference genome covered with

at least one sequencing read. We used a breadth cutoff of 50% to determine "detection" or "absence" in

a sample. This threshold is likely specific (it is difficult to achieve 50% breadth by read mis-mapping or

homology with a different organism) but not extremely sensitive (it will likely miss very lowly abundant

organisms that are truly present).

64/82 (78%) patients with time course samples have *E. coli* present at 50% breadth in at least

one sample. Of these, 10/64 (16%) have *E. coli* below 50% breadth in the first sample. 60/82 (73%)

patients with time course samples have *E. faecium* present at 50% breadth in at least one sample. Of

these, 17/60 (28%) have *E. faecium* below 50% breadth in the first sample (Figure 1d). In these patients,

E. coli or *E. faecium* may have been newly acquired into the gut microbiome during the hospital stay.

Alternatively, the organism could have also been present at low abundance and below our limit of

detection in the first sample. It is possible that antibiotic use in the weeks after HCT kills off many of

natural microbiome colonizers, allowing antibiotic resistant HAI organisms to increase in relative

abundance past our limit of detection. Overall, the relative abundance of *E. coli* and *E. faecium* was not

significantly different in first samples compared to later samples (Wilcoxon rank-sum test). While more

patients have newly detectable E. faecium than E. coli, the difference was not statistically significant

(p=0.09, binomial likelihood ratio test).

Antibiotic use and its effect on HCT patient microbiomes

HCT patients are frequently prescribed antibiotic, antiviral and antifungal drugs, especially in the

days immediately after transplant. These drugs can have a significant impact on the microbial

populations in the gut and contribute to the loss of microbial diversity frequently observed following

HCT[6]. Antibiotic use likely impacts the dynamics of bacterial transmission in this patient population, as

both natural colonizers, which may provide resistance to newly invading species, and potentially

transmitted species can be killed by the drugs. We gathered electronic health record data to understand

the characteristics of antibiotic prescription in our patient cohort and its potential impact on the gut

microbiome composition.

Patients were prescribed a median of five different antibiotics (range 1 - 10) and had a median of

90 cumulative antibiotic-days (range 14 - 416). The most common antibiotics prescribed were

ciprofloxacin (98% of patients prescribed for at least one day), IV vancomycin (80%), cefepime (66%)

and piperacillin-tazobactam (57%). Prescription of most antibiotics peaked in the 14 days following HCT,

while administration of antifungal drugs like posaconazole and antiviral drugs like ganciclovir were higher

up to 50 days following HCT (Figure 2a). We found that antibiotic usage in the prior seven days before a

stool sample was collected was strongly negatively associated with bacterial diversity (linear regression

on cumulative antibiotic-days and Shannon diversity, R^2 =0.18, 0.14, p=8.9e-11, 2.6e-8 for species and

genus level, respectively). Samples with a single species dominant at 30% relative abundance or higher

also typically had higher antibiotic usage in the past seven days (p=0.001, Wilcoxon rank-sum Test)

(Figure 2b-d).

Patients who share time and space in the hospital do not converge in microbiome

composition or frequently share strains

To understand the overall impact of temporal and spatial overlap on patient microbiomes, we first

studied the taxonomic (Bray-Curtis) similarity between samples from different patients. For each sample

pair, we calculated the maximum time the two patients had overlapped in the hospital or as roommates,

determined by the earlier sample time. There was not a significant linear association between time of

overlap and taxonomic similarity (linear regression, p=0.42 for roommate, p=0.068 for hospital, Figure

2e,f), indicating that the broad taxonomic composition of patient microbiomes may not converge under

temporal and geographic overlap. However, there may be isolated strains that are shared between

patients. We used the strain diversity-aware, SNP-based method inStrain[48] to conduct a sensitive

analysis of bacterial strains shared between patients. InStrain compares alignments of short reads from

multiple samples to the same reference genome and reports two metrics: Consensus ANI (conANI) and

PopulationANI (popANI). ConANI counts a SNP when two samples differ in the consensus allele at a

position in the reference genome, similar to many conventional SNP calling methods. PopANI counts a

SNP only if both samples share no alleles. For example, if A/T alleles were found at frequencies of

90/10% and 10/90% in two samples, a consensus SNP would be called because the consensus base is

different. A population SNP would not be called because both samples share an A and T allele.

We mapped sequencing reads from all samples against the collection of 1615 unique MAGs and

compared strains in samples from different patients with >50% coverage breadth at a depth of five reads

(see methods). This coverage breadth threshold ensures ANI is calculated across the majority of the

strains being compared and is recommended by the authors of inStrain. The maximum log-scaled

popANI value was taken as representative of the maximal strain sharing between all pairs of patients.

Length of hospital overlap was significantly associated with having a more similar microbiome strain

(linear regression on log-scaled popANI values, p=0.0017), while time of roommate overlap was not

significantly related (Figure 2i,j). However, we note that this comparison excludes pairs of patients with

strains below ~97% ANI or with very lowly abundant strains, as they would not be detected by inStrain.

Taken together, these results suggest that the microbiomes of patients who share time and space in the

hospital are not converging, either at the broad taxonomic level, or frequently at the specific strain level.

We followed up on the few cases of high-identity strains as evidence for possible transmission events.

Figure 2: The impact of antibiotic prescription and geographic overlap on patient microbiomes.

a) Aggregated prescription history of 20 of the most frequently prescribed antibiotic, antifungal and

antiviral drugs. Each panel shows the percentage of patients who were prescribed a drug at the given

day, relative to the date of HCT.

Shannon diversity at the species (b) or genus (c) level compared to total antibiotic-days in the seven

days prior to sample collection.

(d) Samples with or without a single species dominant (≥30%), compared with total antibiotic-days in the

prior seven days.

Taxonomic similarity at the species level (1 - Bray-Curtis dissimilarity) between samples from different

patients, evaluated against days of hospital overlap (e) or hours of roommate overlap (f) prior to the

earlier sample.

Maximum inStrain popANI achieved by comparing all strains in all samples from two patients, evaluated

against hours of roommate (g) or days of hospital overlap (j) prior to the earlier sample.

In all panels, trend lines are calculated as the best-fit linear regression between the X and Y variables. R

and p-values are the Pearson correlation coefficient and correlation p-value, respectively.

HAI organisms that colonize HCT patient microbiomes are part of known, antibiotic resistant and globally disseminated clades

301   *E. coli* and *E. faecium* are common commensal colonizers of human microbiomes[49–51]. These

302 species can also be pathogenic and contribute to inflammation, dysbiosis and infection in the host[52,53].

303 The specific strain of these species is key in determining the balance between a healthy and diseased

304 state in the microbiome. We compared patient-derived *E. coli* and *E. faecium* MAGs with several

305 reference genomes (Table S6) to identify the closest strains or sequence types.

Escherichia coli

The 95% identity, or species-level, cluster of *E. coli* MAGs contained 47 genomes from 26

patients (Figure 3). Within this alignment average nucleotide identity (ANI) based tree, we observed two

clades of genomes where MAGs from multiple patients had >99.9% ANI. These clades were investigated

further as they may represent common sequence types. The first clade contained 15 MAGs from 7

patients; these MAGs had >99.9% ANI to pathogenic *E. coli* sequence type (ST) 131 clade C2 genomes,

including EC958[54] and JJ1886[55]. ST131 is an extraintestinal, pathogenic, multidrug resistant *E. coli* strain

which frequently causes urinary tract infections[56]. *E. coli* ST131 often carries extended-spectrum β-

lactamase (ESBL) genes which convey a wide range of antibiotic resistance. This sequence type is

believed to colonize the intestinal tract even in healthy individuals without antibiotic exposure[57], and there

are reports of this pathogen causing urinary tract infections in multiple individuals within a household[58].

