23 **Abstract**

24 Infectious pancreatic necrosis (IPN) is an important viral disease of salmonids that can affect fish
25 during various life cycles. In Atlantic salmon, selecting for genetically resistant animals against
26 IPN has been one of the most highly praised success stories in the history of fish breeding. The
27 findings that resistance against this disease has a significant genetic component, which is mainly
28 controlled by variations in a single gene, has helped to reduce the IPN outbreaks over the past
29 decade to a great extent. In this paper, we present the identification of a new isolate of the IPN
30 virus, from a field outbreak, that had caused mortality, even in the genetically resistant animals.
31 We recovered and assembled the full-length genome of this virus, following deep-sequencing of
32 an infected tissue. The comparative sequence analysis revealed that for the critical amino acid
33 motifs, previously found to be associated with the degree of virulence, the newly identified isolate
34 is similar to the virus's avirulent form. However, we detected a set of deduced amino acid residues,
35 particularly in the hypervariable region of the polyprotein, that collectively are unique to this strain
36 compared to all other reference sequences assessed in this study. We suggest that these mutations
37 have likely equipped the virus with the capacity to escape the host defence mechanism more
38 efficiently, even in the genetically deemed IPN resistant animals.

43 Locus (QTL); Atlantic salmon;

44 **Introduction**

45 Infectious pancreatic necrosis (IPN) is one of the leading viral diseases of the Norwegian farmed
46 Atlantic salmon (*Salmo salar* L.). The disease was first reported in 1941, following an outbreak in
47 brook trout (*Salvelinus fontinalis* L.) in Canada (M'Gonigle, 1941). Further, the characterisation
48 of the causative agent, the IPN virus (IPNV), was performed in 1960 (Wolf et al., 1960). In
49 Norway, the virus was first isolated in 1975 from freshwater rainbow trout (*Oncorhynchus mykiss*
50 L.) (Hastein and Krogsrud, 1976) and was designated as a notifiable disease from 1991 till 2008
51 (Sommerset et al., 2020). The virus can infect Atlantic salmon during all of its developmental
52 stages, but the fish are especially susceptible as fry, during start-feeding, and post-smolts, soon
53 after transfer to seawater (Roberts and Pearson, 2005; Sommerset et al., 2020). As suggested by
54 the name, the pancreas is the primary target tissue of IPNV. However, the liver has also been
55 shown to be one of the key organs affected by this virus (Ellis et al., 2010; Munang'Andu et al.,
56 2013). In addition to significant economic losses, this disease is a concern for animal welfare, as
57 survivors following infection can continue to infect naïve fish (Roberts and Pearson, 2005).

58 IPNV is a double-stranded RNA virus that belongs to the *Birnaviridae* family. A characteristic
59 feature of the birnaviruses is their possession of a bi-segmented genome (i.e., A and B segments),
60 contained within a non-enveloped, icosahedral capsid (Dobos and Roberts, 1983; Duncan et al.,
61 1987; Duncan and Dobos, 1986). The smaller genomic segment, the B segment, is about 2.5 kb in
62 size and consists of a single open reading frame (ORF), encoding an RNA-dependent, RNA
63 polymerase VP1 (approximately 90 kDa) (Duncan et al., 1987; Duncan and Dobos, 1986). The A-
64 segment is approximately 3 kb, and it contains two, partially overlapping ORFs (Duncan and
65 Dobos, 1986). The first ORF, encodes VP5, a small, cysteine-rich, non-structural protein of about
66 17 kDa. A precursor polyprotein (NH₂-preVP2-NS VP4 protease-VP3-COOH) of approximately

67 106 kDa constitutes the second and the larger ORF. The encoded VP4 protease cleavages the
68 polyprotein into its two main components, the preVP2 and VP3. The preVP2 further matures to
69 become VP2 and forms the outer capsid protein, containing the neutralizing epitopes and sites that
70 facilitate cell attachment (Dopazo, 2020; Heppell et al., 1995b). The VP3 is the inner capsid protein
71 (Duncan et al., 1987; Duncan and Dobos, 1986) but also in association with the VP1 it seems to
72 be involved in viral packaging and replication (Tacken et al., 2002).

