11	Abstract
12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31	While the quality of fat (e.g. saturated/unsaturated) and carbohydrate (e.g. whole grain/simple sugars) intake has been of great interest, less attention has been made to the type of protein and resulting amino acid intake profiles in human diets. Studies at the molecular level however demonstrate that dietary amino acid intake produces substantial effects on health and disease such as cancer by modulating metabolism. How these effects may manifest in human food consumption and dietary patterns is unknown. We developed a series of algorithms to map, characterize and model the landscape of amino acid content in human food, dietary patterns, and individual consumption including relations to health status, covering over 2,000 foods, ten dietary patterns, and over 30,000 dietary records. We found that the type of amino acids contained in foods and human consumption is highly dynamic with variability far exceeding that of fat and carbohydrate. Some amino acids positively associate with diseases such as obesity while others contained in the same food negatively link to disease. Using linear programming and machine learning, we show that these health trade-offs among can be accounted to satisfy biochemical constraints in food and human eating patterns to construct a Pareto front in dietary practice, a means of achieving optimality in the face of tradeoffs that are commonly considered in economic and evolutionary theories. Thus this study may enable the design of human protein quality intake guidelines based on a quantitative framework.
32	

33 Introduction

Diet is generally considered to be a major determinant of human health and disease¹⁻⁵. Numerous 34 dietary recommendations, such as the Dietary Guidelines for Americans⁶, have been developed. 35 36 These dietary recommendations often focus on two major goals: to increase the diversity and nutrient density of the foods consumed, and to reduce the intake of certain components known to 37 increase risk of disease⁷⁻⁹. Such restrictions involve limiting the intake of certain types of 38 carbohydrate and fat such as added sugar, saturated fat and trans-fat, and has rationale based on 39 epidemiology, human¹⁰⁻¹² and model organism research^{13,14}. While it has been widely 40 acknowledged that the types of dietary carbohydrate and fat are important determinants of the 41 quality of a diet, protein the other macronutrient¹⁵, is often neglected. In most human nutritional 42 studies albeit with exceptions, protein is considered as a single variable and often held constant¹⁶. 43 Nevertheless, each amino acid has its specific metabolism¹⁷ and is important for numerous cellular 44 and physiological processes. A growing number of studies shows that variation in dietary intake 45 of amino acids such as serine, glycine, asparagine, histidine, and methionine mediates health and 46 disease including cancer through defined molecular mechanisms¹⁸⁻²⁸. Altogether there is a 47 rationale for investigating in a systematic manner amino acid intake in human diets and possible 48 consequences on health. 49

In this study, we investigated the variability of amino acids in human food and diets and find variability commensurate with what is observed in fats and carbohydrates. Based on optimizing associations with health status, we use these analyses to devise guidelines for dietary amino acids. Finally, we implement machine learning algorithms to design personalized diets based on amino acid intake that correspond to optimality in specified health statuses.

55

56 Amino acid landscape of human food

57 To characterize the variability of amino acid levels in human food, we first constructed a database 58 consisting of amino acid profiles in three levels of human dietary components: individual foods, 59 dietary patterns or representations of patterns of food consumption (e.g. Western, Mediterranean,