The second clade contained 12 MAGs from 5 patients with >99.8% ANI to the pathogenic ST648

representative IMT16316[59]. ST648 is also an ESBL-producing *E. coli* strain, but it is not as widespread

as ST131. Both STs have been isolated from wastewater[60] and ST648 has been isolated from the gut of

humans[61] and other mammals[62]. Our finding that *E. coli* ST648 is also prevalent in HCT patient

microbiomes suggests that it may become a pathogen of interest in this patient population in the future.

To understand the antibiotic resistance capabilities of the *E. coli* strains colonizing these HCT

patients, we searched for β-lactamase genes in the *E. coli* MAGs (see methods). The most commonly

detected genes were *ampH* and *ampC*, which are part of the core *E. coli* genome and likely do not

contribute to antibiotic resistance[63] (Figure S2A). CMY-132 was detected exclusively in MAGs in the

ST131 clade, and mutations conveying resistance in *gyrA* were detected in MAGs in multiple clades.

CTX-M-type β-lactamases were detected in several samples, but often within the metagenome rather

than within the *E. coli* MAG, indicating they may be on plasmids or mobile genetic elements that did not

bin with the rest of the *E. coli* genomes.

Escherichia coli

Figure 3: Alignment average nucleotide identity (ANI) tree of *Escherichia coli* MAGs. MAGs identified as

E. coli, medium quality or above and at least 75% the mean length of the reference genomes are

included. Several reference genomes are included and labeled with an asterisk. Clusters at the 99% ANI

level corresponding to ST131 (purple) and ST648 (orange) are highlighted. Alignment values used to

construct this tree can be found in Table S7.

Enterococcus faecium

The species-level cluster of *E. faecium* MAGs contained 30 genomes from 20 patients (Figure

4a). All MAGs were ≥99% identical, suggesting a single ST is present in most patients[50]. These genomes

matched closest to *E. faecium* ST117, a well-described vancomycin-resistant strain that frequently

causes bloodstream infections[64]. Notably, five other MAGs had ~94% ANI (below the 95% clustering

threshold, and therefore not shown in Figure 3a) to the ST117 clade and >99% ANI to commensal *E.*

faecium strains, including strains Com15 and Com12[50]. To understand the vancomycin resistance

capabilities of these strains, we searched for the seven genes in the *vanA* operon[65]. Only 2/30 samples

had the full operon present within the *E. faecium* MAG (Figure S2b). When we looked in the entire

metagenome, 22/30 samples had the full operon present, and the *vanA* genes were usually detected on

a contig that was not assigned to any MAG. *Van* genes are often carried on mobile genetic elements or

plasmids in *E. faecium,* which frequently do not assemble and bin well due to repetitive sequences.

Interestingly, no *van* genes are present in sample 11342_02, but the full operon is present in the

E. faecium MAG in sample 11342_03, collected 14 days later from the same patient. In sample

11342_03, the *vanA* operon appears on a contig 8.7 kb long with 143x coverage, much lower than the

~2000x coverage of the rest of the *E. faecium* MAG. Mapping reads against this contig revealed

scattered coverage in 11342_02, leading us to believe the operon is present, but not at high enough

coverage to be assembled in the earlier sample. We attempted to culture vancomycin-resistant

Enterococcus (VRE) from these samples (see methods), and positively identified *E. faecium* by MALDI

coupled to time-of-flight mass spectrometry in samples 11342_02 and 11342_03. Taken together, these

results suggest that there were at least two strains of *E. faecium* in the gut microbiota of patient 11342.

The low relative coverage of the *vanA* operon indicates that the VRE strain may have been a small

fraction of the total *E. faecium* population. Patient 11342 was never prescribed vancomycin (Figure S7a),

so the VRE strain may have not had an advantage in this environment.

VanA genes were also not detected in sample 11349_01, where we observed a nearly identical

E. faecium strain to patient 11342 after the patients shared a room for 11 days. When we attempted to

culture VRE from 11349_01, a bacterium grew poorly on plates containing vancomycin and was

identified as *Klebsiella pneumoniae.* Therefore, we believe the *E. faecium* strain in the microbiome of this

patient was vancomycin sensitive. If transmission from patient 11342 was responsible for colonization of

patient 11349, the vancomycin-sensitive strain may have been transmitted.

Figure 4: *Enterococcus faecium* strains compared between patients.

a) Alignment average nucleotide Identity (ANI) based tree of *E. faecium* MAGs. MAGs identified as *E. faecium*, medium quality or above and at least 75% the mean length of the reference genomes are included. Several reference genomes are included and labeled with an asterisk. Two clades containing samples from multiple patients are highlighted for further comparison. Alignment values used to construct this tree can be found in Table S7.

b, c) Heatmaps showing pairwise popANI values calculated with inStrain for clades B and C. Color scale ranges from 99.99-100% popANI and is in log space to highlight the samples with high popANI. Cells in the heatmap above the transmission threshold of 99.999% popANI are labeled. Four groups containing samples from multiple patients with popANI values above the transmission threshold are highlighted on the top of the heatmaps.

Nearly identical strains indicative of putative patient-patient *Enterococcus faecium*, but not *Escherichia coli transmission*

We used the results from the inStrain comparison to search for nearly identical bacterial strains, which may be indicative of transmission between patients. To determine a threshold for putative transmission, we examined comparisons in several "positive control" datasets where we expect to find identical strains, either as the result of persistence or transmission: time course samples from the same HCT patient, stool samples from mother-infant pairs[18] and samples from fecal microbiota transplantation donors and recipients[23]. We often observed 100% popANI in these "positive control" comparisons, indicating that there were no SNPs that could differentiate the strain populations in the two samples (Figure S3, S4). Due to expected noise and errors in sequencing data, we set the lower bound for transmission in our HCT cohort at 99.999% popANI, equivalent to 30 population SNPs in a 3 megabase (Mb) genome. The same threshold was used to identify identical strains by the authors of inStrain[48].

Escherichia coli

While *E. coli* genomes in samples collected from the same patient over time were always more similar than the putative transmission threshold, in no case did we observe a pair of samples from different patients with ≥99.999% popANI (Table S8). This result suggests that all *E. coli* strains observed are patient-specific, and argues that there are not common strains circulating in the hospital environment or passing between patients. Alternatively, patient-patient transmission or acquisition of common environmental strains is either notably rare or rapid genetic drift after a patient acquires a new strain is reducing popANI levels below the threshold. Deeper metagenomic sequencing or isolation and sequencing of *E. coli* strains may allow us to detect transmission in previously missed cases.

Enterococcus faecium

We performed the same analysis in *E. faecium* and observed four examples where two patients shared a strain with ≥99.999% popANI (Figure 4b,c). In one case, the two patients were roommates and direct transmission appears to be the most likely route. In the other three cases, epidemiological links were less clear, suggesting the patients may have acquired a similar strain from the hospital environment

or through unsampled intermediates. In the following descriptions, samples are referred to by the day of

collection, relative to the first sample from patients in the comparison.

Case 1: Patients 11342 and 11349 overlapped in the ward for 21 days and were roommates for

11 days (Figure 5a). Patient 11342 had a gut microbiome that was dominated by *E. faecium*; the two

samples from this patient have 60% and 87% *E. faecium* relative abundance. A single sample from

patient 11349 was obtained 14 days after starting to share a room with patient 11342. This sample is

dominated by *Klebsiella pneumoniae,* and *E. faecium* is at 0.4% relative abundance. InStrain

comparisons between the *E. faecium* strains in 11342 (the presumed "donor") and 11349 (the presumed

"recipient") of the strain revealed 0-2 population SNPs (popANI 100% - 99.9999%) with 87% of the

reference MAG (2.24 Mb) covered ≥5x in both samples. MAGs from each patient were also structurally

concordant (representative dotplots in Figure S6a). These genomes were the most similar out of all *E.*

faecium genomes compared from different patients. Samples from these patients were extracted in

different batches and sequenced on different lanes, minimizing the chance that sample contamination or

"barcode swapping"[66] (see Supplemental Note) could be responsible for this result. No other strains were

shared between these two patients.

