## 20 Abstract

21 Diarrheal disease, a major cause of morbidity and mortality in dairy calves, is strongly associated with the  
22 health and composition of the gut microbiome. *Clostridioides difficile* is an opportunistic pathogen that  
23 proliferates and can produce enterotoxins when the host experiences gut dysbiosis. However, even  
24 asymptomatic colonization with *C. difficile* can be associated with differing degrees of microbiome  
25 disruption in a range of species, including people, swine, and dogs. Little is known about the interaction  
26 between *C. difficile* and the gut microbiome in dairy calves. In this study, we sought to define microbial  
27 features associated with *C. difficile* colonization in pre-weaned dairy calves less than 2 weeks of age. We  
28 characterized the fecal microbiota of 80 calves from 23 different farms using 16S rRNA sequencing and  
29 compared the microbiota of *C. difficile*-positive (n=24) and *C. difficile*-negative calves (n=56). Farm  
30 appeared to be the greatest source of variability in the gut microbiota. When controlling for calf age, diet,  
31 and farm location, there was no significant difference in Shannon alpha diversity ( $P=0.50$ ) or in weighted  
32 UniFrac beta diversity ( $P=0.19$ ) between *C. difficile*-positive and -negative calves. However, there was a  
33 significant difference in beta diversity as assessed using Bray-Curtiss diversity ( $P=0.0077$ ), and *C. difficile*-  
34 positive calves had significantly increased levels of *Ruminococcus (gnavus group)* (Adj.  $P=0.052$ ),  
35 *Lachnospirillum* (Adj.  $P=0.060$ ), *Butyrivibrio* (Adj.  $P=0.060$ ), and *Clostridium sensu stricto 2* compared  
36 to *C. difficile*-negative calves. Additionally, *C. difficile*-positive calves had fewer microbial co-occurrences  
37 than *C. difficile*-negative calves, indicating reduced bacterial synergies. Thus, while *C. difficile* colonization  
38 alone is not associated with dysbiosis and is therefore unlikely to result in an increased likelihood of  
39 diarrhea in dairy calves, it may be associated with a more disrupted microbiota.

40

## 41 Introduction

42 Infectious diarrheal disease is one of the main causes of mortality in dairy calves (1, 2), and calves  
43 less than 30 days of age are at highest risk of developing diarrhea (3, 4). Studies have shown that gut  
44 microbial composition is associated with gut health and the likelihood of diarrhea: reductions in microbial  
45 diversity are associated with an increased incidence of diarrhea (5), and the colonization of the calf gut  
46 with beneficial bacteria along with the decreased colonization of potential pathogens decreases the  
47 likelihood of calf diarrhea (6).

48 *Clostridioides difficile* is a spore-forming anaerobic, gram-positive bacillus that is a significant  
49 enteric pathogen in many species of animals. Colonization with *C. difficile* has been shown to be  
50 associated with reduced gut microbial diversity and increased colonization of pathogenic bacteria in  
51 people (7, 8), and we recently demonstrated a similar association in puppies (9). Dairy calves, like the  
52 neonates of other species, are colonized with *C. difficile* at high rates, with reported prevalences ranging  
53 from 28-56% (10, 11). While there is some evidence that infection with *C. difficile* can result in diarrhea in  
54 calves (12), the effect of the asymptomatic colonization of calves on the gut microbiome is unknown.  
55 Given the crucial role of the gut microbiome in providing colonization resistance against pathogens that  
56 cause diarrhea (13, 14), a better understanding of the effect of pathogens such as *C. difficile* on the calf  
57 gut microbiome is needed. The goal of this study was thus to define the gut microbiota features  
58 associated with *C. difficile* colonization in dairy calves and to define the effects of calf age, diet, and farm  
59 on the risk of colonization.

60

## 61 Methods

62 Sample collection: Fecal samples were manually collected from up to five randomly selected healthy  
63 calves less than two weeks of age from each of 23 dairy farms in Pennsylvania, Maryland and Delaware.

64 This study was approved by the Institutional Animal Care and Use Committee of the University of  
65 Pennsylvania.

66

67 Detection of *C. difficile*:

68 Individual fecal samples were tested for *C. difficile* using the Xpert *C. difficile* assay (Xpert CD  
69 assay; Cepheid, Sunnyvale, CA, USA) according to the manufacturer's instructions. This assay detects the  
70 cytotoxin gene (*tcdB*) and binary toxin genes (*cdtA* and *cdtB*). Additionally, the assay has a callout for  
71 ribotype NAP1/B1/027.