Japanese, Keto, etc), and dietary records containing daily reported food intake (Figure 1). The 60 abundance of 18 amino acids in 2,335 foods was collected based on nutritional profiles in the 61 62 United States of America Department of Agriculture National Nutrient Database for Standard Reference Legacy Release (USDA SR) (Figure 1a, methods). 18 of the 20 amino acids were 63 considered because during quantitation, amino acids which largely exist in protein-bound forms, 64 require hydrolysis into free amino acids during which amino groups from glutamine and 65 66 asparagine are also hydrolyzed to make glutamic and aspartic acid. Thus, the abundance of glutamic acid and aspartic acid from measurements of free amino acid levels reflects the total 67 abundance of glutamate and glutamine, and the total abundance of aspartate and asparagine, 68 respectively. The distributions of amino acid abundance over 2,335 foods show that each amino 69 acid has considerable variability across foods (Coefficient of variation > 0.2 for all amino acids, 70 71 Figure 1b), and amino acids most abundant in human food are glutamine/glutamate (median = 0.16 g/g total amino acids), asparagine/aspartate (median = 0.095 g/g total amino acids), leucine 72 (median = 0.082 g/g total amino acids), and lysine (median = 0.076 g/g total amino acids). On the 73 74 other hand, amino acids with the lowest abundance in human foods are cystine (median = 0.012g/g total amino acids), tryptophan (median = 0.012 g/g total amino acids), methionine (median = 75 0.024 g/g total amino acids), and histidine (median = 0.028 g/g total amino acids). This ordering 76 largely resembles the abundance of amino acids in the proteomes which are conserved across living 77 organisms^{29,30}. Principal component analysis (PCA) shows that amino acid abundances can be 78 clustered by different categories of foods (Figure 1c, d, methods). Highly variable amino acids 79 include those whose dietary modulation has molecular links to cancer progression and health 80 outcomes, such as methionine (0.031 g/g total amino acids in eggs compared to 0.013 in legumes)81 and serine (0.076 g/g total amino acids in eggs compared to 0.039 in lamb, veal, and game meat). 82 To quantify the variability of amino acid abundance across foods, we computed the F-statistic from 83 one-way analysis of variance (ANOVA), and compared the resulting F-statistic values with those 84 of carbohydrates (i.e. dietary fiber and sugar) and fats (i.e. saturated fat, monounsaturated fat, and 85 polyunsaturated fat). Notably, we found that the ANOVA F-statistics for amino acids were 86

comparable to or higher than those for carbohydrates and fats (Figure 1e, methods), especially for the amino acids methionine, histidine, lysine, and proline (F-statistic = 816.2 for methionine, 566.1 for histidine, 504.3 for lysine, and 362.9 for proline compared to the range of 45.0 to 119.6 for carbohydrates and the range of 125.2 to 746.3 for fats, Figure 1e, f), highlighting the variability of amino acid abundance in foods which has been largely overlooked previously. Taken together, these results suggest that differences in food intake due to the high variability in amino acid content may lead to differences physiological and cellular effects on metabolism.

94

95 Human dietary patterns are variable in amino acid content

Dietary patterns can be grouped according to eating patterns that often have a cultural or societal 96 element. They can be characterized by a combination of certain types of foods consumed (e.g. 97 98 Mediterranean diet, which includes high amounts of plant-based foods, high to moderate amounts of seafood, low consumption of red meat, and olive oil as the main source of added fat³¹), or a 99 specific intake profile of certain nutrients (e.g. ketogenic diet, which is defined by very high intake 100 101 of fat and very low intake of carbohydrate). Adherence to certain dietary patterns, such as the Mediterranean diet or Japanese diet, has been associated with increased lifespan and lower risk of 102 disease³²⁻³⁴. Moreover, some emerging dietary patterns, such as the ketogenic diet and the Paleo 103 diet, have recently been shown in some settings to have benefits on metabolic health, neural 104 function, and longevity³⁵⁻³⁸. However, it is unclear whether these dietary patterns differ in their 105 amino acid content, and whether the variability in amino acid abundance across dietary patterns 106 contributes to the health outcomes associated with these diets. 107

To further understand the relationship between human dietary patterns and amino acid intake, we next developed an algorithm to quantitatively evaluate amino acid abundance in ten representative human dietary patterns (Figure 2a, S1, Supplementary Methods). Among these dietary patterns, the Mediterranean diet and Japanese diet are two traditional diets believed to have beneficial influences on health, while the Dietary Approaches to Stop Hypertension (DASH) diet consists of consumption of a variety of low-fat and minimally processed foods, and the American