Case 2: Patients 11575 and 11568 overlapped on the ward for 36 days but were never

roommates (Figure 5b). Samples from patient 11575 span 97 days, during which this patient experienced

a BSI with *Klebsiella pneumoniae* and treatment with intravenous (IV) vancomycin, ciprofloxacin,

meropenem (Figure S7c). Antibiotic treatment likely resulted in a reduction in microbiome diversity and

domination by *E. faecium* in samples collected on days 16 and 28. Two samples were collected from

patient 11568 on days 28 and 119. The first sample from 11568 was also dominated by *E. faecium,* but

strains from the two patients were distinct (99.95% popANI). 91 days later, the second sample from

11568 has a lower relative abundance of *E. faecium* but a nearly identical strain to patient 11575. Five

population SNPs (99.9997% popANI) were detected with 88% of the reference MAG covered ≥5x in both

samples (representative dotplot in Figure S6b). This suggests that the *E. faecium* strain in 11568 was

replaced by a different strain with high identity to the strain in 11575. Patient 11568 was discharged from

the HCT ward during the period between the two samples. The shared strain may represent an

acquisition from a common environmental source or transmission from unobserved patients, rather than

a direct transmission event between these two patients. While the *E. faecium* strain was different at the

two time points from patient 11568, an *E. faecalis* strain remained identical.

Case 3: Patients 11605 and 11673 did not overlap in the ward (Figure 5c). Two samples were

collected from 11605 on days 0 and 14. This patient experienced a BSI with *E. faecium* and treatment

with meropenem (Figure S7e) prior to a sample dominated by the same species on day 14. Patient

11673 experienced a BSI with *E. coli* and treatment with vancomycin, meropenem and cefepime (Figure

S7f) prior to the single sample we collected from this patient. Comparing *E. faecium* strains between the

two patients revealed 2 population SNPs (99.9998% popANI) with 48% of the reference MAG covered

≥5x in both samples (representative dotplot in Figure S6c). Although slightly below the 50% coverage

threshold, the high degree of similarity caused us to consider this result. While *E. faecium* strains in the

two patients were nearly identical, the samples were collected 161 days apart and the patients had no

overlap in the ward. This suggests both patients may have acquired the strain from the hospital

environment, through transmission from unsampled patients, or another source such as healthcare

workers.

Case 4: Patients 11360 and 11789 did not overlap in the ward. *E. faecium* remained at relatively

low abundance in all samples. Comparing *E. faecium* strains between patients revealed 5-10 population

SNPs (99.9993% - 99.9996% popANI) with 50%-57% genome coverage. Neither patient had a BSI

during the sampling period. As these samples were collected at least 428 days apart, a shared source

again may be the most likely explanation.

Comparisons with *E. faecium* and *E. coli* in published data

The *E. faecium* and *E. coli* strains we observe in our patients may be unique to this patient

population and hospital environment. Alternatively, they may be hospital acquired strains that are present

in other settings around the globe. We searched through several published datasets to differentiate

between these possibilities. Our comparison dataset included metagenomic shotgun sequence data from

189 stool samples from adult HCT patients[67], 113 stool samples from pediatric HCT patients[3,68,69], 732

stool samples from hospitalized infants[70] and 58 vancomycin-resistant *E. faecium* isolates[71]. Sequence

data were downloaded from SRA and processed in the same manner as other short-read data. Each

sample was aligned against the *E. faecium* and *E. coli* MAGs used in the inStrain analysis above,

profiled for SNPs, and compared against samples collected from our HCT patients. Comparisons within

our data and comparisons within individual external datasets frequently achieved popANI values of

≥99.999%, typically from comparisons of samples from the same patient over time. Meanwhile,

comparisons between our samples and external samples had lower popANI values (Figure S5).

Comparisons of *E. faecium* strains in samples from patient 11346 in our dataset and patient 688

in the HCT microbiome dataset collected at Memorial Sloan Kettering Cancer Center[67] demonstrated a

maximum of 99.9993% popANI (16 population SNPs detected in 2.3 Mb compared). While direct

transmission is likely not involved here, this observation does align with the nearly identical *E. faecium*

strains we observed in patients with no geographic or temporal overlap (case 3 and 4) and speaks to the

global dissemination of vancomycin-resistant *E. faecium* ST 117. Comparing *E. coli* to external datasets

revealed a maximum of 99.996% popANI (200 population SNPs detected in 5.0 Mb compared).

Figure 5: Microbiome composition of patients with putative *Enterococcus faecium* transmission events. Each panel shows the composition of two patients over time. The height of each bar represents the proportion of classified sequence data assigned to each taxon. Samples are labeled relative to the date of the first sample in each set. Bars above each plot represent the approximate time patients spent in the

same room (black bars) or in the hospital (grey bars). Red symbols indicate approximate dates of

bloodstream infection with the specified organism. Hypothesized direction of transmission progresses

from the top to the bottom patient. Fractions of the bar with >99.999% popANI strains in each panel are

indicated with solid colors, and different strains are indicated with hashed colors. All taxa except *E.*

faecium are shown at the genus level for clarity.

a) Case 1: Putative transmission from patient 11342 to 11349.

b) Case 2: Putative transmission from patient 11575 to 11568.

c) Case 3: Putative transmission from patient 11605 to 11673.

Putative transmission of commensal bacteria

Next, we extended the inStrain analysis to compare all species that were present in multiple patients. We found nearly identical genomes of commensal organisms that may be the result of transmission between patients, as well as several species shared between patients without clear explanations.

Hungatella hathewayi

Patients 11639 and 11662 overlapped in the ward for 34 days and were roommates for a single day, after which 11639 was discharged (Figure 6a). *Hungatella hathewayi* was at 5-10% relative abundance in the two samples from 11639. Patient 11662 developed *Streptococcus mitis* BSI on day 10 and was treated with IV vancomycin and cefepime (Figure S8b). The microbiome of this patient recovered with markedly different composition, including an abundant *H. hathewayi* strain reaching 54% and 17% relative abundance on days 58 and 100, respectively. Comparing *H. hathewayi* genomes between these two patients revealed 0-1 population SNPs (100% - 99.99998% popANI) with 94%-98% coverage ≥5x (6.9 - 7.1 Mb sequence covered in both samples). This was the single highest ANI comparison among all strains shared between patients. *H. hathewayi* MAGs from these patients were also structurally concordant and had few structural variations (Figure S6d). No other strains were shared between these patients.

Patient 11662 had *H. hathewayi* in the first two samples at 1.2% and 0.3% relative abundance, respectively. Although we were limited by coverage, comparing early to late samples with inStrain revealed 472 population SNPs in 3% of the genome that was covered at least 5X, implying 11662 was initially colonized by a different *H. hathewayi* strain, which was eliminated and subsequently replaced by the strain present in 11639. Given that samples were collected weekly, determining the direction of transmission is challenging. However, 11639 to 11662 appears to be the most likely direction, given the sampling times and perturbation 11662 experienced. However, it is possible that transmission occurred in the opposite direction or from a common source. Interestingly, 11662 was also re-colonized with

Flavonifractor plautii in later samples. This strain was different from the strain in earlier samples from this

patient, as well as all other *Flavonifractor* strains in our sample collection.