73 Based on cross-neutralizing tests, the aquatic birnaviruses are broadly divided into two main
74 serogroups, A and B (Hill and Way, 1995). The serogroup A comprises of nine different serotypes,
75 A₁-A₉. Most of the isolates from the USA fall within the A₁ serotype (West Buxton; WB), the A₂-
76 A₅ include mainly the European isolates (A₂ (Spjarup; Sp), A₃ (Abild; Ab), A₄ (Hecht, He) and A₅
77 (Te)), and A₆-A₉ are predominantly variants from Canada (A₆ (Canada 1; C1), A₇ (Canada 2; C2),
78 A₈ (Canada 3; C3) and A₉ (Jasper)) (Blake et al., 2001; Hill and Way, 1995). The serogroup B
79 consists of only one serotype (B₁ (Tellinavirus; TV1)) that is non-pathogenic in fish. Based on the
80 analysis of variations in the nucleotide and the deduced amino acids of the VP2, Blake et al. (2001)
81 later proposed that aquatic birnaviruses constitute six major genogroups. These groups correspond
82 relatively well with the geographical origins and serological classifications previously suggested.
83 According to this classification, WB and the Jasper strains constitute genogroup 1, the A₃ serotype
84 forms genogroup 2, C1 and Te make genogroup 3, the two Canadian strains, C2 and C3 form
85 genogroup 4, all European isolates of serotype A₂ cluster into genogroup 5 and the He strain
86 constitutes genogroup 6 (Blake et al., 2001). A seventh genogroup was also suggested based on
87 isolates recovered from Japanese aquatic sources (Nishizawa et al., 2005).

88 Despite extensive vaccination efforts, disinfection and targeted breeding programs, IPN outbreaks
89 remains a concern in farmed Atlantic salmon. Related mortalities can be substantial and in part,

90 can be a function of the genetic makeup of the host (Guy et al., 2006; Houston et al., 2008; Moen
91 et al., 2009), management and environmental factors (Jarp et al., 1995; Sundh et al., 2009), and
92 the strain and specific genetic variations carried by the virus (Skjesol et al., 2011; Song et al.,
93 2005). There are ample examples of isolates, belonging to the same serotype, to cause different
94 degrees of virulence in the host (e.g., Bruslind and Reno, 2000; Santi et al., 2004; Shivappa et al.,
95 2004), and indeed, there have been many studies, investigating the molecular basis of IPNV
96 virulence in Atlantic salmon (e.g., Mutoloki et al., 2016; Santi et al., 2004, 2005; Skjesol et al.,
97 2011; Song et al., 2005). Although the genetic details of such processes are not yet fully
98 understood, most studies speculated, and chiefly investigated, the genetic variations in segment A
99 concerning the degree of virulence in IPNV. In particular, specific amino acid motifs in the VP2
100 of the polyprotein have been suggested to be most prevalent and in association with the virulent
101 forms of the pathogen (Bruslind and Reno, 2000; Munang'andu et al., 2016; Mutoloki et al., 2016;
102 Santi et al., 2004; Shivappa et al., 2004; Song et al., 2005). Variations in the amino acid residues
103 in positions 217, 221 and 247 of the VP2 have been of particular focus (Dopazo, 2020; Julin et al.,
104 2013; Munang'andu et al., 2016; Mutoloki et al., 2016; Santi et al., 2004; Song et al., 2005).
105 Further, assessment of the recombinant viral strains, have indicated that the residue 217 of the VP2
106 might be the most crucial amino acid that can result in the loss or gain of virulence (e.g., Song et
107 al., 2005).