diet, which represents the dietary behaviors of a typical individual in western society is also 114 considered. We also include diets that restrict the consumption of certain foods (Paleo diet, 115 116 vegetarian diet, plant-based diet), diets limiting carbohydrate intake (ketogenic diet, Atkins diet), and a USDA recommended diet defined based on the daily nutrient intake goals in the USDA 2015-117 2020 dietary guidelines for Americans⁶. We first computed the range of amino acid intake (i.e. 118 grams of each amino acid consumed per day) for each dietary pattern using a linear programming 119 120 algorithm we developed (Figure 2b, Supplementary Methods) and found that, although none of these dietary patterns includes any constraint on amino acid intake, they still differ greatly with 121 each other in the values of amino acid consumption. Moreover, each dietary pattern allowed for 122 substantial flexibility in the intake of all amino acids (maximal daily intake/minimal daily intake > 123 20 for all dietary patterns and amino acids, Figure 2b), revealing the possibility to modulate amino 124 125 acid intake under a certain dietary pattern.

To quantify the variability of amino acid composition that is independent of energy and protein 126 intake, we developed a sampling algorithm based on the accelerated convergence hit-and-run 127 method³⁹ to quantify the amino acid composition of each diet by sampling 50,000 instances of 128 129 each diet (Supplementary Methods). We first confirmed that the sample size of 50,000 was sufficient to capture the distribution of amino acid abundance in a dietary pattern based on the 130 convergence of the sample mean and standard deviation values (Figure S2a). PCA of the sampled 131 132 diets (Figure 2c) and comparison of mean values (Figure 2d) showed that the ten dietary patterns also have different signatures of amino acid composition. Notably, differences in amino acid 133 composition also exists between dietary patterns similar to each other such as the vegetarian diet 134 and plant-based diet. Indeed, we observed a 30% of difference in methionine abundance between 135 vegetarian diet and plant-based diet (0.019 g methionine/g total AAs in vegetarian diet compared 136 to 0.014 in plant-based diet), suggesting that small changes in the choice of foods result in 137 substantial differences in amino acid intake (Figure 2d, Figure S2b). We also estimated 138 compositions of carbohydrates and fats in these diets (Figure S2b), and quantified the variability 139 of amino acid composition across human diets using F-statistic values from one-way ANOVA, and 140

compared it with the variability of carbohydrates and fats across dietary patterns (Figure 2e). 141 Strikingly, we found that the variability of amino acid composition across diets was much higher 142 143 than that of carbohydrates and fats, with the amino acids lysine, methionine, proline and histidine 144 being the most highly variable across human dietary patterns (F-statistic > 50,000 compared to less than 10,000 for carbohydrates and fats, Figure 2e-f, S2b-c). Among these amino acids, lysine, 145 histidine and methionine are significantly lower in instances of the plant-based diet, and proline is 146 significantly lower in Paleo diet (Figure 2f). The amino acid signatures of human dietary patterns 147 were further validated by measurements of fasting blood concentrations of the amino acids leucine, 148 isoleucine, and alanine in human subjects eating plant-based or ketogenic diet (Figure S2d)⁴⁰. 149 Taken together, these results reveal that the biggest difference in macronutrient composition across 150 human dietary patterns is in amino acid content, and not that of carbohydrates or fats. How the 151 152 diversity in dietary amino acids results in different health outcomes remains an open question, which may begin to be answered with nutritional and health data in large populations of humans. 153 154

155 Landscape of amino acid intake in human dietary records

156 Next, we considered individual dietary amino acid intake records across a population of individuals from diverse ethnic and cultural backgrounds. We reconstructed the dietary amino acid 157 intake profiles in more than 30,000 human subjects in the United States based on dietary records 158 159 in the National Health and Nutrition Examination Survey (NHANES) 2007-2014 datasets (Figure 3a). Since the NHANES datasets do not direct include dietary amino acid intake values, we 160 developed a set of computational tools for data imputation and mapping to reconstruct the amino 161 acid profiles for the dietary records based on two additional datasets, the USDA SR food nutritional 162 database and the Food and Nutrient Database for Dietary Studies (FNDDS) (Figure 3a). Data 163 imputation using random forest (RF) regression, which outperformed other methods in the 164 accuracy of imputation (Figure S3a, b), was applied to estimate the missing values of amino acid 165 levels in the USDA SR dataset. The imputed datasets were then used to construct amino acid 166 profiles for the FNDDS and NHANES records by mapping foods in the USDA dataset to foods in 167