H. hathewayi is known to form spores and is able to persist outside a host for days[72]. Although

these patients were only roommates for a single day, 11662 remained in the same room for 4 days after

11639 was discharged, increasing the chance that a *H. hathewayi* spore could be transmitted from a

surface in the shared room or bathroom. The question remains as to why transmission of *H. hathewayi* is

not more common, given it is found at ≥1% relative abundance in 31 patients. Perhaps the earlier

colonization of the microbiome of 11662 with a different *H. hathewayi* strain was key - the microbiome in

this patient was "primed" to receive a new strain of the same species, despite the significant perturbation

this patient experienced.

Notably, *H. hathewayi* was recently reclassified from *Clostridium hathewayi*[73], and was previously

shown to induce regulatory T-cells and suppress inflammation[74]. Although the interaction of this microbe

in HCT is not known, it may be interesting to investigate further given that the microbe may be

transmitted between individuals and may contribute to inflammation suppression that may be relevant in

diseases such as graft-vs-host disease. However, *H. hathewayi* may not be entirely beneficial or

harmless and has been reported to cause BSI and sepsis in rare cases[75,76].

Akkermansia muciniphila

Patients 11742 and 11647 overlapped in the ward for 11 days and were roommates for nine days

(Figure 6b). Patient 11647 experienced a BSI with *Klebsiella pneumoniae* (perhaps related to previous *K.*

pneumoniae domination of the microbiome) and was treated with piperacillin-tazobactam and cefepime

(Figure S8d). The final sample from 11647 has *Akkermansia muciniphila* at 9.4% relative abundance,

while the single sample from 11742 was dominated by *A. muciniphila* (85% relative abundance).

Comparing these genomes revealed 0 population SNPs and 7 consensus SNPs with 90% coverage, as

well as concordant MAGs from each sample (Figure S6e). No other strains were shared between these

two patients.

In contrast to *H. hathewayi*, *A. muciniphila* is not known to form spores, which may reduce the

chance of this microbe being transmitted. However, it is an aerotolerant anaerobe that may survive in

oxygen for short periods of time[77]. The microbiome domination of 11742 with *A. muciniphila* and the

relatively long overlap period of nine days in the same room may provide a greater "infectious dose"

(abundance * exposure time) to the recipient patient.

Figure 6: Microbiome composition of patients with putative *Hungatella hathewayi* or *Akkermansia*

muciniphila transmission events. Each panel shows the composition of two patients over time. The height

of each bar represents the proportion of classified sequence data assigned to each taxon. Samples are

labeled relative to the date of the first sample in each set. Bars above each plot represent the

approximate time patients spent in the same room (black bars) or in the hospital (grey bars). Red

symbols indicate approximate dates of bloodstream infection with the specified organism. Hypothesized

direction of transmission progresses from the top to the bottom patient. Fractions of the bar with

>99.999% popANI strains in each panel are indicated with solid colors, and different strains are indicated

with hashed colors. All taxa except *H. hathewayi* or *A. muciniphila* are shown at the genus level for

clarity.

a) Putative case of *H. hathewayi* transmission from 11639 to 11662.

b) Putative case of *A. muciniphila* transmission from 11742 and 11647.

Widespread strain sharing of commercially available probiotic organisms

Several organisms were found with identical or nearly identical genomes across multiple patient microbiomes without clear epidemiological links. The largest clade was found for *Lactobacillus rhamnosus*, which included 11 samples collected from eight patients over a span of 2.5 years (Figure 7a,d). All 11 samples in this clade had pairwise popANI of ≥99.999%, and in a subset of eight samples from seven patients, all pairs were identical from a popANI perspective (100%). Of the eight patients in this clade, only two pairs were roommates or overlapped in the hospital (patients 11537/11547 and 11647/11662, roommates for three days and one day, hospital overlap for 20 and 44 days, respectively). All 11 samples in this clade were collected after HCT (median time from HCT to first sample 43 days, range 12-93 days), and *L. rhamnosus* always had <0.1% relative abundance in pre-HCT samples, when present. Five of eight patients were discharged from the hospital after HCT and prior to acquiring *L. rhamnosus,* which we observed in a sample collected during a subsequent admission. We also observe *L. rhamnosus* falling below 0.1% relative abundance in a subsequent sample in five patients, suggesting that this strain may be a transient colonizer of the microbiome (Figure 7E). We evaluated antibiotic prescriptions in these patients and found that acquisition and loss of *L. rhamnosus* typically occurs independently of antibiotic use. For example, in patient 11537, *L. rhamnosus* is first detected and expands to 23.4% relative abundance while the patient is prescribed ciprofloxacin and cefepime. *L. rhamnosus* declines in relative abundance after the antibiotic prescription ends (Figure S9). Similar clades of high-identity genomes from different patients were found for *Lactobacillus gasseri* (Figure 7b) and *Streptococcus thermophilus* (Figure 7c).

Given that we did not observe hospital or roommate overlap between most patients in the *L. rhamnosus* cluster, the most likely explanation is that patients acquired this strain from a common source. *L. rhamnosus* is a component of several commercially available probiotic supplements, is present in certain live active-culture foods such as yogurt, and is among the most commonly prescribed probiotic species in US hospitals[78]. However, HCT recipients were not allowed to take probiotics or consume high-bacteria dairy products, such as probiotic yogurt or soft cheese, while inpatients on the

HCT ward. We also verified that no prescriptions were written for probiotics by examining electronic

health records. A majority of patients were discharged from the hospital between HCT and acquiring the

L. rhamnosus strain, which may have provided them with the opportunity to consume a probiotic

supplement or dairy product. Contact with a family member or other individual who had the strain in their

microbiome could also be responsible for colonization of the HCT patient.

If this *L. rhamnosus* strain is a commonly used probiotic supplement or is found in commonly

consumed dairy products, it may be found in other gut microbiome sequencing datasets. Comparing

MAGs from this cluster against all Genbank genomes revealed a maximum alignment-based ANI of

99.95% to *L. rhamnosus* ATCC 8530[79]. Instrain-based comparisons against this reference had a

maximum popANI of 99.98%, below the putative transmission threshold. We then searched against all

genomes in the Unified Human Gastrointestinal Genome collection[41] and identified two genomes that

were nearly identical to the strain found in HCT patients. These genomes were originally from the Human

Gastrointestinal Bacteria Culture Collection[80] (accessions ERR2221226 and ERR1203919, belonging to

the same isolate per a personal communication with the authors). Assembled isolate and patient-derived

genomes had ≥99.99% ANI; inStrain-based SNP comparisons had ≥99.999% popANI. This suggests

that a *L. rhamnosus* strain that is nearly identical to the genomes in our HCT patients has been isolated

from human stool in the past.

Figure 7: *Lactobacillus* and *Streptococcus* strains are acquired after HCT and identical between many

patients.

Population ANI based tree of (a) *Lactobacillus rhamnosus,* (b) *Lactobacillus gasseri,* (c) *Streptococcus*

thermophilus strains present in patient samples. Clades containing samples from different patients with

≥99.999% popANI are highlighted with a grey background. Clades with 100% popANI between all pairs

are additionally bolded and italicized.

d) Timeline of approximate date of samples containing a *L. rhamnosus* strain in the transmission cluster

in (a). Patients who were discharged from the hospital after HCT and prior to acquiring *L. rhamnosus* are

bolded and italicized.

e) Microbiome composition of patient 11537. *L. rhamnosus* abundance at each time point is indicated

above the bar. This patient received HCT on relative day 3.

Discussion

Our investigation using high-resolution metagenomic sequencing attempts to quantify if and when patient-patient microbiome transmission is involved in the spread of pathogenic organisms. We first found that hospitalized HCT patients frequently harbor HAI organisms in their gut microbiome, validating previous studies which used culture-based approaches or 16S rRNA sequencing[6,26,27]. MAGs created from patient samples had high identity to several globally disseminated and antibiotic resistant sequence types, including *Escherichia coli* ST131 and ST648. Interestingly, whereas ST131 is a well-recognized multi-drug resistant pathogen, ST648 is nearly as prevalent as ST131 in our sample collection, and may thus be an emerging pathogen in this patient population.