108 Despite concerns and economic losses due to infection by IPNV, increased resistance against this
109 virus through selective breeding is among the most remarkable success stories in the history of
110 aquaculture and salmon breeding in particular. The initial attempt to estimate the genetic
111 parameters controlling this trait, which was based on mortality in the field and controlled challenge
112 testing, had shown that resistance to IPNV has a significant and heritable genetic component (h^2)

113 of 0.17-0.62) (Kjøglum et al., 2008; Wetten et al., 2007). However, the breakthrough came with
114 the finding that resistance to IPNV is mainly controlled by variations in a single quantitative trait
115 locus (QTL) on chromosome 26 (Houston et al., 2008, 2010; Moen et al., 2009). Subsequent work
116 identified mutations in the epithelial cadherin gene (*cdh1*) as the causative genetic variation for
117 IPNV resistance in Atlantic salmon (Moen et al., 2015). Following the inclusion of this QTL into
118 the breeding programs in Norway, the industry witnessed a sharp decline in the number of IPN
119 outbreaks throughout the country, dropping from 223 to only 19 reported cases from 2009 to 2019
120 (Sommerset et al., 2020).

121 This paper reports the identification and whole-genome sequence assembly and analysis of a new
122 IPNV variant. The isolate was recovered from a field outbreak in West of Norway following
123 reported mortalities, due to an IPN infection, among QTL homozygous or heterozygous IPN
124 resistant fish. We describe the amino acid motifs that distinguish this isolate from other
125 phylogenetically related variants and suggest that these mutations are likely to play an essential
126 role in this isolate's pathogenicity.

127 **Materials and Methods**

128 **Field outbreak and sample collection**

129 In May of 2019, there was an IPN field outbreak in a Western region of Norway. The affected fish
130 were Atlantic salmon of the SalmoBreed strain, delivered as IPN QTL, all favourable homozygous
131 or heterozygous for the QTL locus (Houston et al., 2008; Moen et al., 2009). Fish were at the post-
132 smolt stage with an approximate average weight of about 700 – 800 gr at the time of the outbreak.
133 The reported mortality reached about 10%, a high percentage for field outbreak among QTL
134 carrying fish. The IPNV infection was identified following an inspection by the veterinary
135 authorities. The diagnosis was later validated by detection of the VP2 segment of the viral genome

136 using polymerase chain reaction (qRT-PCR) of the infected head-kidney and through
137 histopathological and immunohistochemical examinations of the liver and pancreatic tissues
138 (Figure 1A and B), all performed at the Fish Vet Group Norway (<http://fishvetgroup.no>)
139 (Supplementary Table 1). Tissues were fixed in a 4% formalin solution (4% formalin, 0.08M
140 sodium phosphate, pH 7.0), processed using Thermo Scientific Excelsior® and embedded in
141 Histowax with the aid of Tissue – Tek®, TEC 5 (Sakura) embedding system. The embedded
142 tissues were then sectioned at 1.5-2 µm using a Leica RM 2255 Microtome and stained with
143 Hematoxylin-Eosin (HE). The stained sections were scanned in an Aperio ScanScope AT Turbo
144 slide scanner and read using Aperio Image Scope (Leica Biosystems). The scans were examined
145 and scored in a blind fashion, i.e., without information about the animal's history. A clip from the
146 adipose fin was also sampled and stored in 95% ethanol for DNA extraction and genotyping of ten
147 fish, five moribund and five dead. We genotyped these fish for the genetic markers used to assign
148 individuals as QTL carrier (Houston et al., 2008; Moen et al., 2009, 2015), and confirmed all
149 animals carry IPN QTL.

150 **Transcriptome sequencing and viral genome assembly**

151 The head-kidney was collected from six infected fish (<http://fishvetgroup.no/pcr-2/#1452163253406-d81f6dce-bdf9>), all at a moribund state, and stored in RNALater® (Ambion).
152 Total RNA extraction was performed using the RNeasy® Plus mini kit (Qiagen). Nanodrop ND-
153 1000 Spectrophotometer (NanoDrop Technologies) was used to assess the concentration and
154 purity of the extracted genetic materials. The Norwegian Sequencing Centre performed library
155 construction and sequencing the total RNA on an Illumina HiSeq 4000 platform as paired-end (PE)
156 150 bp reads.