72 To rule out the possibility of colonization with non-toxigenic *C. difficile*, pooled fecal samples from  
73 each farm were also submitted for anaerobic culture. Briefly, 0.5 g of formed fecal sample was mixed with  
74 0.5 ml of 100% ethanol. The mixture remained for 60 minutes at room temperature before being  
75 inoculated on Cycloserine-cefoxitin fructose modified agar (CCFA) (Remel™) or *Clostridium difficile*  
76 Selective Agar (BBL™) and Columbia CNA agar (Thermo Fisher Scientific Remel Products). Inoculated  
77 plates and broth were incubated in BD Gas-Pak™ EZ container systems with BD BBL™ CO2 generators and  
78 BD BBL™ Gas Pak™ anaerobic CO2 indicators (Franklin Lakes, NJ) at 36°C ± 2°C under anaerobic growth  
79 conditions for seven days and checked for growth every other day. Suspect colonies were identified and  
80 isolated. Isolates were confirmed to be *C. difficile* by Maldi-TOF identification and/or RapID ANA II System  
81 (Thermo Fisher Scientific Remel Products).

82

83 16S rRNA sequencing

84 DNA was extracted from fecal samples using Qiagen PowerSoil DNA extraction kit. 16S rRNA sequencing  
85 was performed as described previously (9, 15). Briefly, the V4 region of the 16S rRNA gene was amplified  
86 using PCR, which was performed using Accuprime Pfx Supermix and custom primers for 30 cycles (15).  
87 PicoGreen quantification was used to normalize post-PCR products and AMPureXP beads were used to

88 clean the combined pools. Libraries were quantified and sized using a Qubit 2.0 and TapeStation 4200,  
89 respectively. 250bp paired-end sequencing was performed using an Illumina MiSeq.

90

#### 91 Sequence data processing using QIIME2

92 The QIIME2 pipeline (16) was used to process and analyze 16S sequencing data. Samples were  
93 demultiplexed using q2-demux and denoised using Dada2 (17). Sequences were aligned using mafft (18)  
94 and phylogenetic trees were reconstructed using fasttree (19). Shannon alpha diversity, weighted UniFrac  
95 and Bray-Curtis beta diversity metrics were estimated using q2-core-metrics-diversity after samples were  
96 rarefied to 1941 reads per sample, and p-values were adjusted for multiple hypothesis testing using  
97 Benjamini-Hochberg (B-H) false discovery rate (FDR) corrections (20). Taxonomy was assigned to  
98 sequences using q2-feature-classifier classify-sklearn (21) against the Silva reference database (22). Taxa  
99 were collapsed to the genus level, when possible. OTUs with less than 1% average relative abundance  
100 across all samples were removed.

101

#### 102 Correlation analysis and differential feature selection

103 The correlation between *C. difficile* culture status and Shannon alpha diversity was determined  
104 using a linear mixed effects model as implemented in the lme4 package (23) in R where age was  
105 controlled for as a fixed effect and with farm and diet as random effects. The correlation between *C.*  
106 *difficile* culture status on gut microbiota beta diversity was determined using PERMANOVA as  
107 implemented in the vegan package (24) in R controlling for age, farm, and diet. Principal coordinate  
108 analyses were performed using the phyloseq package in R (25). Differentially-abundant taxa were  
109 determined using LDA Effect Size (LEfSe) (26) and Analysis of Composition of microbiomes (ANCOM), and  
110 p-values were adjusted for multiple hypothesis testing using B-H FDR corrections in R. The Dice index (27)

111 was used to determine the co-occurrence of bacterial genera. Boxplots and LEfSe plots were visualized  
112 using ggplot2 (28) and ggthemes.

113

## 114 Results:

### 115 Subject characteristics and *C. difficile* status

116 Fecal samples were collected from a total of 92 Holstein calves from 23 farms. All calves appeared  
117 systemically healthy at the time of sampling and none had received antimicrobial therapy. The mean (SD)  
118 age of the calves was 7.0 (5.0) days. Thirty-six (35.6%) calves were fed waste milk, while the remaining  
119 calves were fed either colostrum or whole milk.