Despite the high degree of temporal and spatial overlap between patients in our study, we found no association between these factors and the taxonomic similarity of patient microbiomes, and only a weak association between hospital overlap and maximum strain identity. These findings suggest that patient-patient transmission is not driving microbiome composition, but individual strains may still be shared between patients. We did not identify any pairs of patients harboring *E. coli* strains with popANI values above the 99.999% popANI transmission threshold. Taken together with the observation that *E. coli* is commonly detected in the patient's microbiome upon admission, this finding argues that patients usually enter the hospital with an "individual-specific" *E. coli* strain and do not frequently transmit it to others. An exclusion principle may be at play, where an *E. coli* niche can only be filled by a single strain and new strains are unlikely to engraft when the niche is already occupied. In contrast to *E. coli*, we observed four pairs of patients with E. *faecium* strains that were more similar than 99.999% popANI. In one case, the two patients spent 11 days sharing a room and bathroom prior to observing the shared strain. Direct links between patients were less clear or non-existent in the other three cases, and transmission through unsampled intermediates or acquisition from an environmental source may have been responsible. We also found evidence for an *E. faecium* strain in a published dataset from HCT patient microbiomes[67] that had above 99.999% popANI to a strain in our sample collection. While this

finding is likely not the result of patient-patient transmission, it does indicate that very similar strains may

exist within patients in different geographic locations.

We then expanded the transmission analysis to examine all species that were present in the

microbiome of multiple patients. Identical *Hungatella hathewayi* strains were found in two patients who

were in the hospital together for 34 days and roommates for a single day. Earlier samples from patient

11662 had a significantly different *H. hathewayi* strain than the strain present in later samples. It is

possible that the earlier colonization with the same species exhibited a priority effect[81] and primed this

individual to be re-colonized. In another set of patients who overlapped in the hospital for 11 days and

were roommates for nine days, we identified identical *Akkermansia muciniphila* strains. In both

examples, the likely "recipient" patient experienced BSI prior to the putative transmission event. The

subsequent antibiotic treatment initiated for the treatment of BSI resulted in vast microbiome modification

and simplification, which may have opened a niche for the new organism to engraft into. Both *H.*

hathewayi and *A. muciniphila* can survive outside the host for periods of time, but *H. hathewayi* can form

spores that enable it to live in aerobic conditions for days[72]. In the case of *H. hathewayi* transmission,

patient 11662 remained in the same room with a shared bathroom after the single day of overlap with

patient 11639. Spores surviving on surfaces may be responsible for transmission, given the relatively

short period of overlap. In these cases, patient-patient transmission may help in the recovery of

microbiome diversity following BSI and may play a role in ameliorating post-HCT inflammatory

processes, such as acute graft-vs-host disease.

Finally, we observed identical probiotic species in multiple patients without clear geographic or

temporal links, including *Lactobacillus rhamnosus*, *Lactobacillus gasseri*, and *Streptococcus*

thermophilus. Acquisition from a commercially available probiotic or live-active culture food appears to be

the most likely explanation. While patients hospitalized for HCT were not allowed to consume probiotics

or high-bacterial dairy foods, a majority of patients were discharged after HCT and prior to a subsequent

admission, upon which *L. rhamnosus* was detected. Many patients lost the strain in later samples,

independent of antibiotic prescription, suggesting that *L. rhamnosus* was a transient colonizer. This

matches the observation that abundance of probiotic species in the gut often declines after

supplementation ends[20].

The healthy adult gut microbiome is relatively resistant to perturbation and colonization with new

strains or species[19]. In contrast, mother-to-infant transmission of bacteria and phages is common and

well-described[16–18]. Patients in our study often shared spaces, were exposed to dramatic "niche clearing"

therapies and were often immunosuppressed. We frequently observed patients acquiring new organisms

into their gut microbiome during their hospital stay, especially following BSI. Still, we found that patient-

patient transmission of gut microbes is relatively rare. This suggests that age, rather than perturbation or

microbial exposure, may play the largest role in microbiome transmission. There are also several

alternative explanations for the relative lack of transmission between patients. First, the adult gut

microbiome may remain densely colonized even when dramatically perturbed by antibiotics and

chemotherapy, and thus resistant to invasion with new strains. Strains we observed in later samples may

have existed at low very levels in earlier samples from the individual, therefore evading detection.

Second, it is possible that the microbiome of healthcare workers, hospital visitors, or other staff serve as

the source of newly colonizing strains. Third, it is possible that the built environment, equipment used in

the care of these individuals, and other environmental sources such as food and personal items harbored

the microbes that were later transmitted. As we did not sample these other potential sources, it is difficult

to know the extent to which they contributed to the collective reservoir of potentially transmitted

organisms. Fourth, genetic drift and adaptive evolution may rapidly act on newly acquired microbes, as

has been described for *E. faecium* in the human gut[82] and *E. coli* in the mouse gut[83–85]. Rapid drift or

evolution would move the genomes of transmitted microbes below the popANI transmission threshold.

Finally, transmitted organisms may be killed by antibiotics before they can establish a community within

the host and thus be detected with metagenomic sequencing.

Our findings have important implications for hospital management and infection prevention.

55/149 patients (37%) in our study experienced BSIs, which is comparable to the rate of BSI in other

transplant centers[86]. Our findings suggest that microbiome transmission does not play a large role in

spreading infections among HCT patients, and that established contact precautions and procedures for

patient isolation were working as intended. Recently, the HCT ward at our hospital moved to a new

location with exclusively single rooms, which may further reduce the opportunity for transmission.

Our analysis of transmission of microbes between HCT patients does have several limitations.

We analyzed hundreds of samples collected over many years, but most sampling was done on a weekly

basis. We did not explicitly collect samples on the day of admission or discharge. Our sample collection

also ignores previous hospital stays, either in a different ward in our hospital, or other hospitals entirely,

that may be responsible for the acquisition of HAI organisms. Many patients in our study had one or two

sequenced samples, limiting our inference about microbiome changes over time. By contrast, the second

largest study using shotgun metagenomics to study the microbiome of HCT patients had much more

dense sampling, analyzing 395 samples from 49 patients[67]. We also did not perform any sampling of the

hospital environment, healthcare workers or visitors, which would allow us to track transmission patterns

in detail and more conclusively state where newly acquired microbes originated[87]. Our work is also

entirely based on metagenomic sequencing data, which has its own challenges and sources of bias,

including "barcode swapping"[66], which could contribute to false positive transmission findings. To

address this, we measured the impact of barcode swapping in linked-read data, and eliminated linked-

read and short-read comparisons where a finding of identical strains could be the result of barcode

swapping (see supplemental note). Additionally, metagenomic sequencing may fail to detect lowly-

abundant colonizers, especially when samples are contaminated with host DNA[88], which is often the

case in stool samples from HCT patients. These challenges undoubtedly affect our sensitivity and

specificity in measuring acquisition and transmission of both pathogenic and commensal microbes. While

our comparison methods were sensitive to strain populations in the gut microbiome, we did not attempt

to phase strain haplotypes. Haplotype phasing with long-read sequencing technology like Nanopore or

PacBio[89–91] could help us determine whether sets of SNPs occurred in the same or different strains.