158 We first cleaned the sequence data by removing low-quality nucleotides and sequencing adapters
159 using Trimmomatic (v.0.36) (Bolger et al., 2014). The ribosomal RNA (rRNA) was then identified
160 through a similarity search against the SILVA rRNA database (Quast et al., 2013) and excluded
161 from subsequent analysis. The host-specific transcriptome was detected by aligning the remaining
162 reads against the Atlantic salmon reference genome assembly (ICSASG_v2) (Lien et al., 2016)
163 using TopHat (v.2.0.13) (Trapnell et al., 2009, 2012). The un-aligned reads were then blasted
164 against the IPNV reference assemblies (ASM397166v1, ASM397170v1, ASM397174v1,
165 ASM397168v1, ASM397172V1 and ViralMultiSegProj15024) by setting “task” as “megablast”,
166 “word size” to 7 and “expectation value threshold” to $1.00e^{-07}$. All the reads that aligned to the
167 IPNV reference sequences were extracted, pooled into a single sequence datafile per animal, and
168 then fed into Trinity (v.2.11.0) (Grabherr et al., 2011) with the default parameter settings to
169 construct assemblies.

170 **Comparative genomics and phylogenetic analysis**

171 We compared the assembled viral genomes to one another (Supplementary Tables 1 and 2), and
172 against various reference isolates, with different degrees of virulence (Dopazo, 2020; Julin et al.,
173 2013; Munang'andu et al., 2016; Mutoloki et al., 2016; Santi et al., 2004; Song et al., 2005) (Table
174 1) or strains representing different genogroups, as previously suggested (Blake et al., 2001) (Table
175 2). Further, we assessed the deduced amino acids of these isolates to any IPNV sequence in the
176 NCBI database with a complete polyprotein or VP1 information (Supplementary Files 1 and 2).
177 The sequences included 90 isolates with the full coding sequence for the polyprotein and 120 for
178 the VP1. Both, the nucleotide and amino acid alignments were performed using ClustalX (Larkin
179 et al., 2007) implemented in Unipro UGENE (v36.0) (Okonechnikov et al., 2012) or Muscle
180 (Edgar, 2004) implemented in Seqotron (v1.0.1) (Fourment and Holmes, 2016). Unipro UGENE

181 and Mega X (v10.1.7) (Kumar et al., 2018) were also used to assess sequence similarity, calculate
182 pair-wise distances for nucleotide and amino acid data, and to construct phylogenetic associations
183 using the neighbour-joining (NJ) method. To assess the confidence of node assignments, we
184 performed 1000 bootstrap replications.

185 **Results and Discussion**

186 **Transcriptome sequencing and genome assembly**

187 This paper describes the genomic features of IPNV isolates, responsible for a field outbreak in an
188 Atlantic salmon population. The post-mortem examination identified IPN infection as the chief
189 cause of mortality among all fish investigated. The histopathological and immunohistochemical
190 examinations (Figure 1A and B and Supplementary Table 1) and the viral genetic material detected
191 through qRT-PCR amplification (Supplementary Table 1) further confirmed earlier diagnosis. We
192 found that the genotypes of all animals examined in this study were consistent with an IPN resistant
193 animal (Houston et al., 2008; Moen et al., 2009, 2015). Further, assessment of the transcriptome
194 sequence data confirmed that all fish carried at least one favourable copy of the causal mutation in
195 the *cdh1* gene, conferring resistance against IPNV (Moen et al., 2015). The causal mutation, which
196 is in the form of a single nucleotide polymorphic (SNP) variation, is located in the protein-coding
197 sequence of *cdh1* (ssa26:15192533; C/T) and can change Proline (P) to Serine (S), with the former
198 amino acid found to be associated with the IPNV resistance (Moen et al., 2015). It is expected that
199 in a heterozygote fish, the favourable allele exhibit close to complete dominant effect in response
200 to the virus (Moen et al., 2015). Among the animals investigated in this study, three fish were
201 homozygous for the favourable allele (C/C), and the other three were heterozygous (C/T). The
202 extracted RNA was sequenced to high depth, with an average of 60 million PE reads per animal.
203 Following the rRNA's exclusion, more than 45 million PE reads per fish remained for the

204 assemblage of the host's viral genome and profiling gene expression. Together, the two segments
205 of the IPNV genome consist of about 5800 nucleotides. On average, we obtained 56-fold coverage
206 of the viral genome from each of the animals in our sequence data. Here, we refer to the assembled
207 viral genomes as BG_x_y, where x denotes the animal's id (1-6) and y refers to the viral genome's
208 specific segment (e.g., VP1 or polyprotein).