the FNDDS dataset which were then used to compute nutrient intake values in the NHANES 168 dietary records (Figure 3a, Supplementary Methods). To assess the limitations of self-reported 169 170 dietary records in the NHANES data, we compared our computed nutrient intake values with measurements of blood concentrations of related metabolites such as Vitamin D (Figure 3b). Next, 171 to validate the reconstructed amino acid intake levels, we first compared the total intake of amino 172 acids and intake of protein in each dietary record and confirmed that the reconstructed total amino 173 174 acid intake closely resembles the known total protein intake (Pearson correlation = 0.99, p-value $< 10^{-323}$, Figure 3c), concentrations of amino acids in human blood (Spearman correlation = 0.52, 175 p-value = 0.03, Figure 3d), uptake fluxes of amino acids in human cell lines, which reflect demands 176 of amino acids in cultured human cells (Spearman correlation = 0.70, p-value = 0.01, Figure 3e), 177 and amino acid composition of several culture mediums (Spearman correlation > 0.5 and p-value 178 < 0.05 for 4 out of 7 culture media, Figure S3c). The high correlation between dietary amino acid 179 intake and physiological parameters related to amino acids suggests that our reconstructed amino 180 acid intake data may reflect some aspects of physiological metabolism, and suggest that the cellular 181 behaviors and tissue microenvironment in amino acid metabolism reflect to some extent dietary 182 intake of amino acids despite the many other factors that influence cellular metabolism. 183

We then evaluated the overall variability in the intake of each amino acid based on the ratio 184 of maximal to minimal intake values in the human dietary records (Figure 3f), and performed PCA 185 on the reconstructed dietary amino acid profiles to report the association between dietary amino 186 acid composition and demographic variables such as age, sex, and ethnicity (Figure 3g). We found 187 that among the population included in the NHANES 2007-2014 cohorts, daily intake of amino 188 acids typically varies by two to six fold (e.g. maximal intake/minimal intake = 4 for tryptophan, 189 2.5 for methionine, 6.2 for glycine, and so on). Dietary amino acid composition profiles showed 190 no difference between batches (Figure 3e), thus confirming that our reconstruction is not biased 191 by batch effect. Interestingly, dietary intake of amino acids was found to correlate with age, while 192 no dependency on other demographic variables such as sex and ethnicity was observed (Fig 3e, 193 Figure S4). These reconstructed dietary amino acid intake profiles allow us to examine the 194

195 quantitative relationship between dietary amino acids and human health.

196

197 Dietary amino acid intake associations with human health

We next attempted to link dietary amino acid intake and incidence of several human diseases based 198 on the reconstructed dietary amino acid intake profiles and clinical records available in the 199 NHANES database. We focused on chronic diseases that are a major concern to human health such 200 201 as cardiovascular disease, diabetes, and cancer. We retrieved the medical records of 18,196 adult subjects in the NHANES 2007-2014 datasets and defined quantitative scores describing the 202 incidences of hypertension, obesity, cancer, and diabetes based on the examination, laboratory, and 203 questionnaire datasets (Figure 4a, Methods). We first computed partial Spearman's rank 204 correlation coefficients as a metric to evaluate the association between dietary amino acid 205 206 composition and the incidences of the four diseases while controlling for confounders including demographic and lifestyle-related factors (Supplementary Figure 5). We identified many amino 207 acid intake-disease associations involving all four diseases considered (statistically significant 208 associations in 21 out of 72 amino acid-disease pairs, Figure 4b, methods), among which obesity 209 showed the strongest association with dietary amino acid composition (obesity incidence 210 positively correlated with the intake of threonine, histidine, alanine, glycine, lysine and methionine, 211 and negatively correlated with intake of tryptophan, phenylalanine, valine, serine, asparagine, 212 213 aspartate, glutamine, and glutamate, Figure 4b). These associations between dietary amino acid 214 intake and obesity were consistent with some observations in molecular studies, such as the antiobesity functions of dietary tryptophan and pro-obesity functions of methionine in mice^{41,42}. As a 215 control, we also correlated the incidence of the four diseases with dietary intake of different types 216 of carbohydrates and fats. Counterintuitively, we found much fewer statistically significant 217 associations between dietary intake of carbohydrate and fat (9 significant associations out of 40 218 disease-nutrient pairs, Figure 4c). These results together highlight the unexpectedly strong 219 association between that dietary intake of amino acids and human disease which exceeds the 220 association for dietary carbohydrates and fats. To further explore these questions, we performed a 221