Our study leaves several questions unanswered that we hope future work on microbiome

transmission will attempt to answer. First, our findings need to be validated in an external cohort in a

different hospital. Collecting stool samples during an infection outbreak may lead to more transmission

events being identified and may implicate microbiome transmission in perpetuating the outbreak. Similar

experiments in a pediatric patient population may reveal more gut-to-gut transmission, as young children

have microbiomes that are still developing and more susceptible to colonization with new species. Our

work did not investigate any possible sources of microbial transmission other than the gut microbiota of

HCT patients. A more granular study where samples are collected from the hospital environment, as well

as hand swabs and stool samples from healthcare workers, visitors, and family members, is clearly

indicated by these early results. As more transmission events are observed with high-resolution genomic

methods, we will start to uncover the general principles governing community assembly in the human

microbiome. These new insights may help prevent infections and other co-morbidities in this patient

population in the future.

Methods

Cohort selection

Hematopoietic cell transplantation patients were recruited at the Stanford Hospital Blood and Marrow Transplant Unit under an IRB-approved protocol (Protocol #8903; Principal Investigator: Dr. David Miklos, co-Investigator: Drs. Ami Bhatt and Tessa Andermann). Informed consent was obtained from all individuals whose samples were collected. Stool samples were placed at 4 °C immediately upon collection and processed for storage at the same or following day. Stool samples were aliquoted into 2-mL cryovial tubes and homogenized by brief vortexing. The aliquots were stored at -80 °C until extraction.

We identified all samples that had been sequenced previously by our group. Samples were selected for linked-read sequencing to augment this collection. We examined the network of patient roommate overlaps to find cases where we were likely to uncover transmission events, if they were happening. These included patient pairs from whom we ideally had samples before and after the roommate overlap period. 96 samples that provided the best coverage of roommate overlaps were selected for linked-read sequencing.

The following clinical data were extracted from the electronic health record: demographic information, underlying disease, type of transplantation (allogeneic vs. autologous), date and type of bloodstream infection, medication prescriptions, time of admission and discharge and location of patients (rooms) over time. Hospital-wide BSI data were obtained from an electronic report generated by the clinical microbiology laboratory. Medication prescription data was filtered by the following criteria:

8. Only entries for antibiotics, antifungals, antivirals, antibacterials, and *Pneumocystis jirovecii* pneumonia prophylaxis were retained.

9. Medications with a missing start or end date were excluded.

10. Medications with a frequency of "PRN" (*pro re nata,* or *as needed*) or a prescription status of "Canceled" were excluded.

11. Medications with a difference between start and end date of less than one day were excluded.

12. Medications prescribed to be taken by eyes, ears, topical application, or "swish and spit" were

excluded.

13. Medication prescriptions occurring outside the window of HCT date +/- 100 days were excluded

for the aggregated analysis.

We do acknowledge the challenge of working with electronic health record data, and recognize that there

is a disconnect between medications prescribed and medications consumed by a patient.

DNA Extraction, library preparation and sequencing

DNA was extracted from stool samples using a mechanical bead-beating approach with the Mini-

Beadbeater-16 (BioSpec Products) and 1-mm diameter zirconia/silica beads (BioSpec Products)

followed by the QIAamp Fast DNA Stool Mini Kit (Qiagen) according to manufacturer's instructions.

Bead-beating consisted of 7 rounds of alternating 30 s bead-beating bursts followed by 30 s of cooling

on ice. For samples subjected to linked-read sequencing, DNA fragments less than approximately 2 kb

were eliminated with a SPRI bead purification approach[92] using a custom buffer with minor modifications:

beads were added at 0.9×, and eluted DNA was resuspended in 50 µl of water. DNA concentration was

quantified using a Qubit fluorometer (Thermo Fisher Scientific). DNA fragment length distributions were

quantified using a TapeStation 4200 (Agilent Technologies).

Short-read sequencing libraries were prepared with either the Nextera Flex or Nextera XT kit

(Illumina) according to manufacturer's instructions. Linked-read sequencing libraries were prepared on

the 10X Genomics Chromium platform (10X Genomics). Linked-read libraries have a single sample

index, and were pooled to minimize the possibility of barcode swapping between samples from patients

who were roommates (see supplemental note). Libraries were sequenced on an Illumina HiSeq 4000

(Illumina).

Sequence data processing

TrimGalore version 0.5.0[93] was used to perform quality and adapter trimming with the flags "–

clip_R1 15–clip_R2 15–length 60". SeqKit version 0.9.1[94] was used to remove duplicates in short-read

data with the command "seqkit rmdup–by-seq". Due to excessive processing time, this step was skipped

for linked-read data. Reads were mapped against the GRCh38 assembly of the human genome using

BWA version 0.7.17-r1188[95] and only unmapped reads were retained. Quality metrics were verified with

FastQC version 0.11.8[96]. Bioinformatics workflows were implemented with Snakemake[93].

Short-read classification with Kraken2

We classified all short-read data with a Kraken2[42] database containing all bacteria, viral and

fungal genomes in NCBI GenBank assembled to complete genome, chromosome or scaffold quality as

of January 2020. Human and mouse reference genomes were also included in the database. A

Bracken[40] database was also built with a read length of 150 and k-mer length of 35. Classification results

were processed into matrices and taxonomic barplots with the workflow available at

https://github.com/bhattlab/kraken2_classification. Bray-Curtis distances were calculated with the R

package vegan[97] version 2.5-7.

Assembly and binning

Short-read sequencing samples were assembled using SPAdes version 3.14.0[33] using the '--

meta' flag. Linked-read sequencing samples were assembled with Megahit version 1.2.9[34] to generate

seed contigs, which were then assembled with the barcode-aware assembler Athena[29]. Metagenome-

assembled genomes (MAGs) were binned with Metabat2 version 2.15[35], Maxbin version 2.2.7[36] and

CONCOCT version 1.1.0[37] and aggregated using DASTool version 1.1.1[38]. MAG completeness and

contamination was evaluated using CheckM version 1.0.13[39] and MAG quality was evaluated by the

standards set in[40]. All assembled contigs were classified with Kraken2 as described above. To generate

bin identifications, contig classifications were pooled such that contigs making up at least two thirds the

length of the bin were classified as a particular species. If a classification could not be assigned at the

species level, the process was repeated at the genus level, and so on.

Genome de-replication and SNP profiling

810   MAGs were filtered to have minimum completeness 50% and maximum contamination 15% as

811   measured by CheckM, then were de-replicated with dRep version 2.6.2[53] with default parameters except

812 the primary clustering threshold set to 0.95. In further steps, a single de-replicated genome will be

813 referred to as a cluster. Reads from all samples were mapped against the de-replicated set of genomes

814 with BWA. Clusters that had greater than 1x average coverage in at least two samples were retained for

815 further analysis. Individual bam files were extracted for each sample-cluster pair with at least 1x

816 coverage. Bam files were randomly subsetted to a maximum of 2 million reads for computational

817 efficiency. Alignments were profiled and then compared across samples with inStrain version 1.3.11[48]

818 using default parameters. A Snakemake workflow for dRep and inStrain analysis is available at

819 https://github.com/bhattlab/bhattlab_workflows.

Building phylogenetic trees

821  MAG Average Nucleotide Identity (ANI) trees (Figure 2 and 3) were created using the pairwise

822 alignment values from dRep, which uses the MUMmer program[99]. MAGs were filtered to be at least 75%

823 the length of the mean length of reference genomes used in the tree. Reference genomes were selected

824 by searching literature for collections of well-described isolates with genomes available. References that

825 were not relevant and clustered in isolated sections of the tree were removed. Pairwise ANI values were

826 transformed into a distance matrix and clustered using the 'hclust' function with the 'average' method in

827 R version 4.0.3[100]. Heatmaps were created using pairwise popANI values from inStrain, transformed into

828 a distance matrix, and hierarchically clustered using the 'ward.D2' method.