120 *C. difficile* was detected by qPCR in 28 calves (30.4%, 95% CI 21.2-40.9%) (**Fig. 1**). Of the 28  
121 samples that were positive for *C. difficile* on qPCR, 1 (3.6%) was positive for Toxin B only, 14 (50%) were  
122 positive for binary toxin only, and 13 (46.4%) were positive for both Toxin B and the binary toxin. None of  
123 the organisms were identified as the NAP1/B1/027 ribotype. On 14 farms, there were both *C. difficile*-  
124 positive and *C. difficile*-negative calves, whereas on the remaining farms, all of the calves were *C. difficile*-  
125 negative. There were no farms where all samples were qPCR-negative but the pooled sample was culture-  
126 positive. Neither calf age nor feeding of waste milk were significantly associated with the likelihood of  
127 detecting *C. difficile* among the calves (OR=1.01, p=0.805 and OR=0.71, p=0.493, respectively) (**Fig. 1**).

128

### 129 Effect of *C. difficile* status on microbiota diversity

130 Microbiota community structure of 87 calf fecal samples was assessed by sequencing and analyzing the  
131 V4 region of the 16S rRNA gene. Three samples were dropped from subsequent analyses because of low  
132 coverage and four additional samples were dropped because there was not enough sample for qPCR

133 analysis. Among the 80 remaining samples, 24 were positive for *C. difficile* by qPCR and 56 were negative  
134 (Fig 1).

135 The relationship between *C. difficile* infection and microbial diversity of the gut microbiota was  
136 assessed. Since calves ranged in age, diet, and farm location, a linear mixed effects model was performed  
137 to assess the relationship between *C. difficile* infection and alpha diversity by setting age as a fixed  
138 variable and farm and feeding type as random-effect variables. The association between *C. difficile* status  
139 and Shannon alpha diversity was not significant ( $P=0.50$ ) as determined by ANOVA when controlling for  
140 age, diet, and farm location (Fig. 2). PERMANOVA was then used to test associations between *C. difficile*  
141 infection status and beta diversity of the gut microbiome. Farm location alone explained most of the  
142 variation in gut microbiota composition across samples using both Bray-Curtis ( $P=1e-4$ ;  $R^2=0.43$ ) and  
143 weighted UniFrac ( $P=1e-4$ ;  $R^2=0.46$ ) beta diversity metrics (Fig. 3, Fig. 4). Age and diet were not  
144 significantly associated with gut microbiota composition after controlling for farm ( $P>0.1$ ). After  
145 controlling for farm, age, and diet, *C. difficile* status was significantly associated with Bray-Curtis beta  
146 diversity ( $P=0.0077$ ;  $R^2=0.023$ ), explaining 2.3% of the variation in gut microbiota composition. *C. difficile*  
147 status was not significantly associated with weighted UniFrac beta diversity ( $P=0.1934$ ;  $R^2=0.013$ ) after  
148 controlling for farm, age, and diet (Fig. 3). Some clustering by farm and by *C. difficile* status within farms  
149 was apparent on principal coordinate analysis (Fig. 4).

150

#### 151 Bacterial community composition

152 Since *C. difficile* status was associated with differences in gut microbiota composition as  
153 determined by beta diversity, we next sought to determine the specific bacterial taxa associated with *C.*  
154 *difficile* infection. At the phylum level, there were no significant differences between bacterial  
155 communities in *C. difficile*-positive and -negative samples (Fig. 5). The Firmicutes phylum predominated

156 (57.1% in *C. difficile*-positive samples and 51.4% in *C. difficile*-negative samples), followed by  
157 Proteobacteria (17.1% and 24.3%), Bacteroides (16.7% and 11.5%), and Actinobacteria (8.1% and 9.7%).

158 At the genus level, the only significant difference between *C. difficile*-positive and -negative  
159 samples by ANCOM occurred for Clostridioides. When considering LEfSe analysis, there were four taxa  
160 among the 19 taxa with average relative abundance greater than 1% that were statistically significantly  
161 (*Adj. P*<0.1) associated with *C. difficile* status. *Ruminococcus (gnavus group)* (*Adj. P*=0.052),  
162 *Lachnoclostridium* (*Adj. P*=0.060), *Butyricoccus* (*Adj. P*=0.060), and *Clostridium (sensu stricto 2)* (*Adj.*  
163 *P*=0.064) were all found in higher abundance among *C. difficile*-positive calves than in *C. difficile*-negative  
164 calves (**Fig. 6**). While not statistically significantly different among the two groups, levels of *Lactobacillus*,  
165 *Megasphaera*, and *Streptococcus* were increased in *C. difficile*-positive samples, while levels of *Blautia*,  
166 *Fusobacterium*, *Tyzzereella*, *Enterobacteriaceae*, *Fecalibacterium*, *Dorea*, and *Collinsella* were decreased.