comparison of the association between nutrients and human health using machine learning models 222 predicting health outcomes from different types of nutritional variables (Figure 4d). We 223 224 categorized nutritional variables included in the NHANES database into six groups, including energy, macronutrients, macronutrient compositions (i.e. fractions of different types of 225 carbohydrate and fat in total carbohydrate and fat intake), vitamins, minerals, amino acid 226 compositions (i.e. intake of each amino acid with the unit g/g total AA), and other nutrients. For 227 each disease, nutritional variables in each group were used as covariates to build a logistic 228 regression model to predict the incidence of that disease. The area under receiver operating 229 characteristic curve (AUC) with 5-fold cross validation was used to assess the performance of each 230 group of nutritional variables in predicting disease incidence, which reflects strength of the 231 association between dietary intake of those nutrients and that disease. We found that dietary amino 232 acid composition was predictive of incidence of all diseases except for cancer (AUC > 0.5, 5-fold 233 cross validation), and achieved accuracy of prediction comparable to or higher than that of dietary 234 carbohydrate and fat intake for obesity and hypertension (AUC = 0.55 for amino acids compared 235 to 0.55 for macronutrient composition in predicting obesity, and AUC = 0.53 for amino acids 236 237 compared to 0.52 for macronutrient composition in predicting hypertension, Figure 4e). The reason that dietary amino acid intake was unable to predict cancer outcome was probably for the reason 238 that different types of cancers were not distinguished in the analysis, the population included 239 240 remissions, and the frequency of cancer in the dataset is relatively low (1844 cases out of 18469 241 individuals). Nevertheless, the higher accuracy of amino acid intake in predicting obesity and hypertension incidence in humans provides a rationale for optimization of dietary amino acid 242 intake. 243

244

245 Guidelines for dietary amino acids and diet design

Dietary recommendations, such as these in the USDA Dietary Guidelines for Americans, often involve suggestions to consume a variety of minimally processed foods and recommended ranges for intake of nutrients including macronutrients, vitamins, and minerals. Since dietary intake of

amino acids has been associated with health outcomes both in molecular studies and by our analysis thus far, we sought to develop an Artificial Intelligence (AI) -based approach for identification of dietary guidelines for amino acids and design of personalized human diets optimizing their amino acid composition.

First, we developed an algorithm for identification of amino acid intake guidelines based on 253 the associations between dietary amino acid intake and human health (Figure 5a). We focused on 254 255 obesity since it had the highest incidence and was found to have the strongest association with dietary amino acid intake among the four diseases considered in this study (Figure 4b). We 256 classified obesity-associated amino acids into three categories (Figure 5b), including amino acids 257 for which the intake positively associate with obesity incidence ('positive association'), negatively 258 associate with obesity incidence ('negative association'), or associate with obesity incidence with 259 260 a non-monotonic, U-shaped relationship ('U-shaped relationship'). The amino acids phenylalanine, aspartate/asparagine, tryptophan, valine and glutamate/glutamine fell into the negative association 261 group. On the other hand, the amino acids glycine, alanine, methionine, lysine, histidine were 262 categorized into the positive association group. The association between intake of dietary amino 263 acids and obesity was not due to changes in calorie intake, since amino acids positively associated 264 with obesity were either negatively or positively correlated to calorie intake, and vice versa (Figure 265 S6a). 266