Determining transmission thresholds

830  To determine the ANI threshold to call a comparison a "putative transmission event" we evaluated

831 the distributions of ANI values for within- and between-patient comparisons for different species (Figure

832 S3). We often detected zero population SNPs in time course samples from the same patient, including *E.*

833 *faecium* in a pair of samples collected from the same patient 323 days apart. Meanwhile, between-

834 patient comparisons typically had lower ANI values. To verify that transmission events would also result

835 in population ANI values near 100%, we examined external datasets where transmission of bacteria in

836 the microbiome is known to occur as a "positive control". We gathered sequencing data from stool

837 samples of matched mother-infant paris[18] and fecal microbiota transplantation donors and recipients[23]

and processed them with the same methods. In these datasets, we regularly observed genomes with

100% popANI between matched individuals, and did not find cases of 100% popANI between unmatched

individuals (Figure S4). In the ideal cases, we expect transmission of bacteria between the microbiomes

of HCT patients to result in genomes with 100% popANI. However, the measured genomes may not

reach this level of identity, due to mutations or genetic drift since the transmission event, sequencing

errors, or other factors. Therefore, we set the transmission threshold at 99.999% popANI, equivalent to

30 population SNPs in a 3 megabase (Mb) genome. Although this threshold is stringent, we recognize

that it may allow for false positives where two closely related strains exist in different patients solely by

chance.

Despite our efforts to minimize the impact of barcode swapping on detecting transmission (see

Supplemental Note), we still identified many comparisons with >99.999% popANI that we believe to be

false positives. These were filtered out based on the following criteria: short read samples from different

patients that were sequenced on the same lane and shared one index sequence or linked read samples

that were sequenced on the same lane and reads mapping to the organism shared >40% of barcodes.

We also removed pairs that could be affected by "secondary" swapping, where the two samples were not

directly affected, but an interaction between other samples from the two patients could cause false

positives. In total, we removed 31 comparisons from the final table with >99.999% popANI.

Pairwise MAG comparison

MAGs were aligned with the mummer program using default settings[99] and filtered for 1-1

alignments. Dotplots were visualized with the "Dot" program[101] filtering for non-repetitive alignments ≥1

kb.

Antibiotic resistance gene detection

Antibiotic resistance genes (ARGs) were profiled in contigs from all samples using Resistance

Gene Identifier (RGI) and the Comprehensive Antibiotic Resistance Database (CARD)[102] with default

parameters. Genes were counted if they met the "strict" or "perfect" threshold from RGI. ARGs were

annotated both if they occurred on a contig in the MAG of interest, or anywhere in the metagenomic

assembly.

Isolation, culture and identification of VRE organisms

Stool samples from patients 11342 and 11349 were resuspended in glycerol and streaked on

SpectraVRE (R01830, ThermoFischer Scientific) plates and incubated at 35 °C overnight. The following

day, four colonies from each of the plates that displayed growth were picked and streaked out on a

separate quadrant of fresh SpectraVRE plates. These Round 1 (R1) plates were incubated at 35 °C

overnight and checked for growth the following day. For each R1 plate, a colony was picked from each

quadrant and streaked out on a new quadrant of a fresh SpectraVRE plate. These Round 2 (R2) plates

were incubated at 35 °C overnight and checked for growth the following day. For each R2 plate, a colony

from each quadrant was subjected to MALDI-TOF bacterial species identification analysis on a Bruker

Biotyper (Burker) per manufacturer instructions

Acknowledgements

We would like to acknowledge the contributions of several members of the Bhatt lab for their assistance in the experimental design, laboratory work and manuscript preparation, including C. Severyn, D. Maghini, S. Vance, A. Natarajan, P. West, A. Behr, M. Chakraborty and S. Zliniti. We would also like to thank B. Wu at Stanford Health Care for providing information on the geographic layout of the HCT ward, K. Chen for providing information relevant to restrictions on patients consuming probiotics, A. Sidow and Z. Weng for their instruction and assistance in preparing linked-read sequencing libraries, K. Siranosian for edits to the manuscript, and S. Madison for providing information on HCT patient isolation practices. We would like to thank the Stanford Clinical Microbiology Lab for assistance in identifying isolated and cultured bacterial strains. This work was supported by NIH P01 CA049605 (PI: R. Negrin; Cell Therapy for Leukemia and Lymphoma), and NIH R01 AI143757, CDC BAA 75D30118C02921, and a Damon Runyon Clinical Investigator Award to A.S.B. B.A.S. is supported by a NIST JIMB training grant. Computing costs were supported via a NIH S10 Shared Instrumentation Grant 1S10OD02014101. This work utilized computing resources provided by the Stanford Genetics Bioinformatics Service Center. Finally, we would like to acknowledge the patients and nurses on the Blood and Marrow Transplantation service for their enthusiastic participation in this project.

Author Contributions

B.A.S., A.S.B., H.T., N.B., T.A. designed the study. B.A.S. performed laboratory and computational work, conducted the analysis and wrote the manuscript. E.B. performed laboratory work and contributed to writing the manuscript. T.A. performed laboratory work. A.R.R. and T.A. Designed the stool sample collection effort. N.B. assisted with analysis of BSI data. H.T. assisted with computational analysis. A.S.B. oversaw the project and contributed to writing of the manuscript. All authors contributed to editing the manuscript.

Competing Interests statement

The authors have no competing interests to declare.

Data availability

Raw sequence data for this manuscript, when not previously published, have been uploaded to NCBI

SRA under project number PRJNA707487, which will be released under publication. MAGs generated in

this study are available in a tar.gz archive (8.4 Gb) from Google Cloud Platform:

https://storage.googleapis.com/gbsc-gcp-lab-bhatt_public/transmission/MAGs.tar.gz. Workflows for data

processing, Krarken2 Classification, MAG binning and inStrain comparisons can be found at

https://github.com/bhattlab/bhattlab_workflows. Days of roommate and hospital overlap between patients

is provided in Tables S9 and S10.

Table titles

1. Aggregated characteristics of patients with samples investigated in this study.
2. Aggregated statistics of temporal geographic data for all patients on the ward during the study period.
3. Aggregated statistics of sequencing datasets and metagenome-assembled genomes (MAGs) generated in this study.

Supplemental table titles

1. Clinical metadata of patients with samples investigated in this study.
2. Sequencing datasets analyzed in this study.
3. Statistics on MAGs generated in this study.
4. Kraken2 classification results for all samples at the species level. Species with less than 0.01% abundance have been removed.
5. Kraken2 classification results for all samples at the genus level. Genera with less than 0.01% abundance have been removed.
6. Source and publication for each reference genome used in Figures 2 and 3.

7. Pairwise alignment-based ANI for Escherichia coli and Enterococcus faecium genomes analyzed in Figures 2 and 3. MAGs are identified by a concatenation of the seq_id and Bin columns in Table S3.

8. InStrain results for all comparisons made between samples in this manuscript. Filtered to remove comparisons <99.99% popANI, <0.5 percent_compared and potential barcode swapping results.

9. Matrix of number of days patients overlapped in the hospital.

10. Matrix of number of days patients overlapped as roommates.

11. Antibiotic prescription data for each patient, limited to $\mp$ 100 days relative to HCT.

Supplemental note: Mitigation of laboratory contamination and barcode swapping

Supplemental note: Mitigation of laboratory contamination and barcode

swapping

Any study of transmission is susceptible to confounders that may introduce false positives. Two

major sources are laboratory contamination and barcode swapping, both of which can make it appear as

if identical strains were present in multiple samples. To minimize the chance of laboratory contamination,

samples selected for linked-read sequencing were randomized prior to extraction into groups of 16,

subject to the constraint that the number of samples from roommate pairs in the same extraction batch

were minimized. These groupings were carried out through library preparation. Similar constraints were

used when preparing pooled libraries for sequencing.