209 **Comparative sequence analysis of the polyprotein**

210 Comparative genomic analysis between the six assembled genomes revealed at least two different,
211 closely linked variants, caused the field outbreak in the population investigated (Figure 2A and B;
212 Supplementary Table 2A and B). The nucleotide sequences of the polyprotein are identical in four
213 of the assemblies (BG_1_polyprot to BG_4_polyprot) and contain nine polymorphic sites
214 compared to the other two assembled sequences (i.e., BG_5_polyprot and BG_6_polyprot). Two
215 of the polymorphisms are nonsynonymous, changing the amino acid residues in positions 47
216 (aspartate (D) to glutamate (E)) and 717 (lysine (K) to glutamine (Q)).

217 In a study, aiming to trace the IPNV infection signatures from hatcheries to the sea (Kristoffersen
218 et al., 2018), the authors have recovered a partial fragment of the polyprotein from an isolate
219 (accession number: MH562009), with very similar nucleotide sequence to the ones reported here.
220 Recently, in controlled infection challenge testing, the mortality induced by this isolate among
221 full-sib families was compared with a standard, virulent form of the virus (AY379740.1). While
222 the infection with the latter variant resulted in approximately 30% mortality, mainly among the
223 non-QTL fish, the former isolate caused more than 75% mortality, treating the QTL and non-QTL
224 fish alike (Ørpetveit et al. in preparation; <https://www.vetinst.no/nyheter/endinger-i-ipn-viruset-gjor-fisken-mer-utsatt-for-sykdom>,
225 <https://www.fishfarmingexpert.com/article/changes-in-ipn-virus-make-salmon-more-susceptible>,
226 <https://salmobreed.no/articles/benchmark-genetics->

227 [intensiverer-forskningen-pa-nytt-ipn-virus](#)). Comparison between the nucleotide sequences of this
228 isolate with our assembled genomes shows divergence ranging from 0.003-0.004 (Supplementary
229 Figure 1A). However, this isolate has deduced amino acid sequences identical to the translated
230 sequences from our first four assemblies (Supplementary Figure 1B), indicating that this variant
231 is likely to be the ancestral form and the other variants (i.e., BG_5_VP2 and BG_6_VP2) are more
232 recently derived. One of the main characteristics of RNA viruses is their high mutation rates,
233 mainly attributed to their lack of an effective proofreading activity. Therefore, finding different
234 sequence variants from the same outbreak might not be surprising, but it indeed is important, as it
235 will allow one to follow the trajectory of pathogen evolution through time and space.
236 Comparative assessment of the polyprotein nucleotide (data not shown) as well as the amino acid
237 sequence data with multiple reference strains (Figure 2A) shows our assemblies are most closely
238 related to the Sp serotype (genogroup 5). However, they also constitute a distinct group within this
239 serotype compared to Sp isolates assessed in this study (Figure 2A; Supplementary Figure 2A).
240 Several investigations have previously reported variations in some amino acid residues,
241 particularly in the VP2 of the polyprotein, to be associated with the degree of the IPNV virulence
242 (Bruslind and Reno, 2000; Munang'andu et al., 2016; Mutoloki et al., 2016; Santi et al., 2004;
243 Shivappa et al., 2004; Song et al., 2005). Interestingly, the amino acid motifs found in the six
244 assembled genomes in this study are mainly consistent with the virus's avirulent form (Table 1)
245 (Santi et al., 2004; Shivappa et al., 2004; Song et al., 2005). For instance, for the most critical
246 positions associated with the virulence, i.e., 217, 221 and 247 of the VP2, the amino acid residues
247 of our assembled genomes are proline (P), threonine (T) and alanine (A) (Table 1; Supplementary
248 File 1), while it is expected that in the virulent form, the corresponding residues to be T, A and T,
249 respectively (Mutoloki et al., 2016; Santi et al., 2004; Song et al., 2005). On the other hand, we