We also examined whether there exists a dietary pattern that can minimize the intake of the 267 amino acids positively associated with obesity while maximizing the intake of the amino acids 268 negatively associated with obesity. To our surprise, no dietary pattern was able to satisfy all of 269 these requirements. For instance, the Paleo diet has the highest levels of aspartate and asparagine, 270 271 which negatively associate with obesity. Nevertheless, the Paleo diet also has the highest intake of alanine, methionine and lysine, which all positively associate with obesity incidence. These results 272 reveal the complexity in the relationship between dietary amino acid intake and obesity, indicating 273 trade-offs between the goals of maximizing or minimizing different groups of amino acids which 274 should be considered while designing dietary guidelines for amino acids. 275

We therefore sought to define dietary amino acid intake guidelines based on the association 276 between dietary amino acids and obesity (Figure 5c), that is, to minimize the total intake of amino 277 278 acids that positively associate with obesity (i.e. AAs-to-minimize, including glycine, alanine, 279 methionine, lysine, histidine), and to maximize the total intake of amino acids that negatively associate with obesity (i.e. AAs-to-maximize, including tryptophan, phenylalanine, valine, 280 aspartate+asparagine, glutamate+glutamine). We first confirmed that both total AAs-to-minimize 281 and total AAs-to-maximize were significantly associated with obesity incidence (Chi-squared p-282 value = 9.0×10^{-8} for total AAs-to-minimize and 4.9×10^{-10} for total AAs-to-maximize, Figure 5c). 283

We then further characterized the trade-off between the requirements of minimizing total AAs-284 to-minimize and maximizing total AAs-to-maximize by constructing the Pareto surface based on 285 the two requirements (Figure 5d). The concept of Pareto optimality has been widely applied in 286 economics and engineering, and introduced to biology to characterize the trade-off between 287 multiple tasks of bacteria, cancer cells, and $organisms^{43-46}$. For each dietary pattern, there exists a 288 Pareto surface consisting of diets that best balance the needs to minimize total AAs-to-minimize 289 and to maximize total AAs-to-maximize, meaning that for a diet within the Pareto surface, any 290 291 other diet following this dietary pattern would never have both higher total intake of AAs-tomaximize and lower total intake of AAs-to-minimize at the same time. We hence developed an 292 algorithm to construct the Pareto surface for each of the ten dietary patterns considered in this 293 294 study (Figure 5d, S6b, Methods), and quantified the extent by which a specific diet satisfies the two requirements of maximizing total AAs-to-maximize and minimizing total AAs-to-minimize 295 using the deviation from Pareto surface (Figure 5d). For each dietary pattern, we computed the 296 deviation of each NHANES dietary record from its Pareto surface, and found that the deviation 297 from the Pareto surface strongly correlates with obesity incidence (Chi-squared p-values $< 10^{-10}$ 298 for all dietary patterns), implying that diets on the Pareto surface of each dietary pattern are 299 associated with lower risk of obesity. On average, an individual that eats a diet that is the top 20% 300 furthest away from the Pareto surface has a 34% higher chance of being obese compared to one 301 eating a diet among the 20% closest to the Pareto surface (Figure 5e). 302

These findings not only reveal novel relationship between dietary amino acid intake and health, but also allow us to design diets that have amino acid profiles associated with lower risk of obesity and satisfy personalized needs and requirements such as preferred dietary patterns according to the constructed Pareto surface of the preferred dietary pattern. Hence, based on such strategy, we developed an AI for designing diets including the Mediterranean, Paleo, and ketogenic diet (Figure 5f). Each diet contains a variety of foods from diverse sources and keeps the features of the corresponding dietary pattern.