167 Because microbes work synergistically in the gut, we sought to determine the associative  
168 interactions between bacteria using a co-occurrence analysis based on the Dice index. When considering  
169 all levels of abundance, more co-occurrence of bacterial taxa appeared in the *C. difficile*-negative  
170 samples, with 1,488 (65.5%) highly (correlation coefficient>0.6) and significantly (*p*<0.01) correlated  
171 genera pairs. Most co-occurrences were among members of the Firmicutes phylum (1295, 55.0%).  
172 However, members of Firmicutes also showed high co-occurrence with Actinobacteria and Bacteroidetes.  
173 In the *C. difficile*-positive samples, there were fewer highly co-occurring genera, with 830 (73.3%) highly  
174 and significantly correlated genera pairs. When only considering taxa with levels of abundance greater  
175 than 1%, there were no significant differences in co-occurrence patterns (**Fig. 7**).

176

177 **Discussion:**

178 In this study, we characterized microbial features associated with asymptomatic *C. difficile* colonization in  
179 dairy calves. While the role of *C. difficile* in calf diarrhea remains equivocal (12), exploring the association  
180 between this pathogen and the gut microbiome is important for understanding factors that affect gut  
181 health and enteric diseases. While a number of studies have examined the epidemiology of *C. difficile* in  
182 animals of veterinary importance, the association between the microbiome and *C. difficile* is only  
183 beginning to be explored in dogs (9), horses (29), and pigs (30). Notably, in pigs, the presence of *C.*  
184 *difficile* is associated with significantly reduced microbial diversity and increased levels of  
185 enteropathogens associated with neonatal diarrhea (30).

186 Unsurprisingly, as in other studies (31-33), we found that the farm was the source of most of the  
187 variation in gut microbiota composition. However, even among calves from the same farm, there was  
188 variability in both *C. difficile* colonization status and gut microbial diversity, suggesting, as have other  
189 studies (32, 34), that the farm environment is only one of many competing influencers of the developing  
190 calf gut microbiome. Neither diet nor age were significantly associated with microbiome composition  
191 when controlling for farm, but this is almost certainly due to the small sample size within each farm and  
192 the lack of within-farm variability in factors such as diet. When controlling for age, diet, and farm, we  
193 noted a significant difference in beta diversity between *C. difficile*-positive and *C. difficile*-negative fecal  
194 samples when considering the Bray-Curtis metric but not the unweighted UniFrac metric. While both of  
195 these metrics are weighted by abundance, the latter metric weighs diversity by phylogenetic relationship.  
196 Thus the lack of a significant difference when considering the weighted UniFrac metric suggests that,  
197 while there may be a significant difference in the composition of microbial communities, the  
198 differentially-abundant microbes might be closely related to one another. Indeed, all four genera  
199 identified as differentially-abundant by LEfSe are members of the *Clostridia* class, with two belonging to  
200 the *Clostrideaceae* family.

201

202           While the lack of a consistent difference in alpha and beta diversity between *C. difficile*-positive  
203 and *C. difficile*-negative samples suggests that the effect of *C. difficile* colonization on the gut microbiome  
204 of calves is minimal, other findings suggest that *C. difficile* colonization is associated with a more  
205 disrupted – but not dysbiotic – gut microbiome. *C. difficile* colonization was preferentially associated with  
206 certain bacterial taxa of the class *Clostridia* that do have associations with dysbiosis. Notably, the  
207 overrepresentation of *Ruminococcus gnavus* and *Lachnospiridia* in *C. difficile*-positive calves point to the  
208 possibility of an underlying imbalance in the gut microbiome. *R. gnavus*, a Gram-positive anaerobe that is  
209 typically found in the gut of over 90% of healthy people at abundances less than 0.1%, has been robustly  
210 associated with inflammatory dysbiotic conditions such as Crohn’s disease (35-37), allergic airway disease  
211 (38), eczema (39), and spondyloarthritis (40). Dramatic blooms of *R. gnavus* occur in patients  
212 experiencing flares of inflammatory bowel disease, with abundance levels that can peak at 69% of the gut  
213 microbiota (37). Notably, this association appears to occur across species, as the gut microbiomes of both  
214 infants (7) and piglets (30) colonized with *C. difficile* also had increased levels of *Ruminococcus* species,  
215 including *R. gnavus*. Additionally, *Ruminococcus* was one of six bacterial genera in the gut microbiome  
216 that predicted the occurrence of diarrhea in calves in another study (41). The increased relative  
217 abundance of *Clostridium sensu stricto* and *Lachnospiridia* in *C. difficile*-positive calves also points to the  
218 possibility of a less healthy gut environment. An increased relative abundance of *Clostridium sensu stricto*,  
219 which was also found in *C. difficile*-positive piglets (30), was associated with food allergies in infants (42)  
220 and diarrhea in piglets (43). A tentative association between increased levels of *Lachnospiridia* and  
221 neoplasia of the gastrointestinal tract has been identified in people (44, 45). While no such association  
222 has been explored in animals, the overrepresentation of this taxon in *C. difficile*-positive calves may be  
223 the result of a more disrupted gut microbiota. However, it is also important to note that the increased  
224 relative abundance of these taxa were only detected using LEfSe analysis and not ANCOM, which suggests  
225 that the association is likely relatively weak.