250 identified ten amino acid residues in the assembled genomes' polyprotein, that either exclusively
251 or with a disproportionate frequency are found in the reported isolates (Table 2; Supplementary
252 File 1). Nine of these sites are within the VP2, and one is located in the VP4. In the VP2, these
253 residues are all in proximity to one another, encompassing the hypervariable region (Blake et al.,
254 2001; Heppell et al., 1995b). Specifically, these residues are located in positions 245, 248, 252,
255 255, 257, 278, 282, 285, 321 (Table 2; Supplementary File 1). This data provides additional
256 support for the previously suggested notion that the amino acid motifs in the VP2 capsid protein
257 hypervariable region, might play an essential role in the degree of the virulence displayed between
258 different IPNV isolates (Bruslind and Reno, 2000; Skjesol et al., 2011). It is also likely that this
259 specific constellation of the amino acid residues reported in these isolates has helped the virus to
260 escape the host defence barrier, despite fish being regarded as resistant to IPNV. In the VP4, the
261 deduced amino acid residue, unique to the assembled isolates (Table 2; Supplementary File 1), is
262 located in position 585. The amino acid substitution is a glycine (G) residue, compared to the other
263 sequences investigated in this study, where they carry an aspartate (D) (Table 2).

264 **Comparative sequence analysis of VP5**

265 All assemblies contain the VP5, the partial overlapping, non-structural protein, of segment A.
266 Similar to the polyprotein, the phylogenetic analysis of the VP5, grouped the assemblies into two
267 distinct groups and further clustered them with the isolates from the Sp serotype (Figure 2B). The
268 two assembled groups differ in only one amino acid residue at position 90, with the first four
269 assemblies carrying an arginine (R) while the two other assemblies are having a glycine (G)
270 (Supplementary File 3). Sequence analysis of the deduced amino acids of VP5 did not reveal any
271 unique residue in the assembled isolates compared to all other sequences. Comparing to the other
272 Sp serotypes, however, the amino acid in position 98 differs between the isolates (Supplementary

273 File 3). At this position, all the investigated Sp isolates carry an R while in the assemblies, the
274 residue is tryptophan (W). It has been shown that the VP5's protein is generally produced during
275 the initial stages of replication (Heppell et al., 1995a), and at least in the Ab serotype, it seems that
276 this protein to be involved in anti-apoptotic functions (Hong and Wu, 2002). However, this
277 product's importance in viral growth or virulence has so far remained ambiguous (e.g., Julin et al.
278 2013; Dopazo 2020).

279 **Comparative sequence analysis of VP1**

280 The phylogenetic analysis of VP1 clustered the assemblies into three distinct clades
281 (Supplementary Figure 2B) with the amino acid variations in positions 119 (threonine (T) to
282 methionine (M)) and 701 (T to alanine (A) and serine (S)) (Supplementary File 2; Supplementary
283 Table 3A). The nucleotide sequence comparisons, shows a greater rate of divergence in the VP1
284 of the assemblies compared to those of the polyprotein, suggesting that the B segment of the
285 genome has a higher rate of nucleotide mutation (Supplementary Tables 1 and 2). Comparing the
286 deduced amino acid sequences of the assembled genomes to the VP1 section of 120 IPNV
287 sequences, further revealed only a single, almost unique residue in our isolates (Supplementary
288 File 2). The amino acid residue in position 656 of the assembled isolates is glutamate (E), while in
289 the majority of other strains, the amino acid is either aspartate (D) or alanine (A). The only other
290 isolates, carrying an E in this position, are two sequences recovered from Atlantic salmon
291 (KY548520) and Brown trout (*Salmo trutta* L.) (KY548519) in Finland following outbreaks
292 (Holopainen et al., 2017). However, it should be noted that so far, the role of VP1 in determining
293 the degree of IPNV virulence has remained ambiguous. For example, in a study conducted by Song
294 et al. (2005), through construction and comparative assessment of chimeric IPNV strains, the
295 authors suggested that VP1 is not involved in this pathogen's virulence. On the other hand, the data