310

311 Discussion

This study develops data resources and computational techniques to begin to address two major 312 limitations in the nutritional sciences: 1) the lack of systematic collections of nutritional 313 314 information and 2) the lack of computational tools to probe the connections in food, dietary patterns and practices, and health status. Consequentially, we made a number of findings about 315 the variability of amino acids across different types of human foods and dietary patterns and the 316 317 unexpected associations between dietary amino acid intake, food and dietary patterns, and health. Unexpected links from amino acid intake to pathology such as obesity highlight non-intuitive diet-318 disease associations and inherent tradeoffs in amino acid content in food. 319

While we were able to use the tools we devised to study and make discoveries about the landscape of amino acid intake, these capabilities are generalizable to any systematic analysis of human food and diet. For instance, it is still unclear how dietary patterns and human dietary records differ with each other in micronutrients such as vitamins, minerals, dietary fiber, added sugars, and how personalized diets can be designed to cover more nutritional goals. Application of the algorithms we developed in this study may help address these questions.

This study has some limitations. First, the association between dietary amino acids and human diseases is observational and does not directly imply causality. Nevertheless, some amino aciddisease associations identified by our analysis have been observed in experimental studies. For instance, tryptophan, which was found to be negatively associated with obesity in our study, was

shown in mice to reduce appetite and weight gain through the production of serotonin in brain⁴¹.
On the other hand, dietary restriction of methionine in mice and human has been shown to improve
metabolic health and increase fat oxidation, which may contribute to the anti-obesity effects of
dietary methionine restriction^{42,47,48}. Further studies, such as randomized controlled trials that
directly compare the health outcomes of diets differing with each other in amino acids, are
necessary but also limited to the cohort in consideration and the pre-determined end points.

We also note that the datasets used in this study are not completely free of bias. The majority of records in the databases of foods and human dietary records are western, while foods frequently consumed in other geographical regions and by other cultural groups, such as Asians and Africans, are largely underrepresented. Therefore, application of our findings to non-western populations may be limited. Nevertheless, we are optimistic that this limitation could be addressed by extending the coverage of the existing nutritional and epidemiological datasets to non-western populations^{49,50}.

343

344 Methods

345 Computer algorithms and their implementation

Details about the computer algorithms used in this study, including these for reconstruction of 346 amino acid landscape in human foods, dietary patterns, and dietary records, are explained in the 347 348 Supplementary Methods. The algorithms for imputation and reconstruction of amino acid profiles 349 in the NHANES database, including imputation of missing data, and mapping of foods in the USDA SR, FNDDS, and NHANES databases, were implemented in R. All other algorithms used 350 in this study were implemented in MATLAB. The database for amino acid abundance in human 351 foods, dietary patterns and dietary records was implemented in both Microsoft Access database 352 file and Microsoft Excel files. All database files are freely available for download at the GitHub 353 repository: https://github.com/ziweidai/AA human diet/tree/main/6-Database. 354

355 Statistical analysis

356 Principal component analysis was performed using the MATLAB built-in function 'pca()'. One-

way ANOVA was performed using the MATLAB built-in function 'anoval()'. Logistic regression 357 models were constructed, trained, and evaluated using the MATLAB built-in functions 'glmfit()', 358 359 'glmval()', and 'perfcurve()'. Chi-squared test was performed using the MATLAB built-in function 'crosstab()'. Relationships with p-value < 0.05 were considered significant. Partial 360 Spearman's rank correlation coefficients were computed using the MATLAB built-in function 361 'partialcorr()' with p-values adjusted using the Benjamini-Hochberg procedure. Associations with 362 363 adjusted p-value < 0.05 were considered significant. Average amino acid abundances in food categories or dietary patterns were computed using the mean values of amino acid abundances 364 across all foods in that food category or instances in that dietary pattern. 365

366 Data and code availability

- All code, scripts, and datasets used or generated in this study are available at the GitHub page of
- 368 Ziwei Dai: <u>https://github.com/ziweidai/AA_human_diet</u>.