226 Certain bacterial taxa that predominate in healthy calves were found at lower (but not  
227 statistically significantly lower) levels in *C. difficile*-positive calves. Notably, *Fecalibacterium*, *Dorea*,  
228 *Enterobacteriaceae* and *Collinsella* are among the most abundant genera in healthy pre-weaned calves  
229 (46-49), and some of these taxa provide colonization resistance against *C. difficile* (8, 50). Their decreased  
230 relative abundance in *C. difficile*-positive calves is thus also reflective of a more disrupted gut  
231 microbiome. The decreased co-occurrence of bacterial taxa in *C. difficile*-positive calves compared to *C.*  
232 *difficile*-negative calves when considering all levels of abundance may also corroborate the notion of a  
233 slightly more disrupted gut microbiome in colonized calves. However, because the difference occurred  
234 only in rare taxa (abundance < 1%), this difference appears unlikely to result in dysbiosis.

235 One finding that is in contradiction to the general trend of *C. difficile* colonization being  
236 associated with disrupted microbiota is the increased abundance of *Butyricoccus* in *C. difficile*-positive  
237 calves. In people, *Butyricoccus* species of bacteria are generally found in *lower* levels in people colonized  
238 with *C. difficile* (51) or diagnosed with inflammatory bowel disease (52, 53), and at higher levels in healthy  
239 dairy calves compared to calves with diarrhea (48, 54). It is unclear why they were found at higher levels  
240 in *C. difficile*-positive calves compared to *C. difficile*-negative calves. *Butyricoccus* bacteria produce  
241 butyrate, an important nutrient source for gut colonocytes and a beneficial driver of the immunological  
242 maturation of the gut mucosa (55), and account for one of the most abundant genera in dairy calves 7  
243 days after birth (56). The differential levels in calves compared to people with enteric disease may be due  
244 to species-specific patterns of development of the neonatal gut. Species-specific differences may also  
245 explain why *C. difficile* colonized calves had higher levels of *Clostridial* genera but colonized puppies had  
246 lower levels (9). While rumen development is minimal in pre-weaned calves, they are nevertheless  
247 ruminants and thus have fundamentally different enteric physiologies and microbial ecologies compared  
248 to true monogastric species.

249           Some limitations apply to this study. Heterogeneity in farm location, age, and diet across all of the  
250 sampled calves may have obscured features of the microbiome that would otherwise have been  
251 associated with *C. difficile* colonization. The cross-sectional nature of the study also precludes the  
252 possibility of drawing any conclusions about the duration of colonization and its effect on an already  
253 rapidly evolving gut microbiome. Finally, because we used qPCR to detect *C. difficile* in the calves' feces,  
254 we were unable to detect non-toxigenic *C. difficile*. It is likely that toxigenic and non-toxigenic *C. difficile*  
255 occupy a similar ecological niche and compete for similar resources within the gut microbiota; thus the  
256 presence of non-toxigenic *C. difficile* could account for the lack of a significant difference in alpha  
257 diversity and microbial composition between *C. difficile*-positive and *C. difficile*-negative calves. However,  
258 we believe this possibility to be unlikely, as there were no samples that were negative on qPCR but came  
259 from a farm where the pooled sample was positive for *C. difficile* on anaerobic culture.

260

## 261 **Conclusion**

262 The greatest source of variability in the calf microbiome was the farm, and there were few or no  
263 statistically significant differences in alpha or beta diversity between *C. difficile*-positive and *C. difficile*-  
264 negative calves. *C. difficile* colonization thus does not appear to be associated with dysbiosis or with  
265 increased levels of enteropathogens that cause calf diarrhea. However, microbial community signatures –  
266 including increased relative abundance of bacterial taxa that have been associated with dysbiotic  
267 states in other species and in people - suggest that the microbiota of *C. difficile*-colonized calves is more  
268 disrupted than that of non-colonized calves.