296 reported by Shivappa et al. (2004), is suggestive that the amino acids on the B segment of the
297 genome in combination with specific residues in VP2, might help to modulate the magnitude of
298 virulence. Work in the infectious bursal disease virus (IBDV) has also shown that variations in the
299 amino acid residues of the VP1 can change the kinetics of viral replication and influence the virus's
300 virulence (Liu and Vakharia, 2004). VP1 interacts with VP3 to form VP1-VP3 complexes, and as
301 such, can affect various aspects of the virus biology, including its replication efficiency (Pedersen
302 et al., 2007; Tacken et al., 2002).

303 **Concluding remarks**

304 In light of the findings reported in this study, a key point worth noting is the importance of
305 understanding the genetic interactions between the host and the pathogen in determining an
306 infection's outcome. As a general trend, research studies tend to mainly focus on either the host or
307 the pathogen's genetic polymorphisms while investigating the genetic basis of disease-related
308 phenotypic variations. While the merits of such a targeted approach cannot be disputed, it is
309 becoming increasingly important also to be aware of the detailed genetic and genomic variations
310 and interactions between the host and the microbe. In the case of monogenic infectious diseases,
311 it is relatively trivial to speculate whether a new form of a pathogen interacts in fundamentally
312 different ways with the host's defence mechanism. For instance, considering that resistance to
313 IPNV in Atlantic salmon is mainly determined by variations in a single gene, one might expect
314 that the mutations acquired by the virus strain reported in this paper might have offered an adaptive
315 advantage, assisting the pathogen to establish successful infection, irrespective of the variations in
316 the *cdh1* gene. Of course, pinpointing the causative mutations and understanding and validating
317 the molecular basis of such adaptive variations is a substantial undertaking by itself. The task of
318 identifying and untangling the dynamics of how genotypic variations in the host and the pathogen

319 influence one another and affect the outcome of an infection becomes more challenging while
320 investigating diseases with polygenetic nature. This point becomes even more critical, considering
321 our rapidly changing environments that can facilitate the transmission dynamics and the
322 geographical spread of the pathogens (Reid et al., 2019). For instance, changes in water
323 temperature, pH and oxygen have been linked to saprolegniasis in the Indian major carps (*Catla*
324 *catla*, *Labeo rohita* and *Chirrinus mrigal*) (Das et al., 2012) and to white spot syndrome virus in
325 prawns (*Penaeus monodon* and *Fenneropenaeus indicus*) (Selvam et al., 2012). Fortunately,
326 advancements in technologies such as sequencing, genotyping, computational analysis and
327 molecular biology can now provide us with many necessary tools, if we are set to understand the
328 dynamics of the interactions between the host and the microbe at their detailed molecular levels.

329 **Data availability**

330 All datasets generated for this study are included in the article (Supplementary Data) and have also
331 been deposited in GenBank under the accession numbers MW496366, MW496367, MW496368,
332 MW496369, MW496370, MW496371, MW496372, MW496373, MW496374, MW496375,
333 MW496376 and MW496377.

334 **Funding**

335 There is no external funding to report.

336 **Acknowledgements**

337 We would like to thank the Fish Vet Group Norway and especially Dr Marianne Kraugerud and
338 Mr Simon Rey for all the laboratory work and the Norwegian Sequencing Centre for the excellent
339 work and guidance.

340 **Contributions**

341 G.M., S.J. and B.H. arranged for tissue sampling, shipment and all laboratory and sequencing
342 procedures. H.M. performed analyses of the sequence data. B.H. and H.M. drafted the manuscript.
343 All authors contributed to the development of the paper, interpretation of the results and
344 improvement of the manuscript.