It is a recognized phenomenon that pooled Illumina sequencing libraries experience "barcode

swapping" or "index hopping"[66] when libraries are differentiated by a single sample index. While this

issue is avoided by using unique dual index sequences for all samples in a pool, our laboratory was not

aware of the issue until 2018, and older libraries were prepared without a unique dual indexing strategy.

Linked-read libraries only contain a single sample index sequence, which makes it impossible to

eliminate the effect of barcode swapping, other than the costly option of devoting an entire lane to each

sample.

In linked-read sequencing libraries, we were able to estimate the impact of barcode swapping.

There are ~10 million possible 10X barcodes (these are the barcodes which convey long-range

information, different from the sample index barcodes). While a subset of 10X barcodes will overlap

between two samples, the fraction of barcodes from reads mapping to a single organism should be

limited. We mapped reads from all linked-read samples against the uniquely identifiable p-crAssphage

genome[103]. Then we looked at the fraction of 10X barcodes that overlapped between samples. Samples

sequenced on different lanes typically had 0-30% 10X barcode overlap. Samples sequenced on the

same lane had 60-100% of barcode overlap in some cases. EC958[53] We set a threshold of 40% overlap

of barcode sets to call a comparison "swapped" and remove it from analysis. By counting reads believed

to be assigned to improper samples because of barcode swapping, we estimate the rate in our linked-

read data to be 0.1-0.2%.

While this rate may seem small, at high sequencing depth and with abundant organisms, it

quickly results in enough reads being swapped to assemble a genome or conduct an inStrain

comparison. Indeed, we found cases where multiple species (instead of the single species believed to be

the result of transmission events) were shared between linked-read samples sequenced on the same

lane that were likely the result of barcode swapping.

We also attempted to measure the degree of barcode swapping in dual-indexed lanes of short

read Illumina sequencing. Using the uniquely identifiable p-crAssphage genome as a marker for

swapping, we observed roughly 0.5% of sequencing reads swapped between samples on the same lane

that shared one index sequence. Samples on the lane that shared no sequencing indices often had p-

crAssphage below 1e-5%. Simple relative abundance metrics cannot distinguish between barcode

swapping and a true difference in abundance between samples. However, even with the 0.5% rate of

swapping, we regularly observed >5x coverage of the p-crAssphage genome in what we believe to be

the truly negative samples, and the resulting inStrain comparisons revealed sufficient paired genome

coverage and 100% popANI. We never observed identical p-crAssphage genomes between samples

from different patients sequenced with unique dual indices or on different lanes.

An example of p-crAssphage relative abundance measured with Kraken2 in a single lane of

sequencing is shown in the figure below. Here, we believe the sample 11713_98 in blue is a "true

positive" for p-crAssphage. While measured abundance in the other samples is likely some combination

of true abundance and barcode swapping, the separation between samples that share one or zero index

sequences is clear. For short-read sequencing samples, we know which pairs of samples share one of

two index sequences and have the possibility of being impacted by swapping. We cannot estimate the

impact of barcode swapping like was done for linked-read datasets. We simply eliminated all

comparisons where two samples had the possibility of barcode swapping, and all comparisons that could

be affected by "secondary" swapping, where the samples were not directly affected, but an interaction

between other samples from the two patients could cause false positives. While this filtering may discard

legitimate transmission events, we believe it is necessary to lower the number of false positives.

Previous DNA extraction and short-read sequencing efforts did not follow the randomization

constraints above and we cannot guarantee that laboratory contamination did not happen at some point

in the process. However, we note that cases of laboratory contamination or barcode swapping would

result in the entire microbiome composition of one sample being transferred to another. After our

stringent filters, we only discovered one case where patients shared two separate species. As these

were both *Lactobacillus* species, our hypothesis about probiotic consumption is a possible explanation.

Figure S1: Analysis of hospital geography.

a) Layout of rooms in the HCT ward. Room numbers are indicated and double occupancy rooms are under-lined.

b) Network view of patients who were roommates for at least 24 hours. Each node represents a single patient, colored according to if they have a banked stool sample or metagenomic sequencing data present. Edges are drawn between patients who were roommates, and edge width represents the length of overlap in the same room.

c) Histogram of the number of rooms patients occupied for at least 24 hours.

d) Histogram of the number of unique roommates patients had for at least 24 hours.

Figure S2: Antibiotic resistance genes detected. In each panel, samples are rows and resistance genes are columns. Samples are ordered and clades are highlighted corresponding to the respective figure in the main text. Cells are colored whether the gene was detected in the respective MAG from the sample, or just in the metagenome (indicating it may be on a plasmid).

a) Beta-lactamase genes detected in *E. coli* samples from Figure 2. The *gyrA* gene was detected with the CARD protein variant model, which requires a genetic variant conveying resistance in addition to the presence of the gene.

b) Vancomycin resistance genes of the *vanA* operon detected in *E. faecium* in samples from Figure 3.

Figure S3: Distribution of popANI values comparing samples from the same or different patients. Distributions are split by species and the most common 25 species are shown. While in many cases the two distributions overlap, very rarely did popANI values comparing samples from different patients exceed the 99.999% transmission threshold. Comparisons with <99.5% popANI are omitted from the figure for clarity.

Figure S4: InStrain analysis of the five most common species in external datasets where transmission is expected to occur. Distributions of popANI values are separated based on the individuals the samples came from, with putative transmission events contained in the far right panel.
a) Metagenomic sequencing datasets from mother-infant pairs[18]. The maximum popANI value obtained when comparing samples from different families was 99.995%.
b) Metagenomic sequencing datasets from fecal microbiota transplantation donors and recipients[67]. The maximum popANI value obtained comparing samples from individuals not related by FMT was 99.998%.

Figure S5: *Enterococcus faecium* (a) and *Escherichia coli* (b) strains compared to external datasets, including hospitalized adult and pediatric HCT patients, hospitalized infants and vancomycin-resistant *E. faecium* isolates[3,69-73]. Panels are separated according to whether comparisons were made within the data in this manuscript (Bhatt-Bhatt), between our data and external data (Bhatt-SRA) or within external data (SRA-SRA).

Figure S6: Dotplots showing pairwise alignment of MAGs in cases of putative transmission of the given species. Blue lines along the diagonal indicate 1-1 homology between the two sequences. Green lines indicate inversions that are likely the result of assembly or binning errors.

a) *E. faecium* MAGs from patients 11342 and 11349, corresponding to figure 4a.

b) *E. faecium* MAGs from patients 11575 and 11568, corresponding to figure 4b.

c) *E. faecium* MAGs from patients 11605 and 11673, corresponding to figure 4c.

d) *H. hathewayi* MAGs from patients 11639 and 11662, corresponding to figure 5a.

e) *A. muciniphila* MAGs from patients 11742 and 11647 corresponding to figure 5b.

Figure S7: Antibiotic prescription and taxonomic composition of patients with nearly identical *Enterococcus faecium* strains. *E. faecium* abundance is shown in blue and indicated with text. Other taxa are shown in grey. All dates are relative to HCT for the particular patient. Approximate dates of BSI are shown with red symbols. Circle: *Klebsiella pneumoniae*, X: *Enterococcus faecium*, triangle: *Escherichia coli.*

Figure S8: Antibiotic prescription and taxonomic composition of patients with nearly identical *Hungatella hathewayi* (shown in orange) or *Akkermansia muciniphila* (shown in green) strains. Other taxa are shown in grey. All dates are relative to HCT for the particular patient. Approximate dates of BSI are shown with red symbols. Circle: *Streptococcus mitis*, X: *Klebsiella pneumoniae.*

Figure S7: Antibiotic prescription and taxonomic composition of patients with nearly identical *Lactobacillus rhamnosus* strains. *L. rhamnosus* abundance is shown in purple and indicated with text. Other taxa are shown in grey. All dates are relative to HCT for the particular patient.