345 **Disclosure of potential conflicts of interest**

346 No potential conflicts of interest.

529

530 **Supplementary Figure Legends**

531 **Supplementary Figure 1.** Neighbour-Joining trees, showing the phylogenetic relationships
532 between partial polyprotein nucleotide (A) and the amino acid (B) sequences of the reported
533 assemblies with an isolate (MH562009) previously recovered from a field outbreak (Kristoffersen
534 et al., 2018). BG 1 to 6 represent assembled sequences in the current study. The distances were
535 computed using the Maximum Composite Likelihood method, for nucleotides and Poisson for the
536 amino acid data. The rate variation among sites was modelled with a gamma distribution (shape
537 parameter = 1). There were a total of 1513 nucleotides and 504 amino acids in the final dataset.
538 Evolutionary analyses were conducted in MEGA X.

539
540 **Supplementary Figure 2.** Neighbour-Joining trees, showing the phylogenetic relationships
541 between the assembled polyprotein (A) and VP1 (B) segments of the IPNV genomes for the six
542 samples sequenced in this study. The trees are constructed based on the amino acid sequence
543 information. The confidence of association, estimated using bootstrap testing (1000 replicates), is
544 shown next to the branches. There were 2919 and 845 positions in the final datasets for the
545 polyprotein and VP1 respectively. Analyses were conducted in MEGA X.

546

547 **Supplementary Table 1.** Overview of the laboratory results, confirming the initial diagnosis of the IPNV infection and QTL status of the fish.

Supplementary Table 2. Estimates of evolutionary divergence rate between the amino acid

(A) and nucleotide (B) sequences of the polyprotein of the assembled genomes. The actual number of differences are provided in the parentheses. The rate variation among sites was modelled with a gamma distribution (shape parameter = 1).

A	BG_1_poly	BG_2_poly	BG_3_poly	BG_4_poly	BG_5_poly	BG_6_poly
BG_1_poly	0 (0)	0 (0)	0 (0)	0 (0)	0.00206 (2)	0.00206 (2)
BG_2_poly		0 (0)	0 (0)	0 (0)	0.00206 (2)	0.00206 (2)
BG_3_poly			0 (0)	0 (0)	0.00206 (2)	0.00206 (2)
BG_4_poly				0 (0)	0.00206 (2)	0.00206 (2)
BG_5_poly					0 (0)	0 (0)
BG_6_poly						0 (0)

B	BG_1_poly	BG_2_poly	BG_3_poly	BG_4_poly	BG_5_poly	BG_6_poly
BG_1_poly	0 (0)	0 (0)	0 (0)	0 (0)	0.00308 (9)	0.00308 (9)
BG_2_poly		0 (0)	0 (0)	0 (0)	0.00308 (9)	0.00308 (9)
BG_3_poly			0 (0)	0 (0)	0.00308 (9)	0.00308 (9)
BG_4_poly				0 (0)	0.00308 (9)	0.00308 (9)
BG_5_poly					0 (0)	0 (0)
BG_6_poly						0 (0)

In review

Supplementary Table 3. Estimates of evolutionary divergence rate between the amino acid (A) and nucleotide (B) sequences of the VP1 of the assembled genomes. The actual number of differences are provided in the parentheses. The rate variation among sites was modelled with a gamma distribution (shape parameter = 1).

A	BG_1_VP1	BG_2_VP1	BG_3_VP1	BG_4_VP1	BG_5_VP1	BG_6_VP1
BG_1_VP1	0 (0)	0.00118 (1)	0 (0)	0.00118 (1)	0.00237 (2)	0.00237 (2)
BG_2_VP1		0 (0)	0.00118 (1)	0 (0)	0.00237 (2)	0.00237 (2)
BG_3_VP1			0 (0)	0.00118 (1)	0.00237 (2)	0.00237 (2)
BG_4_VP1				0 (0)	0.00237 (2)	0.00237 (2)
BG_5_VP1					0 (0)	0 (0)
BG_6_VP1						0 (0)

Supplementary Files

Supplementary File 1. Alignment of the deduced amino acid sequence data from the polyprotein section of the IPNV. BG 1 to 6 represent the six assemblies from the current study.

Supplementary File 2. Alignment of the deduced amino acid sequence data from the VP1 section of the IPNV. BG 1 to 6 represent the six assemblies from the current study.

Supplementary File 3. Alignment of the deduced amino acid sequence data from the VP5 section of the IPNV. BG 1 to 6 represent the six assemblies from the current study.
